MINING ENGINEERS' HANDBOOK

WRITTEN BY A STAFF OF FORTY-SIX SPECIALISTS
UNDER THE EDITORSHIP OF

ROBERT PEELE
Late Professor Emeritus of Mining Engineering in
the School of Mines, Columbia University

WITH THE COLLABORATION OF

JOHN A. CHURCH
Mining and Metallurgical Engineer

THIRD EDITION
Tenth Printing

IN TWO VOLUMES
VOL. II

WILEY EASTERN PRIVATE LIMITED
NEW DELHI

Third Edition, 1941
Eleventh Printing, February 1960

This book is not to be sold outside
the country to which it is consigned
by Wiley Eastern Private Limited.
Sales Area : India, Pakistan, Ceylon and Burma.

This book has been published with the assistance of the Joint
Indian—American Standard Works Programme

Price : Rs. 11.00 per volume

[redacted]aji for Wiley Eastern Private Limited,
J 31, South Extension 1, New Delhi 3 and Printed by Sudhir Balsaver
at Usha Printers, 6 Tulloch Road, Bombay 1. Printed in India

TABLE OF CONTENTS FOR VOLUME II

Detailed tables of contents are given at the beginning of each section. An alphabetical index appears following Section 45.

SECTION 28. BREAKING, CRUSHING, AND SORTING OF ORES

SECTION 29. ORE SAMPLING

SECTION 30. ASSAYING

SECTION 31. TESTING OF ORES

SECTION 32. SELLING, PURCHASING, AND TREATMENT OF ORES

SECTION 33. GOLD AMALGAMATION AND CYANIDATION

SECTION 34. PREPARATION AND STORAGE OF ANTHRACITE COAL

SECTION 35. PREPARATION AND COKING OF BITUMINOUS COAL

SECTION 36. MATHEMATICS AND MECHANICS

SECTION 37. CHEMICAL AND PHYSICAL NOTES AND TABLES

SECTION 38. ELEMENTS OF HYDRAULICS

SECTION 39. ENGINEERING THERMODYNAMICS

SECTION 40. POWER AND POWER MACHINERY

SECTION 41. MECHANICAL ENGINEERING MISCELLANY

For contents of other handbooks of this series, see pages following Index of this volume.

SECTION 15

COMPRESSED AIR PRACTICE

FIRST AND SECOND EDITIONS

BY

RICHARD T. DANA, CONSULTING ENGINEER

LARGELY REWRITTEN FOR THIRD EDITION

BY

A. W. LOOMIS, MECHANICAL ENGINEER, INGERSOLL-RAND CO.

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

COMPRESSED AIR PRACTICE

1. ADVANTAGES AND USES OF COMPRESSED AIR POWER

Advantages for mining service: (*a*) air drills are of rugged construction, and (*b*) less susceptible to damage by moisture than electric drills; (*c*) air lines are readily maintained and extended; (*d*) leaks easily detected and repaired; (*e*) air power is safe in gaseous mines; (*f*) exhaust air aids ventilation.

Uses of compressed air in mining, quarrying and smelting (2, 21). Compressed air is widely applied in mining and allied fields, for operating drills and hoists; pneumatic tools, as grinders, drills, riveters, chippers, pneumatic diggers and spades; air-driven sump pumps; direct-acting and air-lift pumps; pile drivers for shaft sheathing; drill-steel sharpeners: air pistons for unloading cars; air motors; compressed-air locomotives; oil furnaces for heating steel; shank- and detachable-bit grinders; cement and paint sprays; stone channellers; mine ventilation; supplying air for blowing converters; agitating cyanide tanks; transferring metallurgical solutions; starting Diesel engines; coal preparation.

2. TERMINOLOGY AND DEFINITIONS (1, 2, 21)

Compressor capacity is usually expressed in vol of FREE AIR, *i e*, air under the press and temp conditions at the compressor intake, the normal atmos conditions of the locality.

Reciprocating compressors. In these, the compressing element is a piston moving in a cylinder.

Positive displacement blowers have two inter-meshing gear-type elements, rotating in opposite directions within a stationary casing. Rotary blowers are positive displacement units which compress by eccentrically-mounted vanes, with a rotary seal separating intake and discharge openings. Liquid-seal blowers are a variation of rotary blower, in which a vaned impeller operates in an elliptical casing, the seal between intake and discharge being water, which is thrown outward during operation, following the form of the casing and acting as a liquid piston. All the above are of the positive-displacement type.

Turbo or centrifugal compressors. Compression is effected by centrifugal action of bladed impellers rotating at high velocities.

Hydraulic compressors are those in which water descending in a vert pipe compresses the entrained air

Single-stage compressors. Compression from initial to final pressure is completed in one step or stage. In reciprocating machines compression is completed in a single stroke of the piston.

Multi-stage compressors. Compression from initial to final press is completed in two or more distinct steps or stages. In a 2-stage reciprocating compressor compression is carried to an intermediate pressure in one cylinder, and the air then passes through an intercooler to another cylinder in which compression reaches the final pressure.

Compressor drives are classified as steam- or power-driven. Also as DIRECT-CONNECTED, in which the driver is an integral part of the machine, as gas or Diesel-engine-driven units, where the power cylinders and air pistons act on the same crankshaft; DIRECT-STEAM-DRIVEN, in which the steam and air pistons are on the same rod and act on the same crankshaft; DIRECT-CONNECTED ELECTRIC, in which the motor is mounted on compressor crankshaft; WATER-WHEEL-DRIVEN, in which the water wheel is mounted on the compressor crankshaft; DIRECT COUPLED, in which the driver is connected to the compressor crankshaft through a flexible coupling, clutch, or gears; BELT DRIVE, in which the driver is connected to the compressor by a flat belt, multiple V-type belt, or rope; CHAIN DRIVE, in which the driver is connected to the compressor by a chain and sprocketed pulleys.

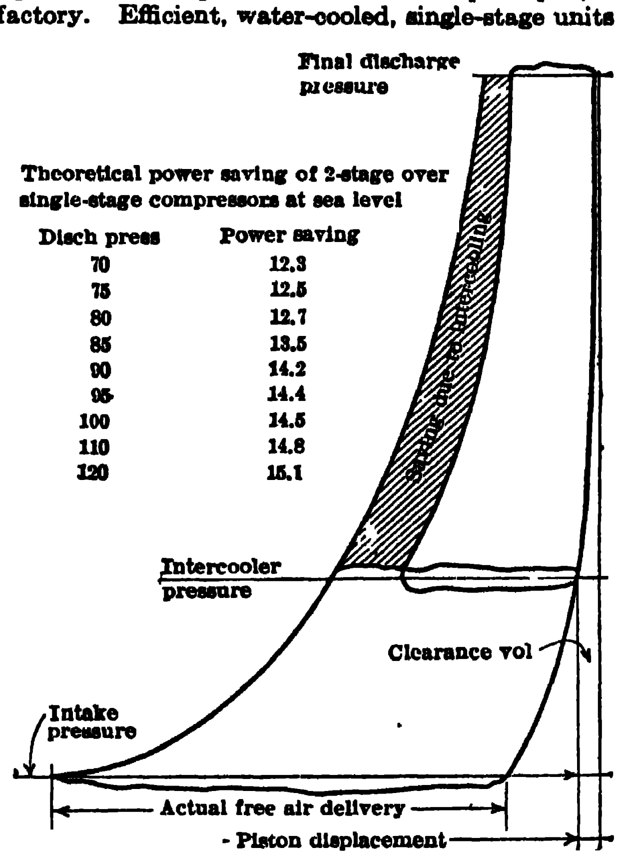
Classification of reciprocating compressors (2, 21). VERTICAL COMPRESSORS have the compressing element in a vert plane. A variation is the V-type, with two or more compressing cylinders oppositely inclined. HORIZONTAL COMPRESSORS have the compressing elements in a horiz plane. ANGLE COMPRESSORS are of the multi-cylinder type, with the cylinder axes at an angle to each other; there are usually one or more horiz cylinders and a corresponding number of vert cylinders. RADIAL COMPRESSORS are those having a series of compressing elements arranged in the same plane around the common crank

from which they are driven. STRAIGHT-LINE COMPRESSORS are usually horiz, of the center-crank type, with a common axis for cylinders and frame. DUPLEX COMPRESSORS have two parallel sets of compressing elements, driven by individual cranks on a common crank-shaft. SINGLE-ACTING COMPRESSORS. Compression takes place on only one stroke per revolution in each compressing element. DOUBLE-ACTING COMPRESSORS. Compression takes place on both strokes per revolution in each compressing element. In WATER-COOLED COMPRESSORS some of the heat of compression is removed by water circulated in jacketed cylinders. The spraying of water directly into the air is now obsolete. In AIR-COOLED COMPRESSORS some of the heat of compression is removed by air circulated over fins cast on the cylinders.

3. OPERATING DATA

Application of single- and multi-stage units. For pressures below 60 lb per sq in, a single-stage compressor is usually satisfactory. Efficient, water-cooled, single-stage units are built for pressures to 125 lb and in sizes to 100 hp. For larger sizes, 2-stage compressors are preferred for the usual 100-lb rating. Except in the smaller sizes, two-stage units are lower in power costs than single-stage, for pressures of 80 to 100 lb, which are normal at most mines and quarries. This is especially true at high altitudes. For starting Diesel engines, air at 250 lb is required; since this is usually the only application for air at this pressure, small two-stage, air-cooled units are used.

Advantages of stage compression: (*a*) less hp required to compress a unit of air (Fig 1); (*b*) lower final temp; (*c*) lower aver press on bearings and greater mech effic; (*d*) increased safety and ease of lubrication. With high final temp, part of lubricant is destroyed, increasing wear on piston and cylinder; (*e*) greater actual air delivery from same piston displacement. The final press in the low-press cyl is much lower than in single-stage work, and clearance air, when expanded to atmos press, occupies less space. Hence, the inflow through suction valves begins earlier in the stroke; (*f*) air delivered by a stage compressor is dryer than from a single cylinder. At constant press, the capacity of air for water vapor decreases with its temp, and in passing through the intercooler much of the original moisture in the air is precipitated; hence, less trouble from condensation in delivery pipe.



Theoretical power saving of 2-stage over single-stage compressors at sea level

Disch press	Power saving
70	12.3
75	12.5
80	12.7
85	13.5
90	14.2
95	14.4
100	14.5
110	14.8
120	15.1

Fig 1

Air compression at altitudes above sea-level (1, 2). The primary effect of altitude is to reduce the hp per unit of vol delivered (Fig 2, 3), permitting larger air cylinders in 2-stage machines. Volumetric effic of 2-stage units is only slightly affected by altitude operation; for single-stage, there is actually a loss in volumetric effic, because of the greater vol of free air trapped in clearance spaces due to the higher compression ratios required for the same discharge pressure. As the reduction in hp per unit of volume at altitudes is smaller for single-stage than for 2-stage units, cylinder sizes in the former are seldom changed. Although compressors deliver more air for the same hp at altitudes, air-operated equipment as rock drills, requires a greater volume of air (Table 2).

Power required for compressors (2). The theoretical hp for single- and 2-stage compressors at sea-level is given in Table 1; for altitudes, see Fig 2, 3. Actual brake hp for both single- and 2-stage compressors is greater than the theoretical, by an amount varying with the press, altitude, and size and type of compressor; for 100 lb press, it is normally 1.2 to 1.3 times the theoretical (Table 2).

Theoretical adiabatic hp required by a single-stage compressor is calculated by:

$$\text{Hp} = 0.0043636\, VP_1 \frac{n}{n-1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{n-1}{n}} - 1\right]$$

in which: V = vol of air delivered, in cu ft free air per min; P_1 = abs intake press, lb per sq in; P_2 = abs discharge press, lb per sq in; n = ratio of specific heats. Absolute press equals gage press plus atmos press, both in lb per sq in.

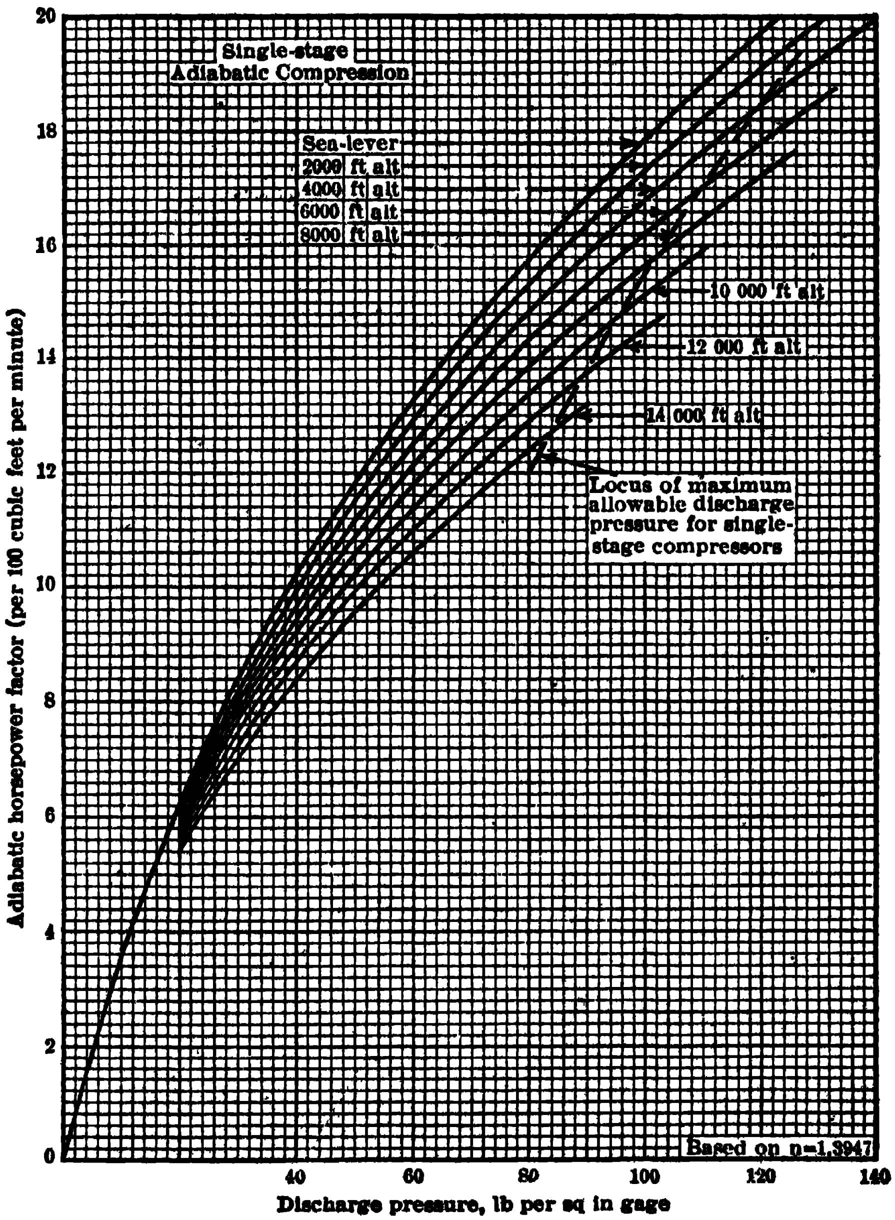


Fig 2. Theoretical Horsepower required by Single-stage Air Compressors (2)

Assuming air containing 0.57% moisture by weight (an aver for a temperate climate), n = 1.3947 and the formula becomes:

$$\text{Hp} = 0.01542\, VP_1\left[\left(\frac{P_2}{P_1}\right)^{0.283} - 1\right]$$

This formula applies to any number of compression stages, by using it for each stage individually with the correct volumes and pressures; and taking the sum of the horse

powers. The formula for the theoretical adiabatic power required by a 2-stage compressor, assuming perfect intercooling and equal division of work between the cylinders, is:

$$\mathrm{Hp} = 0.03084\, VP_1 \left[\left(\frac{P_2}{P_1} \right)^{0.1415} - 1 \right]$$

Capacity of reciprocating compressors (1, 2) is usually stated in terms of piston displacement, which is the vol swept through by the piston, expressed in cu ft per min.

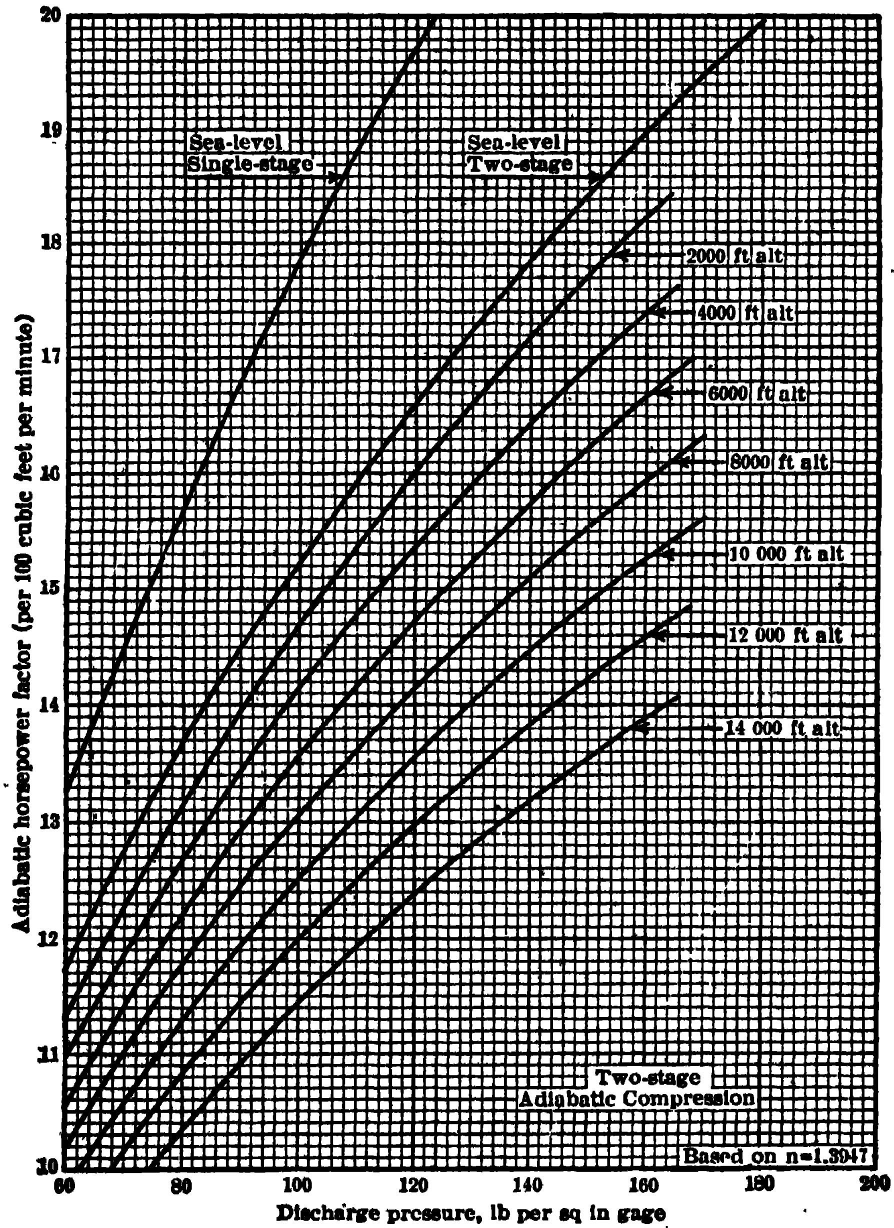

Fig 3. Theoretical Horsepower required by Two-stage Air Compressors (2)

Actual delivered air capac is less than piston displacement, due to clearance, slippage and valve leakage. Ratio of the vol of air delivered, divided by piston displacement is the volumetric effic. For single-stage compressors the actual delivery is usually 65 to 75% of piston displacement; for 2-stage compressors the delivery is 75 to 90% of piston displacement. Capac of portable compressors is usually given in terms of actual free air delivery. Formula for calculating piston displacement of compressors with single-acting cylinders is:

$$PD = \frac{A \times S \times n \times \mathrm{rpm}}{1\,728}$$

* Note: Brake hp varies considerably with size and type of compressor.

in which PD = piston displacement, cu ft per min; A = piston area, sq in; S = stroke, in; n = number of first-stage pistons; rpm = rev per min. With double-acting cylinders,

$$PD = \frac{A \times S \times n \times \text{rpm}}{874}$$

in which a reasonable deduction is made for vol occupied by piston rod. Without this deduction, the divisor would be 864.

In calculating piston displacement, the first-stage cylinders only are considered, as all the air passing through the first-stage passes also through the higher stages.

Discharge temperatures (1). Table 3 gives the theoretical discharge temp of single and 2-stage compressors. Variations occur in practice, due to water jacketing and radiation, tending to lower the temp at the higher pressures. Formulas for computing these temperatures (adiab compression) under conditions not shown in the tables are:

For single-stage compressors, $T_2 = T_1 \left(\frac{P_2}{P_1}\right)^{0.283}$, where T_1, T_2 = intake and disch temp, F deg abs; P_1, P_2 = abs intake and disch press.

For 2-stage compressors (assuming perfect intercooling and equal division of work between the cylinders), $T_2 = T_1 \sqrt{\left(\frac{P_2}{P_1}\right)^{0.283}}$

Table 3. Theoretical Cylinder Temperatures at End of Stroke (based on adiabatic compression, n being 1.3947 with perfect intercooling, intake temp, 60° F and intake press, 14.7 lb abs)

Transmission of compressed air is in wrought iron or steel pipe; "extra-heavy" pipe being used for high pressures such as for Diesel engine starting. For sizes and weights of pipe and fittings, see Sec 41. PIPE JOINTS are made by sleeve couplings, or by flanges into which the pipe ends are expanded or threaded. Sleeve couplings, suitable for all except very large sizes, should be put on with white or red lead, especially where leaks may develop due to shifting ground. Gaskets are used for flange couplings: asbestos near receiver, fiber type elsewhere. EXPANSION JOINTS are necessary on long lines. Welded pipe is widely used, for its convenience and elimination of joints.

Transmission losses in pipes (see also Sec 39, Art 2). The heat of compression is quickly lost in the first few hundred ft of air main, and can not economically be retained by non-conducting covering.

Transmission line hints. Losses from leaky joints or unsound pipe often exceed all other transmission losses. Pipes should be inspected regularly to eliminate waste of power. Pipe of too small diam reduces effective press by causing high velocity and undue friction (Table 4, 5). Veloc in mains should not exceed 20 to 25 ft per sec; in short branch pipes, it may be 40 or 50 ft. Pipe with rough interior causes excessive friction loss. Each length should be cleaned of foreign substances before coupling. Lead forced into the pipe at couplings makes obstructive ridges. Surface mains should be protected, to avoid freezing of the moisture and consequent obstruction. Tees, elbows, and other fittings cause friction and should be avoided wherever possible (Table 7).

Friction losses of pressure in pipe lines are important, and can be determined by the formula (E. C. Harris, *Bull* Univ of Mo, Vol 1, 1912):

$$f = \frac{0.1025LQ^2}{d^{5.31}}$$

where: f = press drop, lb per sq in, L = length of pipe, ft, r = ratio of compression at pipe entrance, Q = vol of air flowing, cu ft per min, and d = internal diam of pipe, in. Table 5, 6 are based on this formula. Table 7 gives loss of press through hose, and friction loss through pipe fittings. Another formula for press loss is that of D'Arcy:

$$V = c\sqrt{\frac{d^5(p_1 - p_2)}{wL}},$$

where: V = cu ft compressed air delivered at final press; c = experimental constant; d = diam pipe, in; L = length pipe, ft; w = wt in lb per cu ft of air at press p_1; p_1, p_2 = initial and final gage press.

Table 4. Values of c in D'Arcy's Formula

Pipe, in	c	Pipe, in	c
1	43.3	7	60.3
2	52.6	8	60.7
3	56.5	9	61.0
4	58.0	10	61.2
5	59.0	11	61.6
6	59.8	12	62.0

Graphic solution of D'Arcy's formula (Fig 4). Find in left-hand margin the vol of compressed air. Pass horizontally to diagonal line for length of pipe; project vertically to intersect the diagonal for initial gage press, then horiz to right to vert line of initial pressures. Using this point as a pivot, swing a straight-edge to cut lines for size of pipe and press drop. To find cu ft of compressed air delivered, divide vol of free air by the ratio of final abs press in the pipe to atmos press. Use of chart can be reversed to find max vol of air transmitted through a given pipe line. To have several branch lines equal in carrying capac to a main line, the pipes should be to each other as the sq root of the fifth powers of their diam.

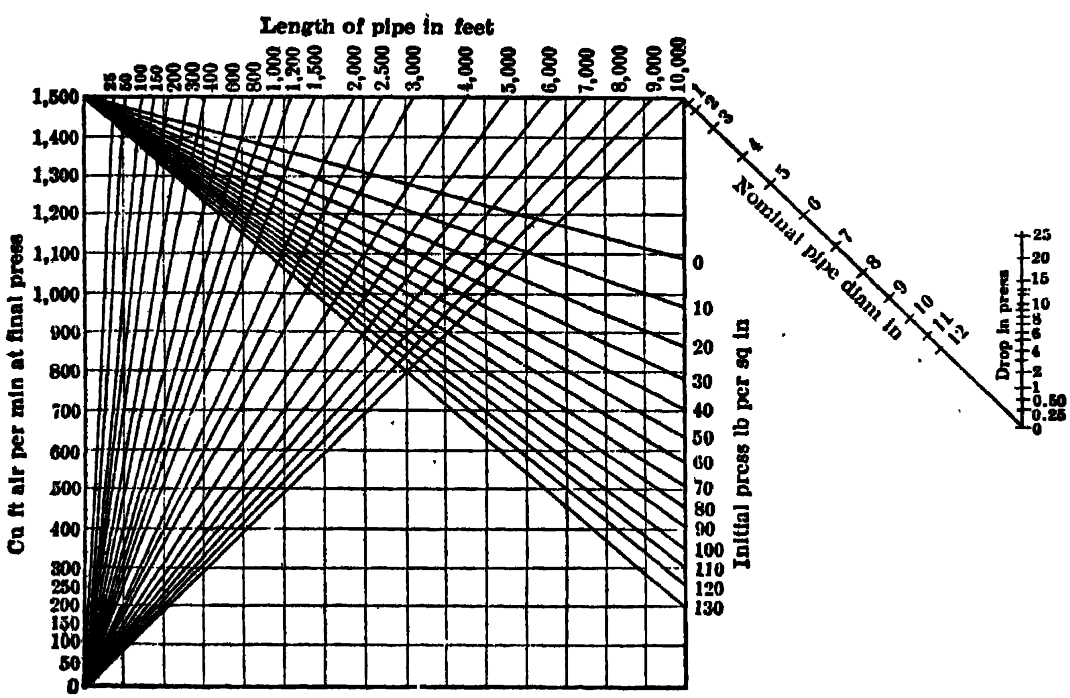

Fig 4. Graphic Solution of D'Arcy's Formula (N. Herz)

Table 5. Friction of Air in Pipes

Divide the number corresponding to diam and vol by the ratio of compression; result is loss in lb per sq in, in 1 000 ft of pipe

For longer or shorter lengths, friction loss is proportional to the length for 25 ft, 1/2 of the above; for 150 ft, 3 times the above, etc.

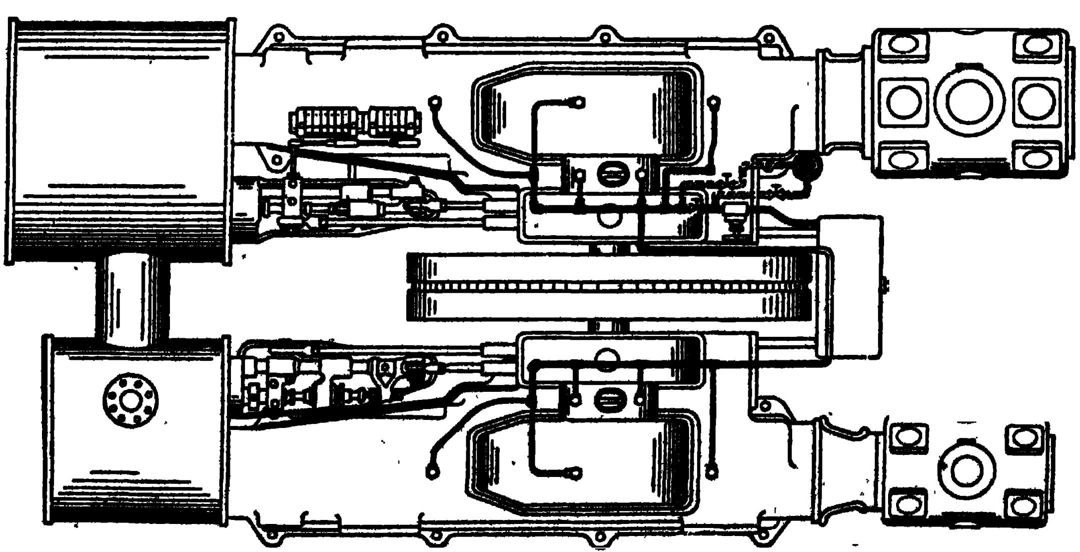

Fig 5. Ingersoll-Rand Duplex, Steam-driven Compressor (intercooler not shown)

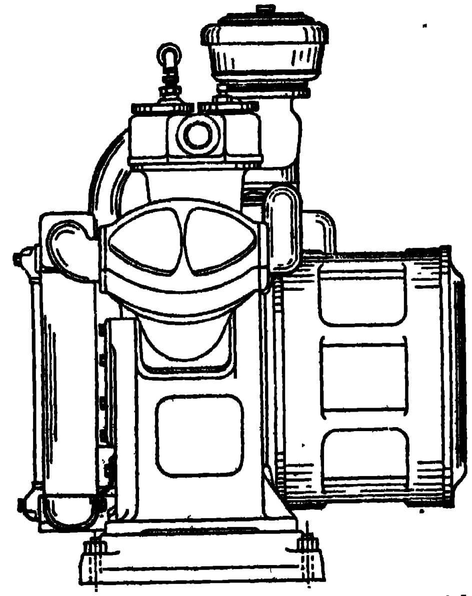
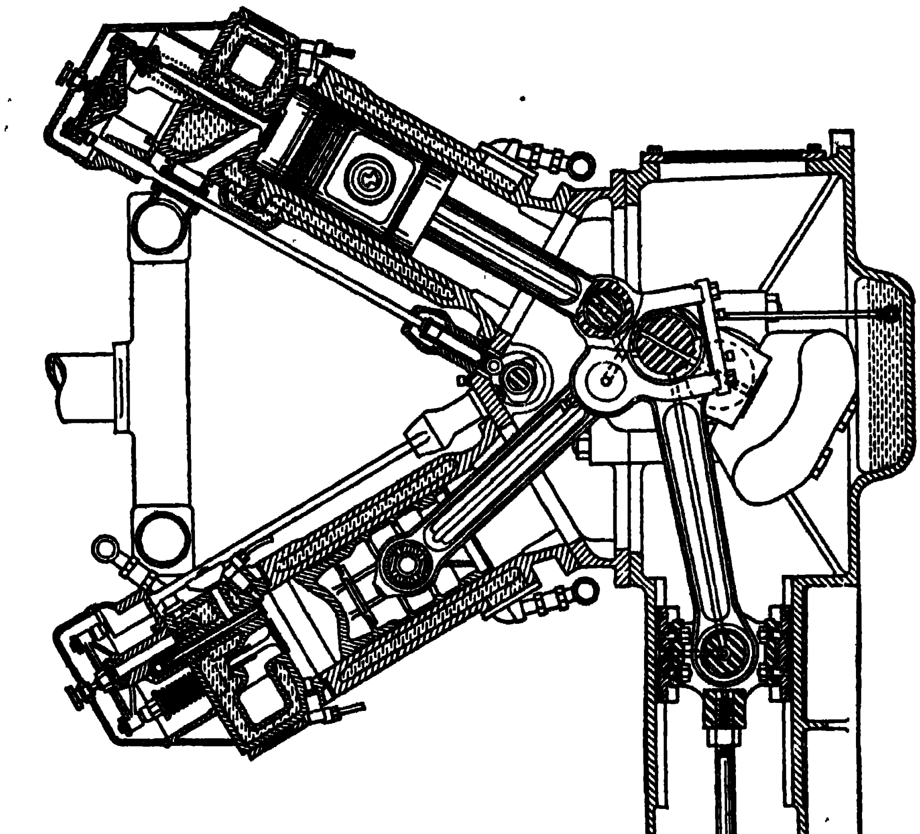
4. RECIPROCATING COMPRESSORS

Steam-driven compressors are used where steam power is most economical; as at coal mines, or where fuel oil or gas is available at low cost, or where steam must be provided for other uses. They are built in capacities from 100 to 8 000 cu ft per min (Fig 5).





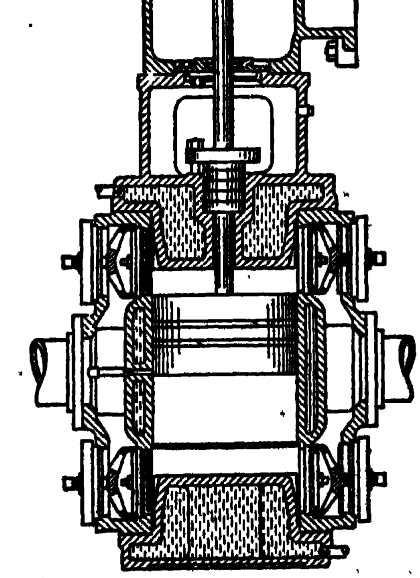


Fig 6. Small Air-cooled Compressor with Direct-connected Motor (Ingersoll-Rand)

Fig 7. Ingersoll-Rand Compressor, Direct-connected with Diesel Engine

Direct-connected, electric-driven compressors are used where electric power is most economical, and where the value of compactness, high efficiency, and the power-factor correction capacity of synchronous motors offsets the slightly higher first cost of this type

Uttarpara Jaikrishna Public Library
No.

Capacities, from 80 to 15 000 cu ft per min. Compact air-cooled units (Fig 6) are available in capacities to 450 cu ft per min.

Diesel engine- and gas-engine-driven compressors are also built as direct-connected machines (Fig 7). They are most used in petroleum production, but are suitable for metal mines where fuel oil or gas is cheap.

Direct-connected compressors are of two forms: (*a*) horizontal, with the power cylinder on one end of the frame and the air cylinder on the other, the connecting rods acting on a

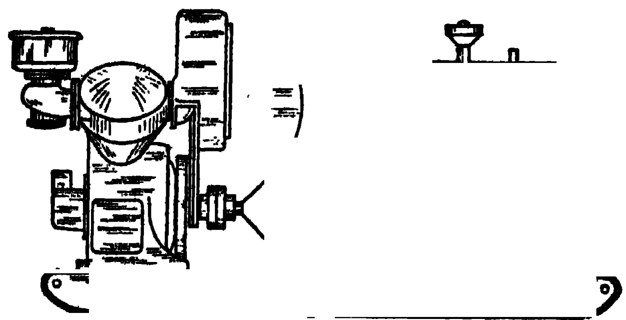

Fig 8. Sullivan Compressor, Direct-connected to Engine

common crankshaft; (*b*) vertical, with power cylinders in a vertical or V-arrangement, and the compressor cylinders in a horiz plane, the connecting rods acting on a common crankshaft. Type (*b*), lighter in weight and more compact, is built in capacities to 4 000 cu ft per min, at 100 lb discharge pressure. Direct-connected compressors may also be driven by an impulse water wheel, mounted on the crankshaft (now obsolete).

Direct-coupled compressors (Fig 8) are largely used where the driving unit can be economically operated at normal compressor speeds, as for portable or mine-car types, and small motor-driven or medium size Diesel-driven compressors. Capacities vary with the kind of driver.

Portable compressors (Fig 9, 10) are well suited to contract work, and exploration or operation of small mines; driven by gasolene engine, fuel oil (Diesel) engine, or elec motor.

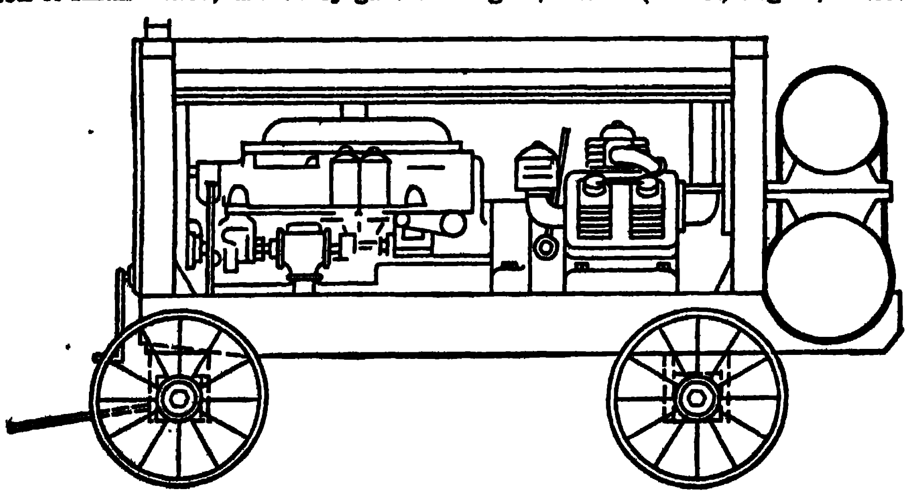

Fig 9. Portable Compressor

They are mounted on skids, steel wheels, solid rubber or pneumatic-tired wheels, or on trucks. Units with flanged wheels, or crawler-type treads, are used for tie tamping on railroads. Most makers offer 2-stage, air-cooled machines; some, water-cooled machines. Portable compressors are rated in actual air deliveries and the sizes are quite well standardized at 60, 85, 160, 210 and 315 cu ft per min. Water-cooled units of about 420 cu ft capac are also built.

Mine-car compressors are designed for electrically-operated mines for local supply of compressed air underground, thus eliminating long pipe lines. They are equipped with standard motors, or, for gaseous mines, with explosion-proof motors and control approved by the U S Bur of Mines. These compressors are air-cooled, usually coupled directly to the motor, and mounted on a frame having flanged wheels to run on mine track. Overall height above the rails is 32 in or less, depending on size and make; capacities, to about 170 cu ft per min (Fig 10).

Belt-driven compressors, widely used for stationary plants, are built in many forms and sizes. Most of them are driven by multiple V-type belts in grooved pulley sheaves, or by short, flat belt with idler, or short belt with driver on pivoted base, or long-belt drive (Fig 11). Long-belt drive, because of space required, is now little used. Any of

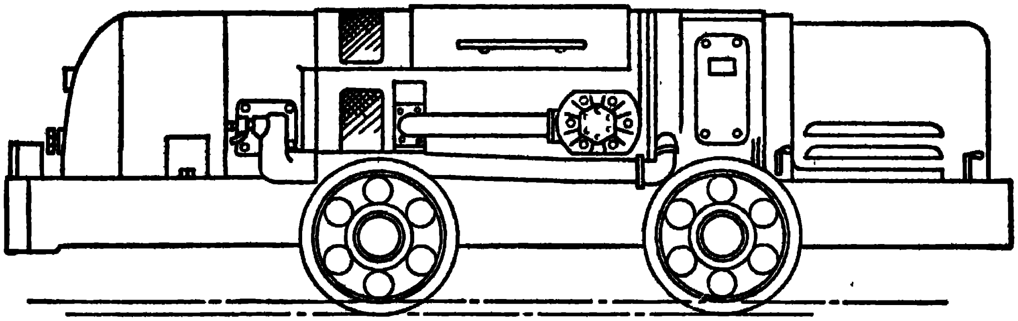

Fig 10. Sullivan Mine-car Compressor

the 3 types of short-belt drives give good results if properly installed. Capacities: 4 to 1 450 cu ft per min; sizes from 4 to 70 cu ft are almost always air-cooled; those from 70 to 450 cu ft are either air- or water-cooled; larger sizes, water-cooled.

Chain-driven compressors are rarely used, because the reciprocating motion introduces severe service and design problems for the chain manufacturer, and usually requires spring-loaded sprockets. Where supplied, they are generally the same as for belt drive, but have sprockets instead of pulleys.

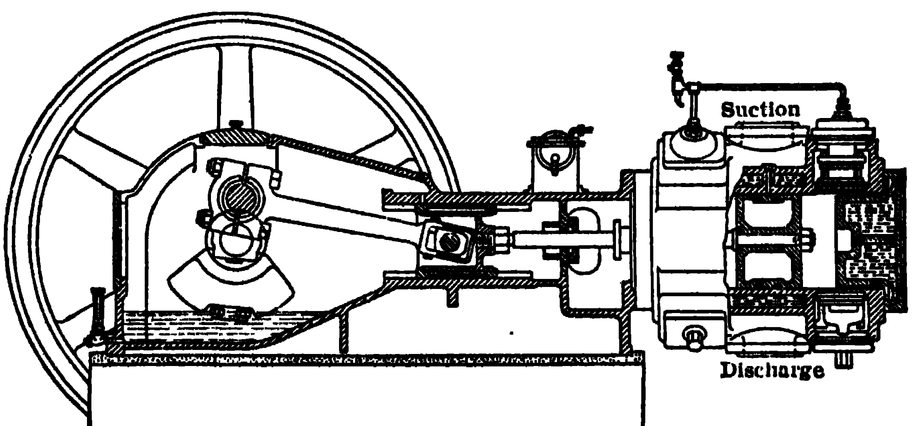

Fig 11. Worthington Belt-driven Single-stage Compressor

Air valves for reciprocating compressors (1, 2, 5). Practically all discharge and inlet valves on present-day reciprocating compressors are of the plate type; other forms, as poppet, Corliss and piston-inlet, are found only on older machines. Poppet valves are controlled by a coil spring. Their weight is a disadvantage, and they are now little used, except in third- or fourth-stage cylinders of some multi-stage compressors.

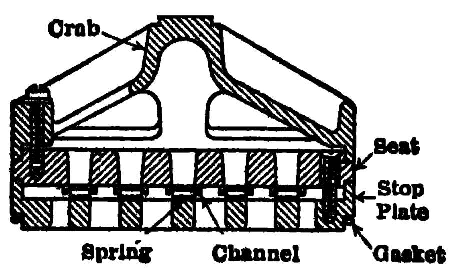

Fig 12. Ingersoll-Rand "Channel Inlet" Plate Valve

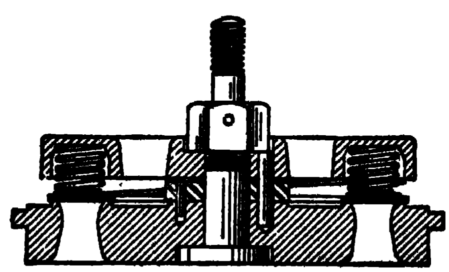

Fig 13. Plate Valve

Plate valves (Fig 12, 13) consist of a seat or grid, having rectangular or annular ports, upon which the valve seats; also a closing spring and a stop plate. The valve, of thin, light-weight alloy steel, is composed of annular rings, rectangular strips, or disks. The

springs may be separate (spiral-coiled, flat-coiled, flat-volute, flat-annular, flat-strip), or form a part of the valve itself. The stop- or cushion-plate limits the valve's lift. A cushioning device, often provided, usually consists of an air space in the stop-plate, a spring stop-plate, or means for trapping air between spring and valve. Fig 14, 15 show other forms. The valve lift is from .03 to .28 in, depending on size and type; valve area, for both inlet and discharge, from 12 to 20% of piston area.

Advantages of plate valves: simplicity, minimizing of inertia by their light weight, large valve area, prompt opening and closing, and more effective water jacketing is permitted.

Governors, regulators and unloaders for reciprocating compressors (1). There are three methods of controlling the output: (*a*) by varying the speed; (*b*) by varying the output at constant speed; (*c*) by automatically starting and stopping the compressor at predetermined pressure limits; (*d*) a combination of (*a*) and (*b*) is sometimes used. APPLICATIONS: method (*a*) to steam and internal-combustion engines, the speed of which is easily varied; (*b*) to belt- and electric motor-driven units running at constant speed; (*c*) is common for moderate capacity compressors, where the demand for air is intermittent; (*d*) is used where method (*a*) does not give the required range of control. Nearly all governors and regulators are controlled by variations of air pressure.

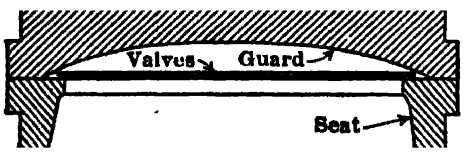

Fig 14. Worthington "Feather" Valve

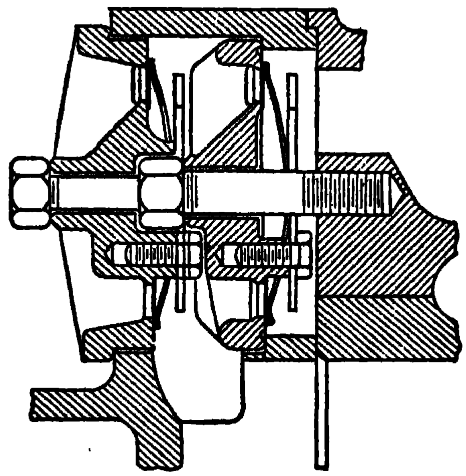

Fig 15. Sullivan "Wafer" Valve

Regulators for steam-driven compressors. AUTOMATIC CUT-OFF GOVERNORS, used on several makes, vary the cut-off point of the steam, thus changing the speed. They are actuated by both speed and air pressure, thus securing proper speed for a given capac and maintaining the most economical steam cut-off for each speed. DIRECT THROTTLING GOVERNORS are also controlled by air pressure and speed, throttling the steam at point of inlet. Cut-off is adjusted by hand. This method gives poorer steam economy than the automatic cut-off governors.

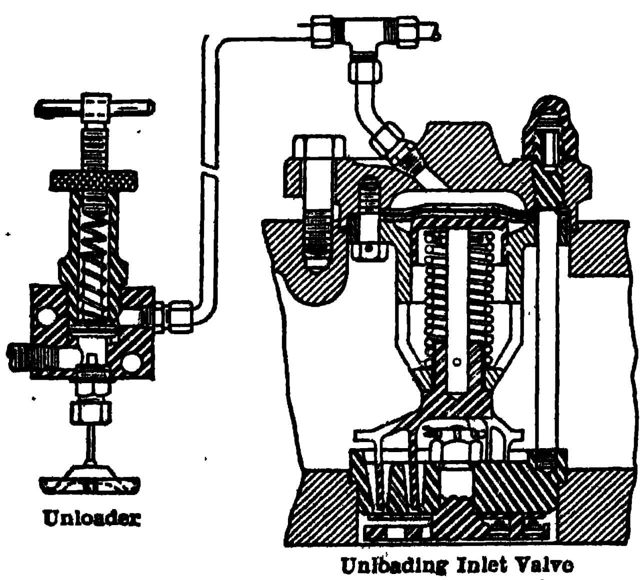

Fig 16. Inlet-valve Unloader and Pilot Valve (Chicago Pneumatic Tool Co)

Cylinder unloaders, for constant-speed compressors (see method *b* above).

Inlet-valve unloader holds the valve open by a fingered yoke, thereby allowing the air to move in and out of the cylinder without compression. This unloader is usually operated by air pressure, controlled by a pilot valve. On duplex compressors, partial unloading is obtained by opening the inlet valves in only one end of the cylinders (Fig 16).

Clearance unloaders consist of clearance pockets at each end of a double-acting cylinder. The pockets are connected with the cylinder by valves. As the pocket volume is added to the normal cylinder clearance, the amount of new air taken into the cylinder is reduced by that amount. By providing enough clearance pockets, an unlimited range of capacity is obtainable. In practice, there are 4 pockets in each cylinder, which are opened in pairs to insure balanced operation. On a duplex compressor this provides five-step control: 0, $^1/_4$, $^1/_2$, $^3/_4$ and full (Fig 17). The

clearance valves are operated by air pressure, controlled by air-operated pilots or by pressure-operated solenoid switches.

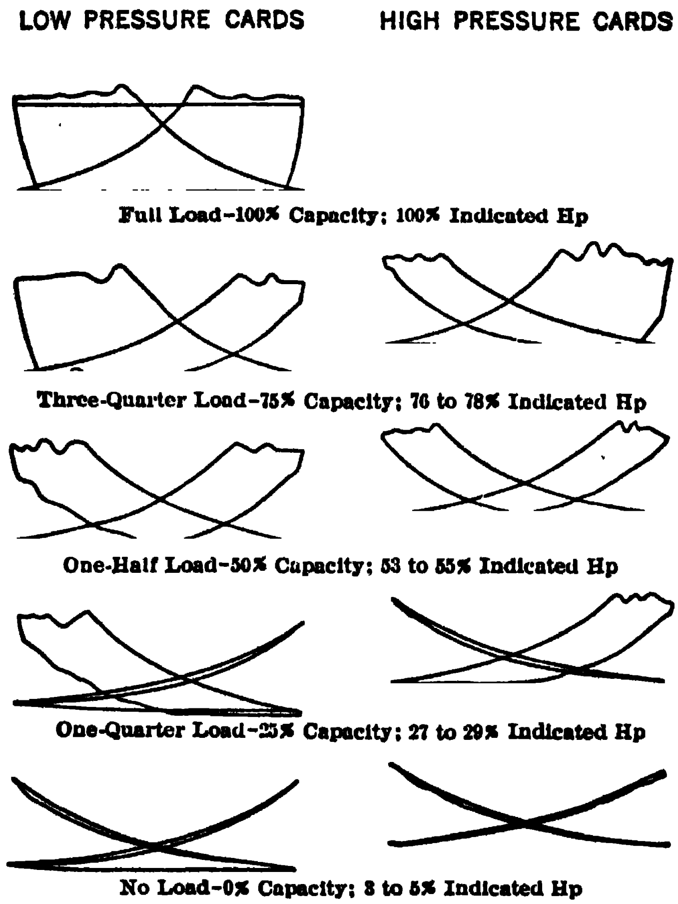

Fig 17. Indicator Cards, showing Operation of Ingersoll–Rand 5-step Clearance Control

Inlet plug unloader, used on some compressors of moderate capacity, consists of a valve which closes the compressor intake passage. It is pressure-operated by means of a small pilot valve (Fig 18).

Centrifugal unloader is an auxiliary used on some compressors having automatic start- and stop-control, so that the motor can come up to speed before compression begins. A small flyball governor opens a line to the high-press cylinder and exhausts it to atmosphere when the compressor stops; when the compressor is started, it closes this line only after operating speed is reached.

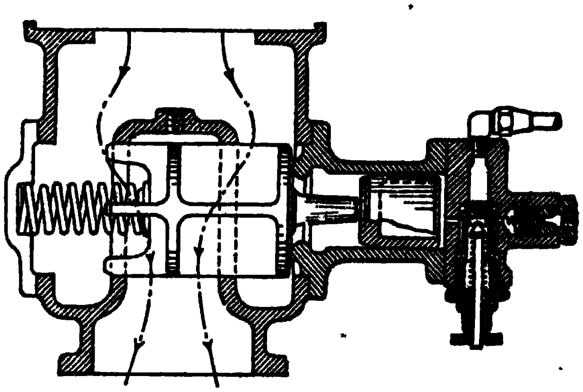

Fig 18. Inlet Plug Unloader

Speed governors are of the regulation flyball type, the compressor cylinders being unloaded by one of the methods already described. Throttling regulators can be employed to slow down the compressor when unloaded. This method is often applied to portable compressors driven by gasolene or oil engines.

Intercoolers cool the air in its passage between stages of a multi-stage compressor. Since cooling of compressed air reduces its volume, less air is handled by the high-press cyl, and proper cooling at this point largely determines the effic of stage compression. In good practice the air is cooled in the intercooler to within 20° F of the intake temp. Fig 19 shows a common type of intercooler; a shell containing horis " finned " tubes, through which water circulates, baffle plates distributing the air around and between the tubes. In AIR-COOLED COMPRESSORS, the compressed air passes through the intercooler

tubes, the fins conducting the heat to the atmospheric air blown over them by a fan. Intercooler press is a good gage for detecting trouble in the compressor cylinders. The correct abs intercooler press is roughly equal to abs intake press × cylinder ratio. Cylinder ratio is the displacement of low-press cyl or cylinders, divided by displacement of the

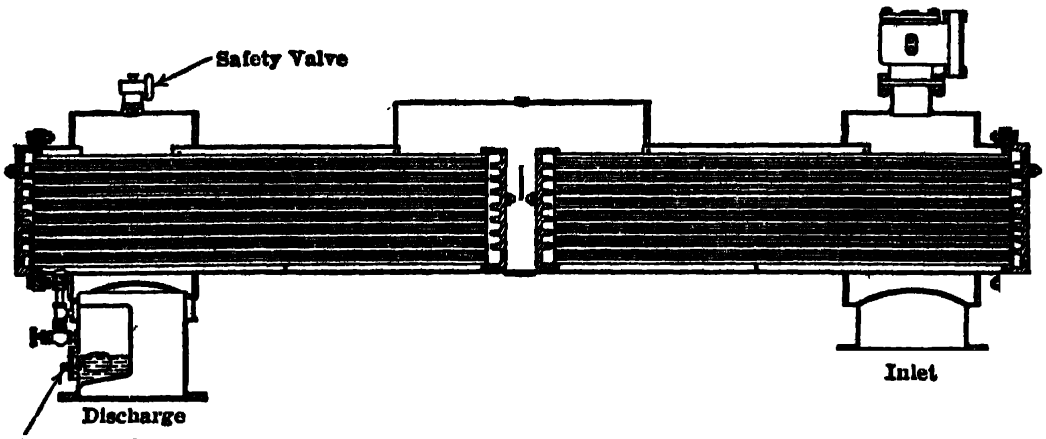

Fig 19. Intercooler (Ingersoll–Rand)

high-press cyl. On 100 lb, 2-stage, sea-level compressors, the intercooler press is usually 27–29 lb gage.

5. POSITIVE PRESSURE AND ROTARY BLOWERS

Positive pressure blowers work on the principle of rotary pump; lobed impellers mesh with each other like gear teeth, and, revolving within a casing, sweep the air before them.

Between casing and impellers, and between the impellers themselves, are clearance spaces through which some compressed air leaks back. This leakage (slip) is constant with speed of the blower, but varies with square foot of the press. Slip is measured by the number of revolutions required to offset it, and is about 20%. Capac is stated in terms of displacement per rpm, and delivery equals displacement times rotative speed, minus slip. Omitting slippage, 5–10% should cover all losses. Intake ports being large, the entering air is not heated; hence, a good vol effic, which, based upon power intake, is 60–85%. Rotative speeds range from 600 in the smaller, to 100 rpm in the larger blowers. They are not well suited to variable delivery, nor to pressures above 10 to 12 lb gage.

Rotary blowers and liquid-seal blowers are of the positive-press type, operating at comparatively high speeds. At present, they are used chiefly for very small vacuum pumps and compressors having little use in the mining field.

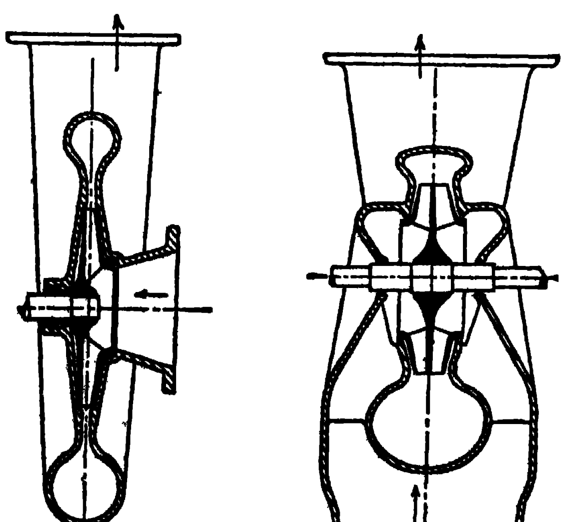

Fig 20. Single-stage Centrifugal Blowers (uncooled)

6. TURBO BLOWERS AND COMPRESSORS (1, 2, 10)

These operate by the centrifugal action of impellers rotating within a casing like a centrifugal pump. They have 1 to 15 stages, depending on the press, each consisting of a separate impeller followed by a diffuser and suitable return passage (Fig 20, 21). Advantages: Simplicity, economy of space and foundation, freedom from vibration, non-pulsating discharge, uniform press with wide variations in capac, light weight, few mechanical parts and oil-free discharge.

Types and applications. Motor-driven single-stage turbo blowers may supply air for mine ventilation, flotation, converters, or scavenging; also for cylinders of 2-cycle Diesel engines and supercharging them. They have capacities of 300–40 000 cu ft per min for

pressures of $^3/_4$ to 3 lb. In the smaller sizes, impellers may be mounted directly on the motor shaft. Steam turbine-driven units are also built. Small, multi-stage blowers for

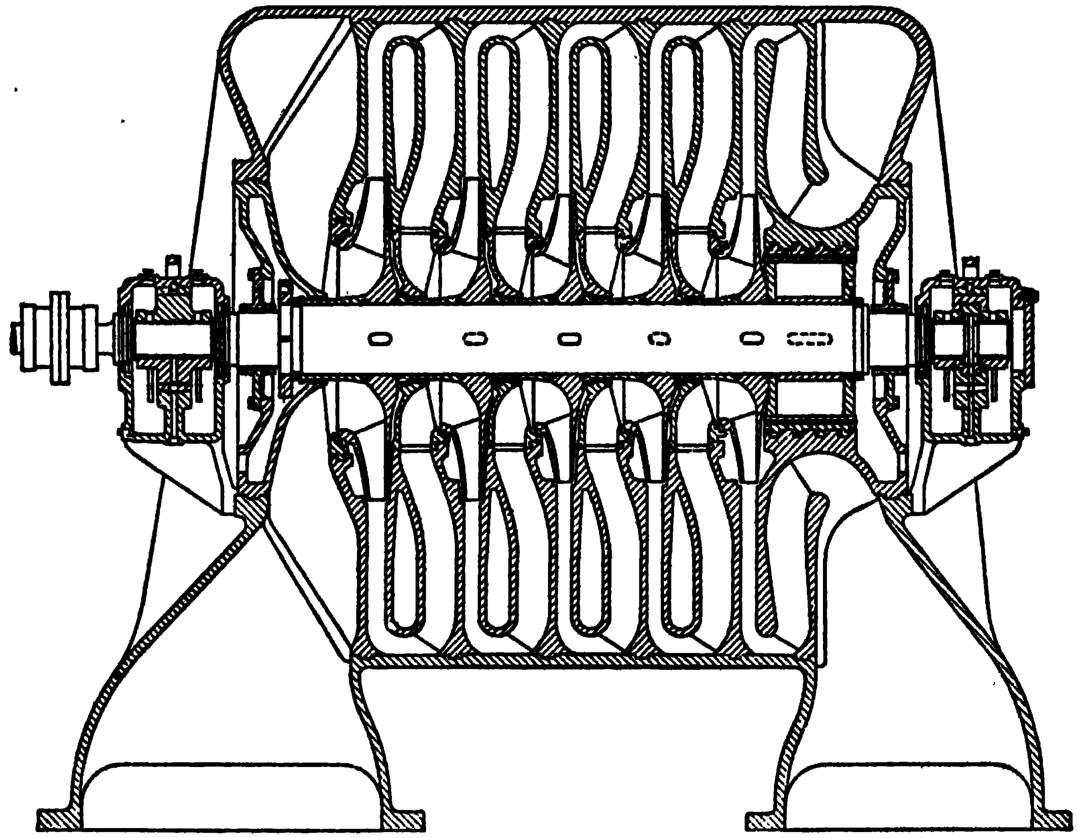

Fig 21. Ingersoll-Rand 5-stage Blower

pressures of 1–6 lb are made in sizes from 300 to 3 000 cu ft per min. Larger units, having 3–5 stages, as used for copper converter work, are available for pressures of 10–25 lb, in sizes to 30 000 cu ft per min, or higher.

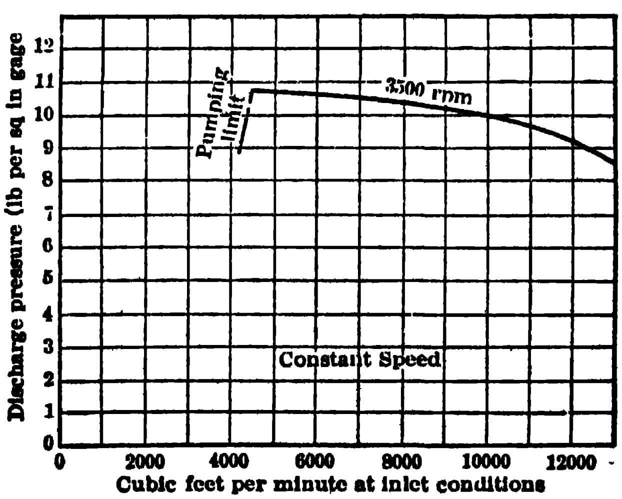

Fig 22. Characteristic Curve of Constant-speed Blower

Multi-stage blowers or turbo compressors for higher pressures can be obtained in capacities of 3 000 to 70 000 cu ft per min. In general, turbo-compressors for 100 lb press, as required in mine service, are practical as to first cost only in capacities above 5 000 cu ft per min.

Turbo units are regulated by constant pressure, constant volume, constant intake-pressure, or constant air-weight methods, as required by local conditions (Fig 22, 23).

The Flin-Flon mine (12), Manitoba, of Hudson Bay Mining and Smelting Co, uses a 20 000 cu ft per min turbo blower, which delivers air at 16 lb press for the copper converter. Fresnillo Mines have in service a 12 000 cu ft per min, 9-stage turbo compressor, operating at 95 lb gage press, and capable of 20% overload. It weighs 6 lb per cu ft per min of capacity (17).

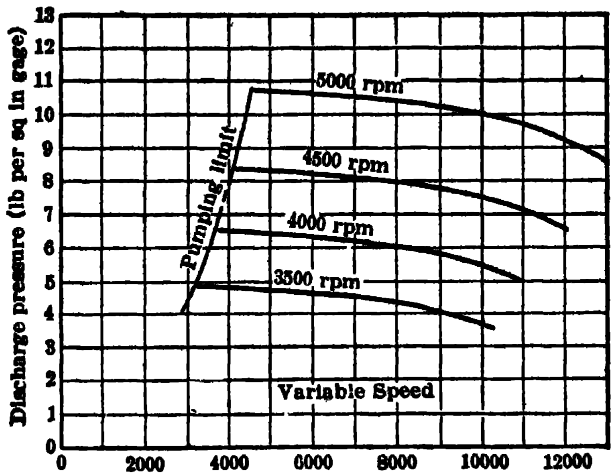

Fig 23. Characteristic Curves of Variable-speed Blower

7. HYDRAULIC AIR COMPRESSORS (1, 5)

These are of two types: (*a*) driven by water wheels (see Art 4); (*b*) operating by direct action of falling water.

Compression by direct action of falling water. Principle: If a stream of water be allowed to fall in a vertical pipe, any air entrained and mixed with the water on beginning its downward motion is compressed by weight of the water. Then, if the direction of flow be suddenly changed to the horiz, and the velocity lessened, the air will be liberated, and may be collected in a suitable container or separating chamber.

This method is most suitable for compressing large volumes of air, and is naturally limited to localities where the necessary quantity and fall of water are available. Air thus compressed has about 3% less oxygen than atmospheric air. A number of installations have been made, the first one at Magog, Quebec, in 1896 (1). Local circumstances will determine the method's feasibility. The alternative of using the water to generate electric power for driving reciprocating compressors should be considered.

8. COMPRESSOR ACCESSORIES

Aftercoolers (Fig 24) cool the air after compression, and hence deposit moisture between compressor and delivery pipe.

This is important, as moisture carried through the pipe lines to machine drills or other tools washes out lubricant and causes wear, freezing and water hammer; also, without aftercooling, pipe lines alternately contract and expand, developing leaks. A 2 000-cu ft per min compressor, running at capacity for 8 hr on intake air at 82° F and 75% humidity, will take in 1 200 lb of water vapor with the air (Fig 25). Condensed, this amounts to 3 bbl of water (43). Some moisture can also be removed by pipe-line separators, placed near the point of air usage (Fig 26).

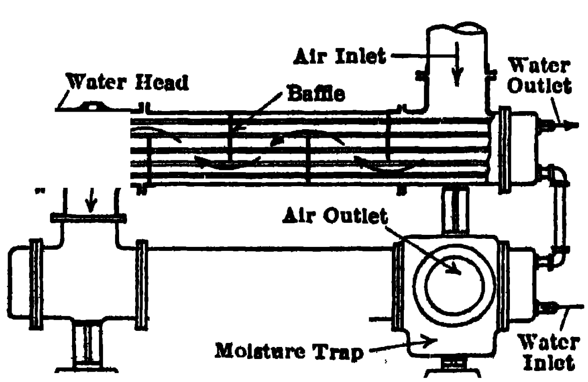

Fig 24. Ingersoll-Rand Horiz Aftercooler

Air receivers act as storage capacity during intervals when the demand exceeds the compressor output, and also help to eliminate pulsations in the discharge line. Some moisture is condensed from the air in passing through the receiver (Fig 27). Receiver size may be

roughly found by the formula $V_2 = \dfrac{14.7\,V_1}{P_2 + 14.7}$, where V_2 = vol of receiver, cu ft; V_1 = displacement of compressor, cu ft per min; and P_2 = discharge press, lb per sq in. This gives the approx minimum size; a larger receiver is preferable (2).

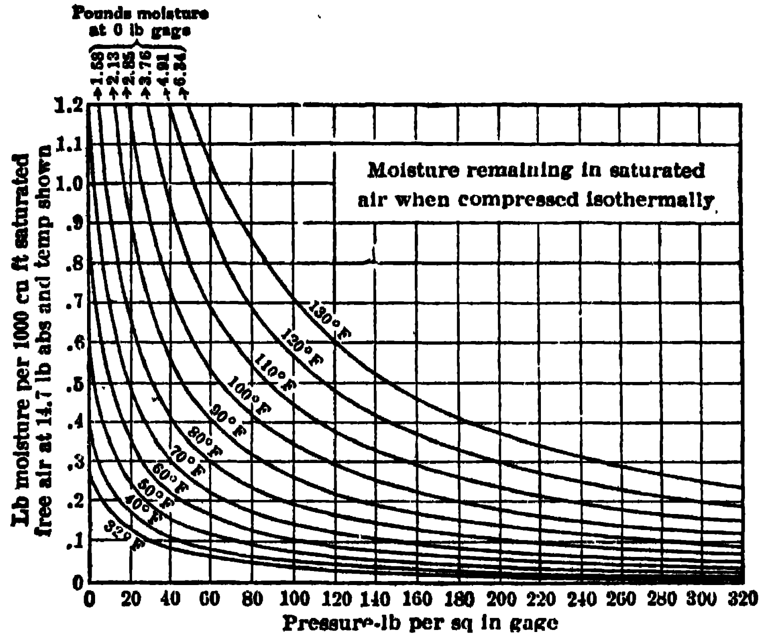

Fig 25. Moisture Carried in Air at Different Pressures

The Anglo American Mining Corp, So Africa, uses a 10 000-cu ft per min compressor to supply dehumidified air underground. Compression is in 3 stages to 130 lb, and air is then expanded in a motor cylinder to freezing point at about 90 lb per sq in. This devaporizes the air, which lowers the mine temp, and reduces the volume of ventilating air required (23, 24, 25).

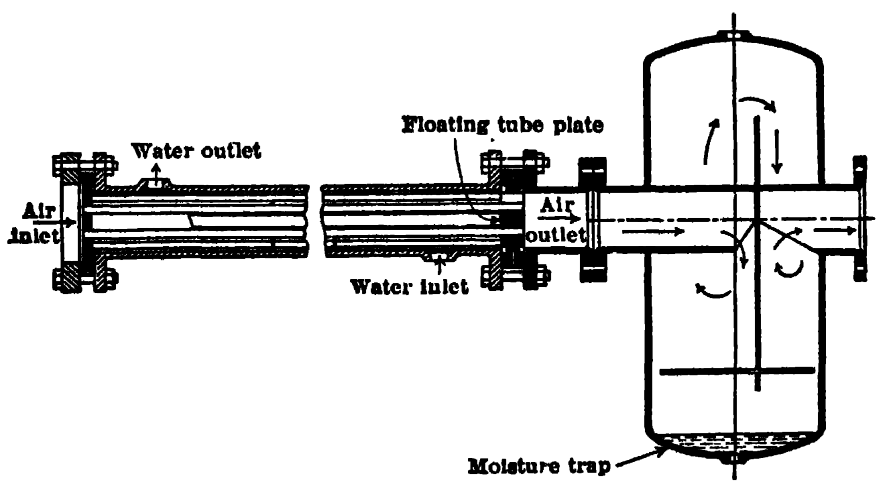

Fig 26. Pipe-line Type of Aftercooler

9. CARE AND OPERATION OF COMPRESSOR PLANTS

Installation layout (Fig 27). The compressor should be in a clean, light room, with ample space for making repairs, removing pistons, rods and intercooler tube nests; also for cleaning and inspection. The compressor intake must not be near any source of heat, as pipes discharging exhaust steam, nor exposed to water, dust, or other waste that can be blown by the wind into the range of intake suction. Concrete foundations are always preferable, though brick or stone can be used if more convenient.

Lubrication is vitally important for proper operation and life of the compressor, but must not be excessive. Oil specifications and instructions of compressor makers should always be followed (2, 21). CRANKCASE. Good quality lubricating oil does not wear out,

and may be re-used in the circulating system when treated by efficient filtering. CYLINDERS. Inlet and discharge valves should be removed occasionally and cleaned; by examining them it can be determined whether the cylinder is receiving proper lubrication. All wearing surfaces should show a greasy appearance; not dry. Oil should not accumulate

in valve pockets or bottom of air cylinder. Table 10, 11 give specifications for suitable lubricants and Table 12, normal quantity of oil.

Intake air and piping. Wherever possible, the intake duct should be run to outside of the building, preferably on the north or coolest side, as the aver outdoor temp is con-

siderably below that of the engine room. Irrespective of the outside temp, the compressed air in a shop pipe-line will be near the temp of the shop when it reaches the tools. If the indoor temp is 70° F, and the compressor takes in 1 000 cu ft free air directly from the shop, it will deliver the same vol at the tools, because initial and final temperatures are the same. If the compressor intake air comes from outdoors, at 40° F, only 943 cu ft of free air will be required to deliver 1 000 cu ft at the indoor temp, a saving of 5.7%. The cooler the climate, the more pronounced the effect (Table 13).

If the compressor intake air comes from an engine room at 100° F, 1 057 cu ft free air will be required to deliver 1 000 cu ft at the indoor temp of 70° F. A case is recorded where, without a cold-air intake duct, 1 500 000 cu ft of free air delivered was costing $43.96 per day. After installing a duct from outside, the cost dropped to $40.42, an annual saving of $1 062 (43). Such savings are obtainable at the small expense of the intake duct.

Table 12. Air-cylinder Oil Required per 10 hr (2)

Cyl diam, in	Piston displacement cu ft	Rubbing surface, sq ft	Oil feed: Drops per min	Oil feed: Pints per 10 hr
Up to 6	Up to 65	Up to 500	1	0.05
6–8	65–125	500–750	1	0.08
8–10	125–225	750–1 100	1	0.11
10–12	225–350	1 100–1 500	1–2	0.14
12–15	350–600	1 500–2 000	2–3	0.20
15–18	600–1 000	2 000–2 600	3–4	0.27
18–24	1 000–1 800	2 600–3 600	4–5	0.36
24–30	1 800–3 000	3 600–4 800	5–6	0.48
30–36	3 000–4 500	4 800–6 000	6–8	0.60
36–42	4 500–6 500	6 000–7 500	8–10	0.74
42–48	6 500–9 000	7 500–9 000	10–12	0.90

Above figures are for 1 cyl only; for duplex or compound compressors, both cyls must be considered; based on approx 8000 drops per pint, at 75° F.

Table 13. Effect of Intake Temperature on Compressor Capacity (intake vol required to produce 1 000 cu ft free air at 70° F)

Temp of intake, °F	Relative intake vol required, cu ft	% hp saved	Temp of intake, °F	Relative intake vol required, cu ft	% hp saved
30	925	7.5	80	1 019	−1.9
40	943	5.7	90	1 038	−3.8
50	962	3.8	100	1 057	−5.7
60	981	1.9	110	1 076	−7.6
70	1 000	0.0	120	1 095	−9.5

The intake for a single compressor should have an area of at least 25% of area of air piston. For a multiple installation, care should be taken to provide a duct of sufficient size. Area of intake duct at the compressor nearest the air source should equal the sum of the areas of all the individual intake pipes; but the area of the main duct can be decreased after each branch to a compressor.

Air filters (2) on each intake duct are highly advisable. Tests show that they return 30% or more on the investment by increasing life and reducing maintenance. There are several kinds. In the ADHESIVE IMPINGEMENT TYPE (Fig 29), air is drawn in against baffles of metal, crimped wire, or glass-wool coated with a viscous substance. Metal filters are cleaned at intervals; the glass-wool, replaced. REPLACEMENT FILTERS are pre-coated with a suitable solution. After cleaning they are dipped in an oil adhesive. For large installations, AUTOMATIC FILTERS are used, in which the filter elements are constantly moving and passing through oil carried in the base (Fig 30). OIL-BATH FILTERS (Fig 31) are of the adhesive impingement type, but the filter element is partially immersed in oil. Capillary attraction and action of the intake air keep the elements properly coated. In FABRIC FILTERS, the air passes through filter cloths, cleaned by a reverse air flow, or a vacuum cleaner, or may be dry cleaned.

From 1 to 4 lb of dirt are taken into a 2 000-cu ft per min compressor, operating 10 hr a day for 10 days (26). The aver dust intake of a 1 000-cu ft compressor is 77 1/2 lb per year (44).

Without a filter, valves on a 5 000-cu ft per min compressor required cleaning every 2 weeks; after installing a filter, the valves were cleaned every 6 months (26).

On a large compressor, filters effected an annual saving of $2 228, or a return of 69.9% on filter cost. In a plant of 2 small compressors, filters effected a yearly saving in maintenance equal to 62.8% on cost of the filters (26).

Explosions in compressors and receivers (1, 32). CAUSES: excessively high internal press, due less to the air press carried than to ignition, in compressor, piping, or receiver, of

an explosive mixture of air and gas from lubricant. The underlying causes are: (*a*) excessive and improper lubrication, resulting in coating receiver, intercooler and air passages with gummy deposits of partly dried oil and dust; (*b*) ignition and volatilization of these deposits by unusual temp, due to broken or leaky valves. LUBRICATION should be in accordance with compressor builders' or oil companies' specifications. All oils give off combustible

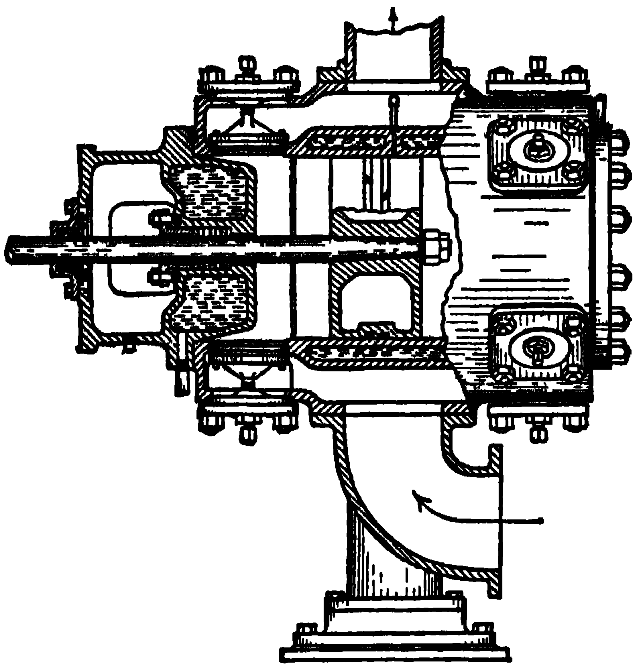

Fig 28. Typical Compressor Air Cylinder

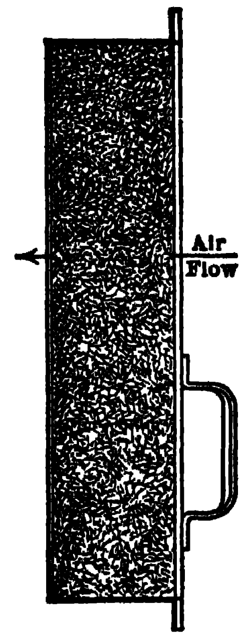

Fig 29. Metal Adhesive Impingement Air Filter

gases when heated. The lowest temp at which this begins is the FLASH POINT, the ignition temp being the BURNING POINT. As ordinary lubricating oils flash at about 250° F (a temp below the usual working temp of compressors), special HIGH-FLASH cylinder oils should be used (see Table 10, 11).

Temp due to compression depends upon initial temp, working press, and effic of the cooling devices (Art 8). A single-stage compressor, working at 100 lb, has a normal discharge temp of less than 470° F; a 100 lb 2-stage compressor at 100 lb, about 235° F (Table 3, Art 3). With leaky exhaust valves, the temp may be materially higher (1).

Precautions for avoiding high temp: (*a*) the compressor should be adapted to the conditions; (*b*) intake pipe covered by insulating material, and air taken from as cool a place as possible, outside of the engine room; a lowering of 5° F may increase effic by 1%;

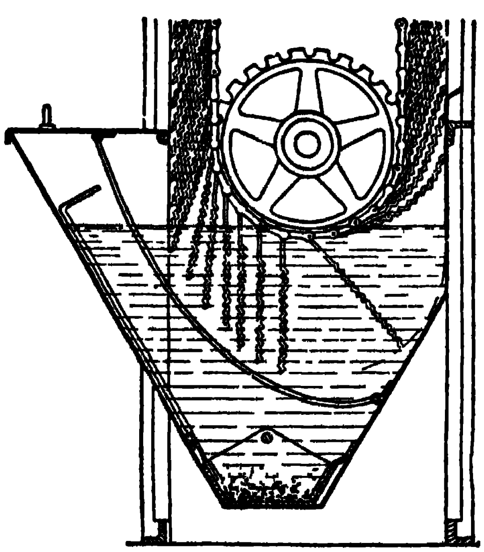

Fig 30. "Automatic" Filter Air

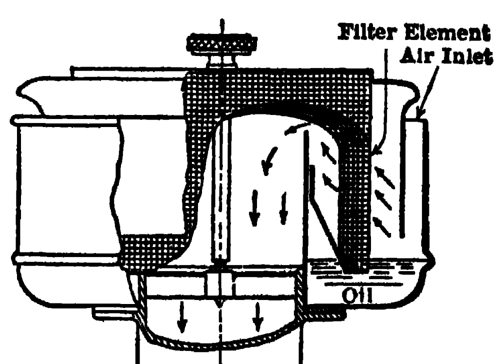

Fig 31. Oil-bath Impingement Air Filter

(*c*) unloader should be such as not to cause excessive heating when in operation; (*d*) largest possible area of cyl surface should be jacketed, and plenty of water used; (*e*) a stage compressor must have effic intercoolers; (*f*) aftercoolers increase effic; they eliminate oil vapor as well as moisture, thus minimizing danger of explosions; (*g*) if circulating water be reused, provide ample water coolers; (*h*) place receiver inlets near the top, and outlets about 1 ft above the bottom, to insure clean air; (*i*) receiver should have blow-off cocks at the bottom, and a man-hole for inspecting the interior; (*j*) place a recording thermometer between high-press cyl and receiver; (*k*) install an automatic safety valve with no shut-off valves between it and the compressor; (*l*) inlet air should be free from dust; (*m*) while running, never inject kerosene into the compressor to cut carbon deposit; (*n*) keep intercooler, aftercooler and receiver clean.

Freezing of moisture in compressed air. Moisture in air, under atmos conditions of 75% relative humidity, amounts to about 1 lb water per 1 000 cu ft air. MOISTURE-CARRYING CAPACITY of air depends upon its temp, but is independent of its press or density. Hence, if saturated air be compressed isothermally to 0.1 of its original volume, its water carrying capac is reduced to 0.1, and 0.9 of the water present is deposited. Hot air from the compressor cyl, on entering the receiver, deposits some of its moisture; the remainder is carried into the mains where it may freeze and so reduce the effective area of the pipe. Lastly, in air tools, the intense cold of expansion at exhaust freezes the moisture, which may obstruct ports and valves (1).

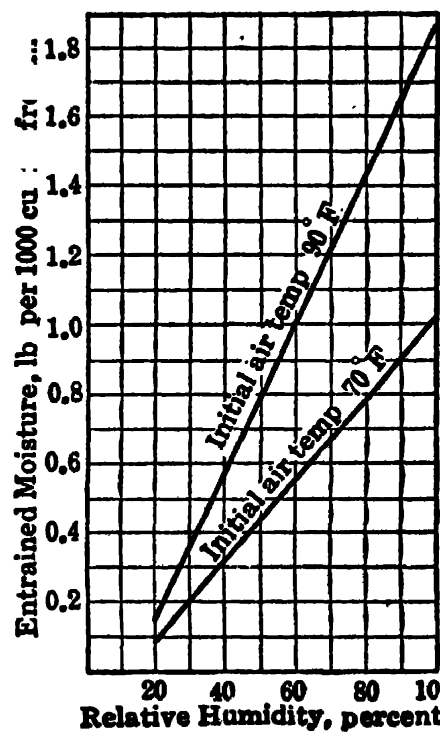

Fig 32. Variation of Entrained Moisture with Relative Humidity and Initial Air Temp (59)

Prevention of freezing. To remove moisture before the air reaches the points at which freezing may take place, several devices may be used, singly or in combination: (*a*) in aftercooler (Art 8), set as close to compressor as possible; (*b*) automatic water traps, at low points in air line; (*c*) a second receiver, near the compressed-air tools, the air being transmitted under higher press, and press reduced as it enters second receiver; (*d*) reheaters.

Quantity of water in compressed air can be approx estimated from Fig 32. To use the chart, start at bottom, with the per cent of relative humidity of the outside air at compressor intake; thence go vertically to the marked or an interpolated temp line; thence horiz to the left-hand scale (see also Fig 25).

Reheating compressed air (1, 3, 5, 35). Large savings are theoretically possible by reheating, due to increase of air volume. But, as it is difficult to apply reheaters to air lines serving rock drills underground, their use is limited to air hoists, pumps and motors. Cost of reheating is about $^1/_8$ of cost of producing the same increase in vol by compressing additional air (5). METHODS IN GENERAL USE: (*a*) passing the air through a cast-iron chamber or coil of pipe, heated by a fire or current of hot gases or steam; (*b*) adding heat within the body of air itself, by combustion of fuel, injection of steam or hot water, or placing in the air line an electric-resistance coil (1). Reheaters in general consist of a hollow shell, having inlet and outlet connections with the air main, and containing tubes, coils or deflecting plates for bringing the compressed air in contact with the heating elements.

10. COST OF COMPRESSED AIR EQUIPMENT AND ITS OPERATION

Installed cost of compressors varies with their size and type, and transport costs involved. Table 14 gives approx costs of compressors without accessories. In general, small compressors cost more per cu ft of capac than large ones.

Cost of compressed-air power includes a number of factors: (*a*) operating cost of compressor, for power attendance, lubricating oil and repairs; (*b*) depreciation; (*c*) interest on investment, plus taxes and insurance. Power cost is the largest item, especially for

continuous operation. The other charges amount to so small a proportion of the total that comparisons are often made on basis of power costs alone (2).

Table 14. Approx Cost of Compressors, Without Accessories (various sources, 1940). Based on compressors working at 100 lb, except as noted; freight not included

Type of compressor for 100-lb delivery press	Piston displacement, cu ft per min	Cost per cu ft per min output	Type of compressor for 100-lb delivery press	Piston displacement, cu ft per min	Cost per cu ft per min output
Small air-cooled, including motor	1–50	$46–12	Two-stage, duplex, power-driven	325–1 350	$ 7–4
Two-stage, air-cooled, including motor	70–450	16–5	Two-stage, duplex, steam-driven	275–7 200	13–5
Single-stage, power-driven, straight-line	70–630	7–3	Two-stage, duplex, including direct connected motor	340–6 200	13–5
Single-stage, steam-driven, straight-line	100–600	16–5	Portable, including engine	50–420	24–13
Single-stage, straight-line, including direct-connected motor	200–630	13–6	Mine-car, including motor	60–180	31–18
			Turbo-compressors	5 000–10 000	10–7

Mark W. Booth (22) gives cost of steam- and motor-driven compressors for inbye power as $7.50 to $10 per cu ft per min.

In general, compressed air costs between 2 and 20 cts per 1 000 cu ft, based on the factors listed above. "Compressed-air Data" gives a cost of 6.1 cts per 1 000 cu ft, including labor, interest, deprec, power and repairs, for an elec-driven compressor, based on a sliding current cost of 1 to 20 cts per kw-hr (2).

Cost of compressed-air tools varies considerably. Table 15 gives approx costs of machines commonly used in mines.

Table 15. Approx Cost of Air-operated Equipment (various sources, 1940)

Type of tool	Weight	Cost	Type of tool	Weight	Cost
Hand-held drill	27–80	$165–300	Drill-steel sharpeners	350–4 500	$400–2 400
Sinkers (heavy, hand-held drills)	75–120	300–400	Oil furnaces for heating drill steel	550–900	200–350
Drifters	120–300	350–650	Air-line lubricators	7–12	8–15
Stopers, hand-rotated	60–105	250–300	Wagon-mounted drills	900–2 400	900–1 600
Stopers, automatic rotation	80–125	350–400	Columns and tripods	100–250	80–125
Air-operated sump pumps	50–120	150–350	Clay diggers	20–30	90–115

Tables 16, 17 and 18 give costs of compressed-air service, including drill steel, at different mines.

Winzes	......	......	......	0.66	......

At United Verde copper mine, Ariz, cost of compressed air per ft of drift was $1.30, and drill steel, $1.10 (38).

During experiments at the DC&E mine, Orango, Mo, in 1937, cost of compressed air only was 30 cts per ton mined; compressed-air cost for sharpening bits, 1.62 cts per bit (45).

11. ROCK DRILLS (1, 2, 34)

Reciprocating or piston drill, in which the steel is clamped to the piston, was the original type; not now used, except in special cases, as underwater drilling. In HAMMER

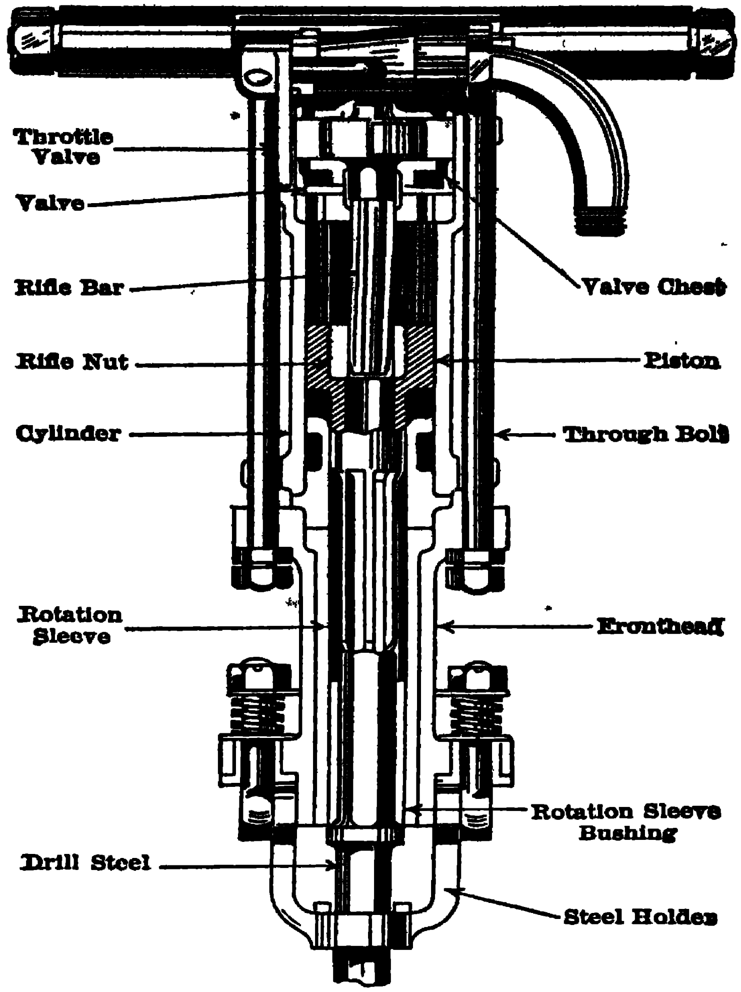

Fig 33. Typical Hand-held Hammer Drill

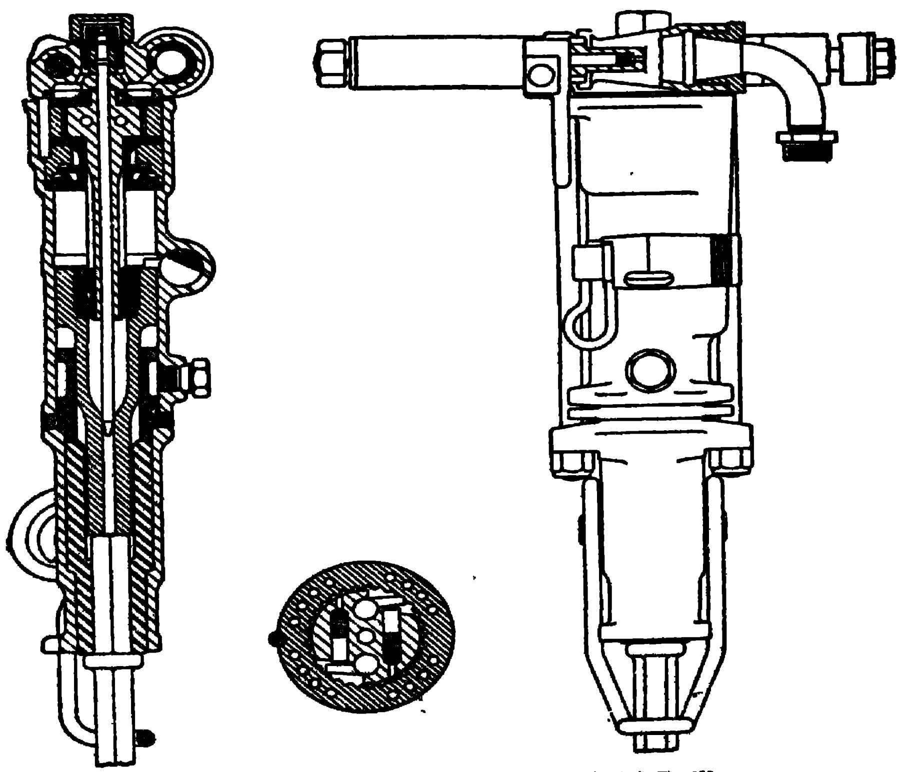

Fig 34. Ingersoll-Rand Hand-held Drill

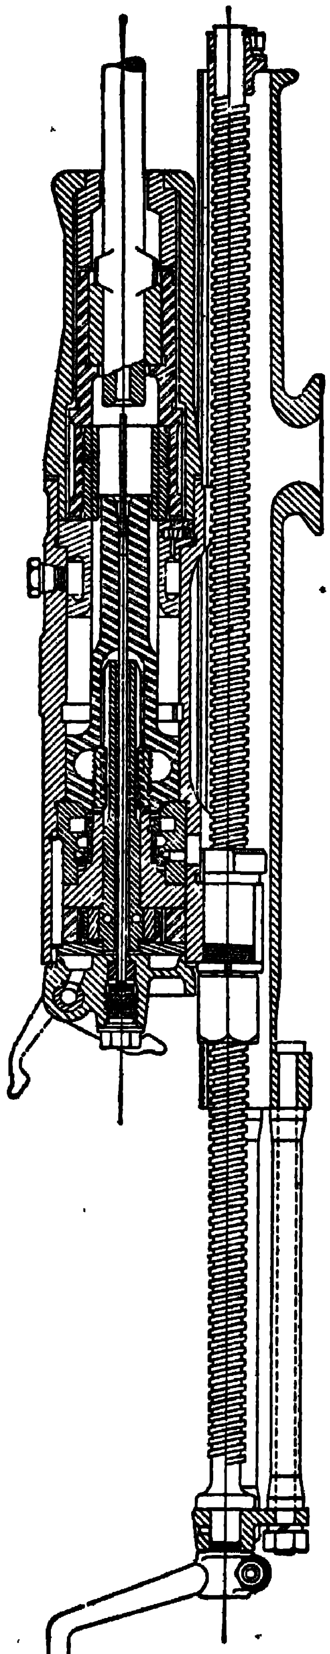

Fig 35. Sullivan Drifter Drill

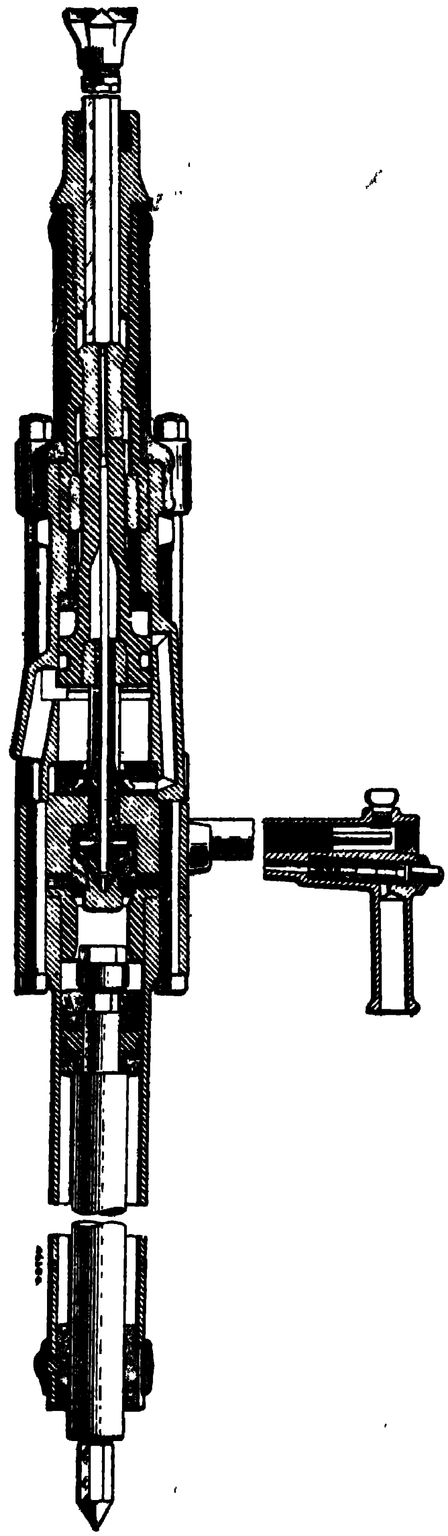

Fig 36. Ingersoll-Rand Automatically-rotated Stoper Drill

DRILLS, the piston strikes the drill steel, which is loosely held in a chuck, the bit remaining in contact with the bottom of the hole except during a slight rebound. In certain types, an " anvil block " is placed between the piston and end of drill steel.

Drill steel ordinarily used has a small hole running through it longitudinally; it is called " hollow steel." " Solid steel," without a hole, is sometimes used for auger drills and hand-rotated stopers. Either water or air, or a combination of both, is forced through hollow steel to remove cuttings from the hole. According to the mode of cleaning the

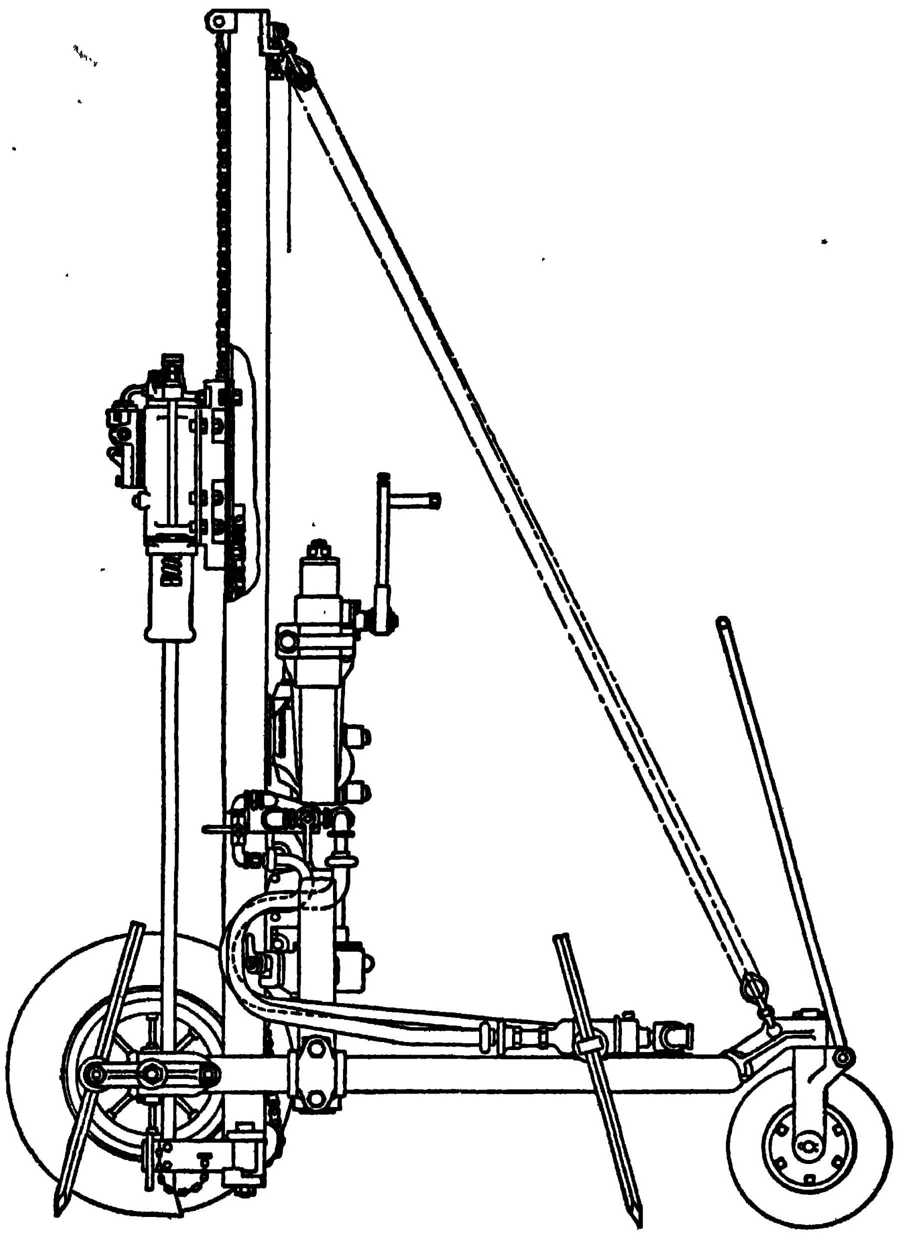

Fig 37. Ingersoll-Rand Wagon Drill

hole, drills are classed as " dry " and " wet." Modern drills strike from 1 600 to 2 200 blows per min.

Hammer drills. Principal classes, and the field of work for each are: (*a*) HAND-HELD DRILLS, mounted, and self-rotating, used chiefly for down-hole work (Fig 33, 34); (*b*) DRIFTERS, mounted drills designed for holes at or near the horiz (Fig 35); (*c*) STOPERS, designed for drilling upward (Fig 36); (*d*) WAGON-DRILLS, drifter or hand-held type, mounted in guides on portable rigs (Fig 37). Guides usually adjustable, for drilling at any angle. Other classes, variations of the above, might be cited; as " SINKERS," large, powerful hand-held drills, for shaft sinking and other heavy work. Hand-held drills are sometimes mounted for horiz drilling, and drifters set on tripods or quarry bars for down

holes. Drills are of many sizes, varying in weight and rotative and blowing power. The most effective drill for given service depends on character of the rock, depth of holes, air press available and other factors; experience is the best guide.

Table 19. Classification of Rock Drills (21)

Hand-held machines	Hand-held machines proper	Non-rotating	Drills	Plug drills	Light drills for plug-and-feather work
			Breakers	Known as paving breakers and classified by wt	Light, 30–40 lb
					Medium, 50–60 lb
					Heavy, 80 lb
			Drivers	Pile-drivers, classified by size of sheeting they will drive	Light, 120–130 lb
					Heavy, 150 lb
		Self-rotating	Usually known as hand-held sinkers; classified by wt		Very light, 25–40 lb
					Light, 40–50 lb
					Medium, 50–65 lb
					Heavy, 65 lb and up
	Converted drifters	Heavy sinkers; classified by cyl bore		3 in	Some intermediate sizes are made, but these are the usual sizes
				3 1/2 in	
Drills on fixed mountings	Hand feed	Drifters, classified by cyl bore	3 in	Some intermediate sizes are made, but these are usual sizes	
			3 1/2 in		
			4 in	Drifters may be mounted on portable carriages or jumbos; differ from wagon-drills in that the mounting is not an integral part of the unit, and not sold with it	
	Mechanical feed		3 in		
			3 1/2 in	Some drifters have air feeds; differ from stopers in that the drill is not supported by feed cyl	
			4 in		
Drills on air legs	Hand-rotated	Stopers, classified partly by wt, partly by bore, into 2 classes: light and heavy			Light, 60–75 lb
					Heavy, 80–100 lb
	Self-rotating	Distinction based on kind of work they are suited for			Light, 80–100 lb
					Heavy, 110–130 lb
Wagon-mounted drills	Classified according to length of feed and bore of drill			Light wagon-drill, feed 6 ft or less	With 3-in drill, or smaller
					With 3 1/2-in drill
					With 4-in drill
				Heavy wagon-drill, feed 10 ft or more	With 3 1/2-in drill
					With 4-in drill

Hand-held drills (Figs 33, 34) are made in dry, wet or blower types. The blowers have greater hole-cleaning capacity than the standard dry type, due to the greater vol of air blown through the steel. They weigh from 30 to 85 lb. Sinker drills weigh from 75 to 135 lb. A special drill, weighing about 40 lb, and having strong rotation and light blow, uses solid twisted auger-steel for drilling coal and soft ground. Hand-held drills are ordinarily employed for down holes; sometimes for drifting by using a conversion mounting or a plank or sling. They are also adapted for stoping by adding an air-feed leg (38).

Drifter drills (Fig 35) are generally self-rotating, and used wet. A few have independent air-motor-operated rotation. Drifters weigh from 115 to 225 lb. They are usually

clamped to a cross arm on a column. In quarries, the mounting is often a horiz bar, supported on legs or a tripod. In some regions, as used for stoping, they are fed by a screw which pushes the drill forward on its carriage, or withdraws it for changing the steel. Recently, several mechanical feeds have come into use; some are air feeds, using air pressure or air motors to move the drill forward; a successful form has a ratchet device operated by the vibration of the drill. Drifters usually have 3-, 3 $^1/_2$-, or 4-in cylinders. The 3-in drill weighs about 125 lb, the 3 $^1/_2$-in 145 lb, and the 4-in 180 to 220 lb. Other sizes, as 2 $^5/_8$ in, 3 $^1/_8$-in and 3 $^3/_4$-in, are furnished by some makers.

Stoper drills are primarily for overhead work, as raising and back stoping. Standard-feed stopers have the air-feed cylinder attached to the backhead of the drill, the air-feed-

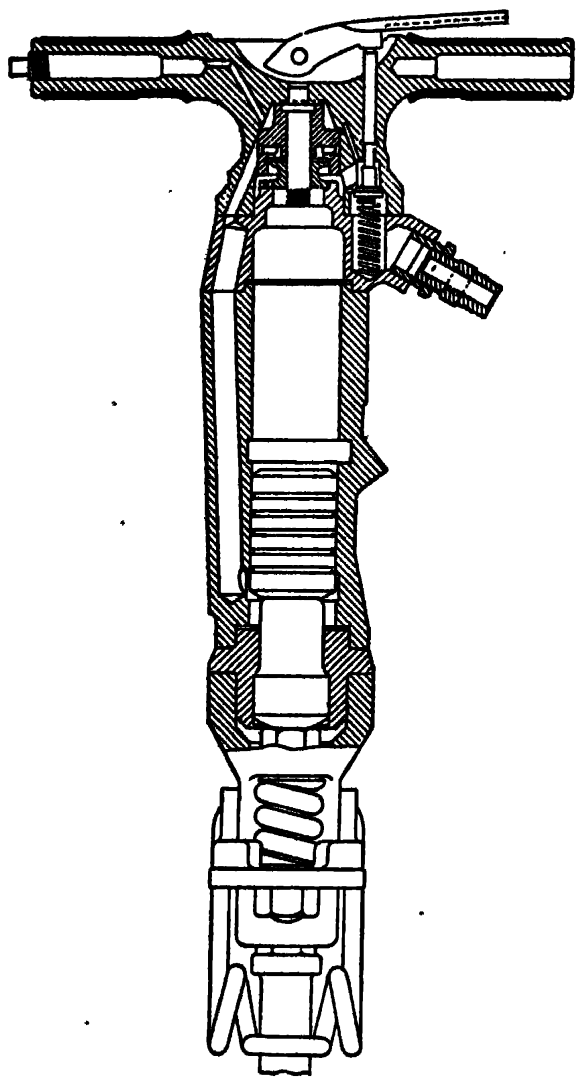

Fig 38. Chicago Pneumatic Demolition Tool

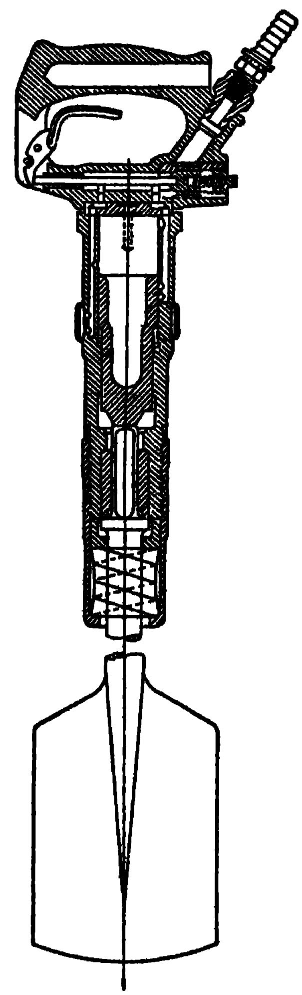

Fig 39. Thor Clay Digger

piston extending out of the lower end. In reverse-feed stopers the feed piston is attached to the backhead, the air-feed cyl moving away from it. This permits clamping the drill to a bar, for either vert or horiz holes. Hand-rotated stopers, both wet and dry, weigh 80 to 100 lb. They usually have chucks for hexagon or quarter-octagon steel. Automatically-rotated stopers (Fig 36), weighing 90 to 125 lb, are made for wet or dry drilling, the wet being ordinarily used. Length of feed, 20 to 25 in; total length of drill extended, 70 to 90 in. In excavating a 15 × 8 ft mine shaft, 866 ft deep, with stopers, the cost in moderately hard schist was $52.00 per ft (29). Other air-driven tools are shown in Fig 38, 39.

Valves for hammer drills comprise: SPOOL VALVES, contained in a short valve-chest; TUBULAR VALVES, of several forms, sometimes called sliding-sleeve or double-seated spools. They reciprocate on a central core, which is often the upper portion of the rifle-bar of the drill. In some, the air passes through the center of the valve. DISK VALVES are circular

disks or annular rings seating on the flat surface of the ring. They are usually placed on the upper portion of the rifle bar. FLAPPER and BUTTERFLY VALVES rock back and forth, have a fulcrum or pivot, seating on flat surfaces at either side. BALL VALVES are spherical steel balls, seating on ground seats. In VALVELESS DRILLS the piston acts as the valve. This construction is used mainly on the lighter tools, as clay spades.

Rotation devices comprise: RATCHET AND RIFLE-BAR ROTATION, in which the rear end of the helical fluted rifle-bar has pawls working in a ratchet ring in the backhead. Rotation is transmitted to the chuck or rotation sleeve by straight flutes in the front part of the piston. PNEUMATIC ROTATION utilizes the fluted piston and rifle-bar as in the preceding method, but the pawls are forced into position by compressed air instead of springs. INDEPENDENT ROTATION is separate from the piston action. In some types an air motor

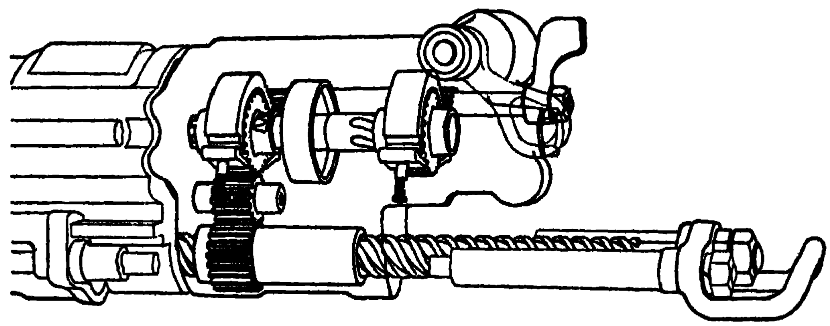

Fig 40. Gardner-Denver Motor Feed for Drifter Drill

drives the chuck sleeve through gears; or the motor drives eccentrics, transmitting power to gyrating yokes, which in turn drive the chuck sleeve.

Drill feeds. HAND-FEED for drifters consists of a long screw turned by a crank engaging a nut attached to the drill head. One type of AUTOMATIC FEED uses a ratchet device, which turns the feed screw by the drill's vibration; another form uses an air motor (Fig 40). PNEUMATIC FEEDS use air pistons similar to the stoper feed. Air-motor feeds are also used on wagon-drills and heavy drills for down hole work in quarries.

Drill mountings. TRIPOD MOUNTING is used for drifter drills in open-cut work and quarries. COLUMN MOUNTINGS are employed in tunnelling and general underground work. PNEUMATIC-FEED COLUMNS are telescopic; extended and held in place by compressed air. HYDRAULIC COLUMNS are similar to single-screw columns, but a hydraulic jack operated by a short lever replaces the jack screw. HAND-HELD DRILL MOUNTINGS are separate feed-screw mountings, to which a hand-held drill can be clamped for converting it temporarily to a light drifter. QUARRY-BARS are 10- or 12-ft horiz bars, supported on 4 legs. Chief application is for dimension-stone quarrying, with drifter drills and channelling tools. They usually have rack and pinion to control travel of the drill on the bar. BROACHING MOUNTINGS are heavy mountings, usually quarry bars, with air-motor feed, for heavy drills on broaching and down-hole work. DRILL CARRIAGES (jumbos) are portable mountings for 1 to 12 or more drills, standing on a track; used in driving headings of large tunnels. WAGON MOUNTINGS are portable mountings for drifter drills (see *ante*).

Note. Use of tunnel columns and carriages, and shaft bars, is treated in Sec 6; tripods, quarry bars, gadders, channelers, and towers for submarine drilling, in Sec 5.

Tripod parts (Fig 41): *a*, saddle clamp; *b*, clamp jaw; *c*, saddle throughbolt; *d*, front leg and ear bolts; *e*, side and back-leg bolts; *f*, right ear; *f'*, left ear; *i*, weight hanger; *j*, *k*, leg collar and set-screw; *l*, leg pointer; *m*, weight. VARIATIONS of the tripod: Lewis-hole tripod, for drilling parallel holes close together; quadrant tripod, for submarine drilling from a platform. With the latter, the drill is swung aside when changing bits.

Parts of double- and single-screw columns (Fig 42): 1, column top; 2, column pipe; 3, jack screw for double-screw column; 4, base-block bolt (large); 5, base-block bolt (small); 6, jack-screw cup; 7, column base block (2 pcs); 8, jack-screw nut, double-screw column; 10, safety clamp; 11, column arm; 12, column-arm cap and bolts; 15, cap set-screw; 16, jack-screw cap; 17, jack-screw; 18, lock nut; 19, jack-screw nut. COLUMN CLAMP: *b*, clamp-jaw; *c*, clamp through-bolt; *p*, *q*, column clamp, top and bottom; *r*, *s*, front and back clamp bolts.

Air pressure for rock drills. Most drills are designed for press of 70–100 lb, and are most efficient at these pressures. Higher press cause abnormal wear and breakage of drill parts, and increased steel breakage. Low press decreases drilling speed; at press as low as 40 lb, stopers are damaged by pounding of the steel on anvil block and front head.

Relation of air consumption and pressure to drilling speed. Elaborate tests at United Verde mine, Ariz (70), to determine the most ECONOMICAL AIR PRESS for hammer drills, lead to following

conclusions: 1. Pressure exceeding 90 lb gives little increase in mech effic. 2. Depth drilled per air ihp is greatest for sinker type of drill at 90 lb press, and increases slowly at higher press for other hammer drills. 3. Factor of desirability increases only slowly at press above 100 lb. 4. Press higher than about 85 lb at the drill increases upkeep. 5. High press increases breakage and loss of drill runner's time. 6. Increased breakage of drill steel tends to limit the press. 7. Under conditions at this mine, the most economical press appears to be 90–95 lb.

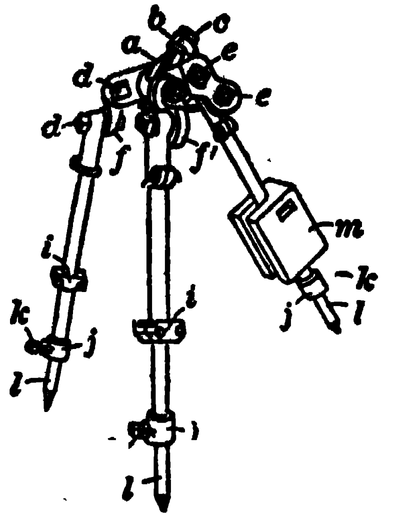

Fig 41. Tripod Drill Mounting

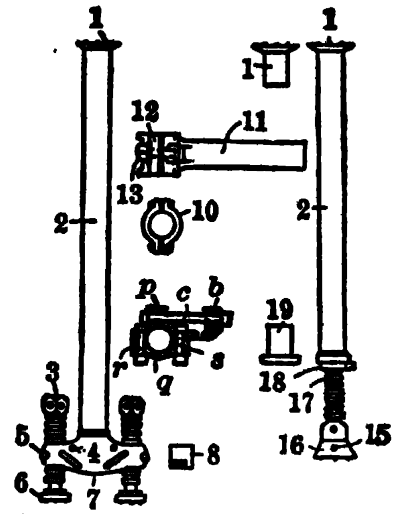

Fig 42. Double- and Single-screw Columns

For tunneling, where overall economy may depend upon speed of advance, drills are run at max rather than at most economical speed. In Table 20, based upon above data, drilling speed at 80 lb press is taken as 100%.

Factory tests with blocks of selected stone (71): drills were mounted on column, and run at press of 60, 70, 80, 90 and 100 lb (Fig 43). Each machine drilled 1 min with each of 3 bits, 1 7/8, 1 3/4 and 1 5/8-in gage. Air consumed was measured by a displacement meter (Art 19).

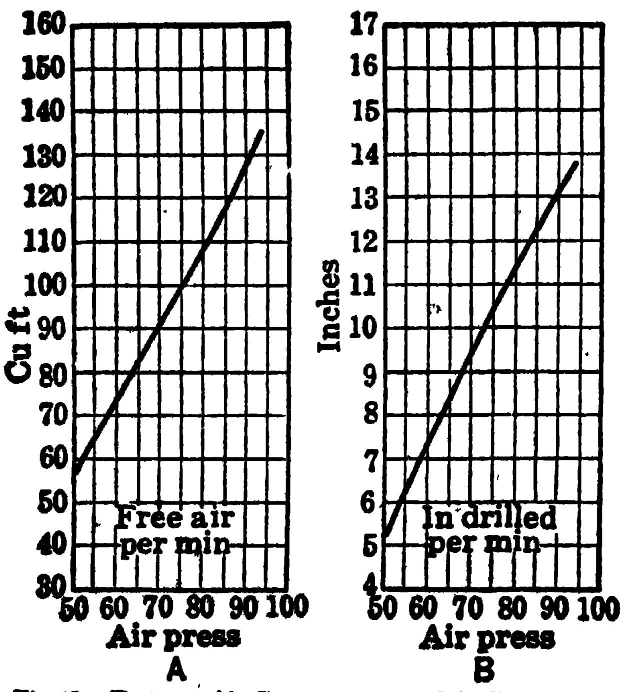

Fig 43. Tests on Air Consumption and Drilling Speed

Standardization of drills and their equipment, though desirable, can not be expected in machines undergoing frequent improvement; but, where different makes or types of drills are run in the same mine, they should be so selected as to use the same sizes of steel, and interchangeable hose connections. Columns, column-arms, and fittings should be reduced to fewest number of types that will do the required work. Nuts and bolts on arm, collar, and clamp, that are frequently used, should take the same wrench; or, at least, their number should be minimised.

Table 20. Relation of Drilling Speed to Air Press

Gage press	Speed, %	Gage press	Speed, %
40	31	90	119
50	47	100	140
60	64	110	160
70	82	120	180
80	100	130	198

Suggestions to rock drillers (33). Keep side rods drawn up snug, but not so tight as to close the springs. If piston repeatedly strikes the cyl head, when feeding, send machine to the shop. Don't run with wide-open throttle when cranking a bit out of the hole, or when cranking back in soft ground; crowding the crank reduces drilling speed. Don't remove feed-screw support. Keep oil plugs tight. Don't twist off lubricator or valve

bolts by careless use of wrench. Don't use red rubber gaskets in water spud. Don't drill with machine out of line. Don't drill with loose swing-clamp. Don't use too much water, especially in down holes. Don't take a chance on using a chipped or slightly upset shank. Examine anvil block frequently, to see if it is causing shank trouble. Don't run bits too far when drilling. Call the nipper's attention to the trouble with the machine, when sending it to shop for repairs.

Care and treatment of hammer drills (34). The bit must be held down to its work; otherwise the shank slips and hammer strikes the cyl head, causing breakage; bit shank should receive full force of blow. Drills should be washed with kerosene about once a week, and should be oiled before reassembling. The hardened steel bushing, taking the wear incident to screwing the air hose on and off the drill, must not be removed from the handle by drill runner, otherwise the threads are sooner worn or stripped. Examine and gage bit shanks at intervals, to see that they are not too short nor too badly worn to fit the socket properly.

Air consumption. In hammer drills the type of valve and piston, and the speed of blows per min, vary so greatly that it is impossible to prepare a general table of air consumption. For any drill it will vary widely with hardness of rock, air press, and skill of the driller. Manufacturers can furnish the approx air consumption of a particular drill, or it can be measured by an air meter (Art 19). Table 21 gives approx figures.

Table 21. Approx Air Consumption of Rock Drills (various sources, 1940)

Type of drill	Air consumed, cu ft free air per min, compressed to 90 lb gage	Type of drill	Air consumed, cu ft free air per min, compressed to 90 lb gage

Table 22 is used as shown by the following example: Required the vol of free air to operate 30 drills at 9 000 ft altitude, at a gage press of 80 lb. Sea-level consumption per

drill assumed as 190 cu ft per min. From Table, the factor for 30 drills at 9 000 ft is 20.38; multiplying 190 cu ft by 20.38 gives 3 872 cu ft free air per min, which is the actual free air delivery of a compressor for the above outfit under aver conditions, to which must be added pipe-line losses of friction and leakage. The multipliers in the table allow for time consumed in changing bits, cleaning hole and moving drill; all drilling operations being intermittent. In soft rock, where the actual time of drilling is short, more drills can be run with a compressor of given size than when working in hard rock, where the drills work continuously for longer periods. Soft material, therefore, increases the air consumption for a given number of drills, and hard material decreases it. Compressor capacities are those required at the drills, no allowance being made in the table for losses due to transmission pipe friction or leaky pipes. In selecting a compressor, these factors must be taken into account.

Following are formulas for dealing with rock-drill work:

Time to change bits and clean hole, e min; to drill 1 ft, d min per ft; to move drill and lost time, l min; to set up drill, g min.

Length of feed, ft, f; depth of hole, ft, D; time to drill length of feed, $fd = r$. Number of bits per hole, $D \div f$.

Total time per hole $= (e + fd)(D \div f) + (l + g)$, including moving and setting up drill. Working minutes per day $= M$ (say, 600).

$$\text{Number of holes per day} = \frac{M}{(e + fd)(D \div f) + (l + g)}$$

$$\text{Ft hole drilled per day} = \frac{DM}{(e + fd)(D \div f) + (l + g)}$$

Cost per day $= C$ on standard basis: hence, cost per ft of hole

$$= \frac{C(e + fd)(D \div f) + (l + g)}{DM} = R = \frac{C}{M}\left[\frac{e}{f} + d + \frac{l + g}{D}\right]$$

If $l + g = S$, or aver time to move drill and set up; and $e + r = T$, or aver time for changing bits, cleaning hole, and drilling the length of feed, the above formula reduces to:

$$R = \frac{CT}{Mf} + \frac{CS}{MD}$$

Note that length of feed (f) is the difference in length between successive bits, which is ordinarily 2 ft. In the formula the possible length of feed is immaterial; the value is affected only by the lengths of bit. If it be difficult to get a follower bit into the hole, the feed should be several inches longer than the difference between lengths of bits, since this affects time of changing bits and cleaning the hole.

Water pressure for wet drills is from 20 to 90 lb; if greater than the air press, water will be forced into the drill cyl and carry away lubricant. Normally, 25 to 35 gal of water

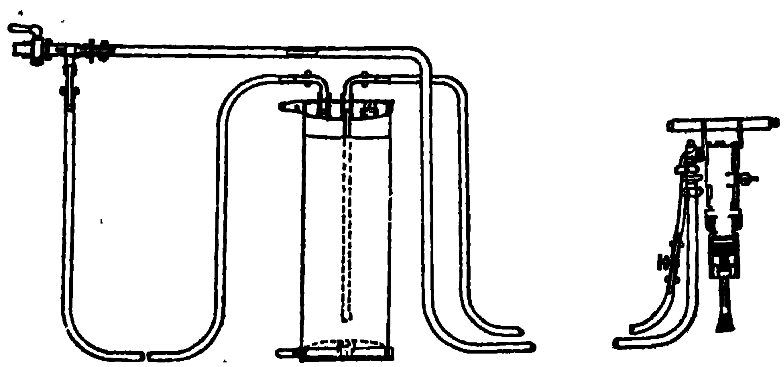

Fig 44. Water-feed Tank for Hand-held Drills

are required per drill per shift. A mode of regulating water press is to set up in the mine workings, at about 200-ft intervals, several tanks overflowing into one another. Drill-makers furnish 15 to 18-gal tanks, in which compressed air gives the desired water press (Fig 44).

Lubrication of drills (3) is of great importance. There is little possibility of their getting too much oil; with enough, oil will appear on the drill-steel shanks. Oil for rock drills must resist washing away, withstand low temp (often below 32° F) caused by sudden expansion of air in the tool, and flow to all parts requiring lubrication. Poor oil becomes sticky. All major oil companies supply lubricants that have been tested and approved.

Most hammer drills have automatic lubricators. Air-line lubricators (Fig 45) are equally satisfactory; an oil container is placed in the pipe leading to each drill, the oil being picked up by the air and carried under press to all parts of the drill. They are dependable, but not vital to adequate lubrication, as the regular oiling system suffices, if the oil is suitable. Drills must be kept clean. They should be dismantled at regular intervals, the parts cleaned with kerosene, and oiled as they are reassembled. If any part has been scored because of inadequate lubrication, the scored surfaces should be smoothed.

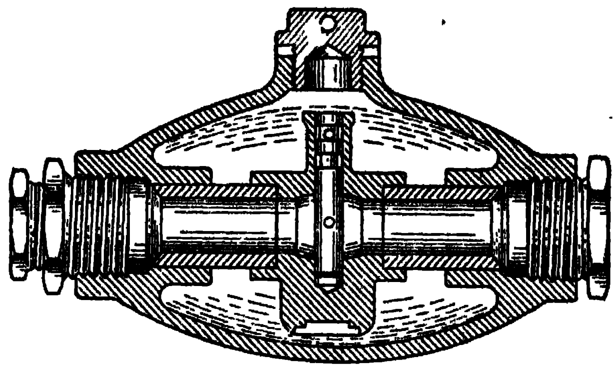

Fig 45. Gardner-Denver Air-line Lubricator

Ingersoll-Rand Co (Drill Doctor's Book) gives the following specifications for a lubricant for drills, drill-steel sharpeners, and bit and shank punches. 1. QUALITY: (*a*) lubricant shall be well-refined petroleum oil, free from suspended matter and water, or a good petroleum oil compounded with enough animal oil to form a satisfactory lubricant for drills where water or wet air is encountered, or a good grade of free-flowing liquid grease, which will not separate upon standing; (*b*) Castor machine oil (aluminum soap), and oils containing graphite, are not approved. 2. PHYSICAL PROPERTIES of oils found good in actual field service are: flash point (open cup), 350° F min; viscosity 100° F (Saybolt Universal), 450 sec min, 700 sec max; pour point, 15° F max; mineral-acid neutralization number, 0.10 max; free fatty acid (% Oleic), 0.40 max; steam emulsion number, 300 max. Viscosity of liquid greases can not always be determined; in any event, the lubricant should be free-flowing, conforming to above specifications except for viscosity.

12. OIL FURNACES AND SHARPENERS FOR DRILL STEEL

Note. Data on Drill Steel, Bits for Hand and Machine Drilling, Hand Sharpening and Tempering of Bits, are given in Sec 5.

Power sharpeners, operated by compressed air, are now in general use at large mines and wherever rock drilling is done on a large scale. Chief advantages over hand-sharpen-

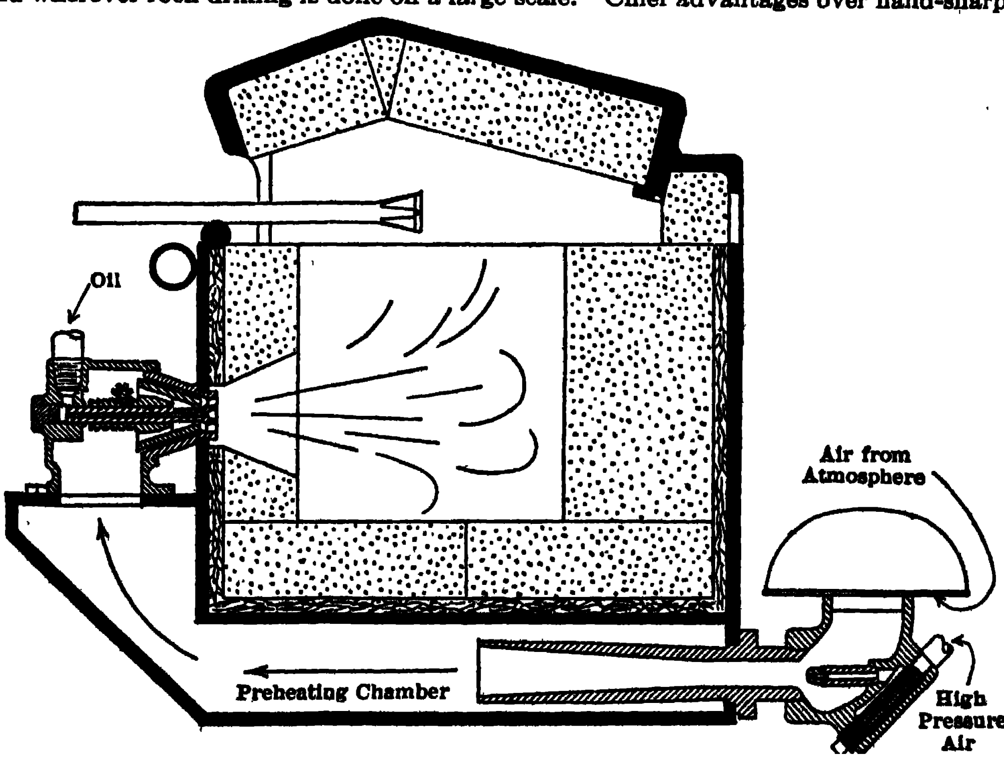

Fig 46. Ingersoll-Rand Oil-fired Furnace for Heating Drill Steel

ing: (*a*) greater rapidity and economy, since 1 smith can sharpen as many bits as several hand blacksmiths with their helpers; (*b*) more accurate shaping and gaging of bits compos-

ing a set. Dies being used, all bits of same shape and gage are identical, with symmetrical wings and sharp, square corners. Hence, mechanically forged bits always " follow " well, decreasing trouble from stuck (fitchered) bits. Accurate shanks formed by power sharpeners decrease drill piston breakage. Shanking done by hand is facilitated by small devices, giving quicker and more accurate results than hand work alone.

Detachable bits are widely used. They can be resharpened several times before discarding. Air, elec- and gasolene-driven grinders, with special bit holders and grinding guides, are furnished for this purpose. Some makes of detachable bits are attached to drill rod by threads, which may be forged on rod by a power sharpener and special dies.

Oil-fired furnaces (Fig 46) with compressed-air blowers are widely used to heat steel for forging. See also Fig 47.

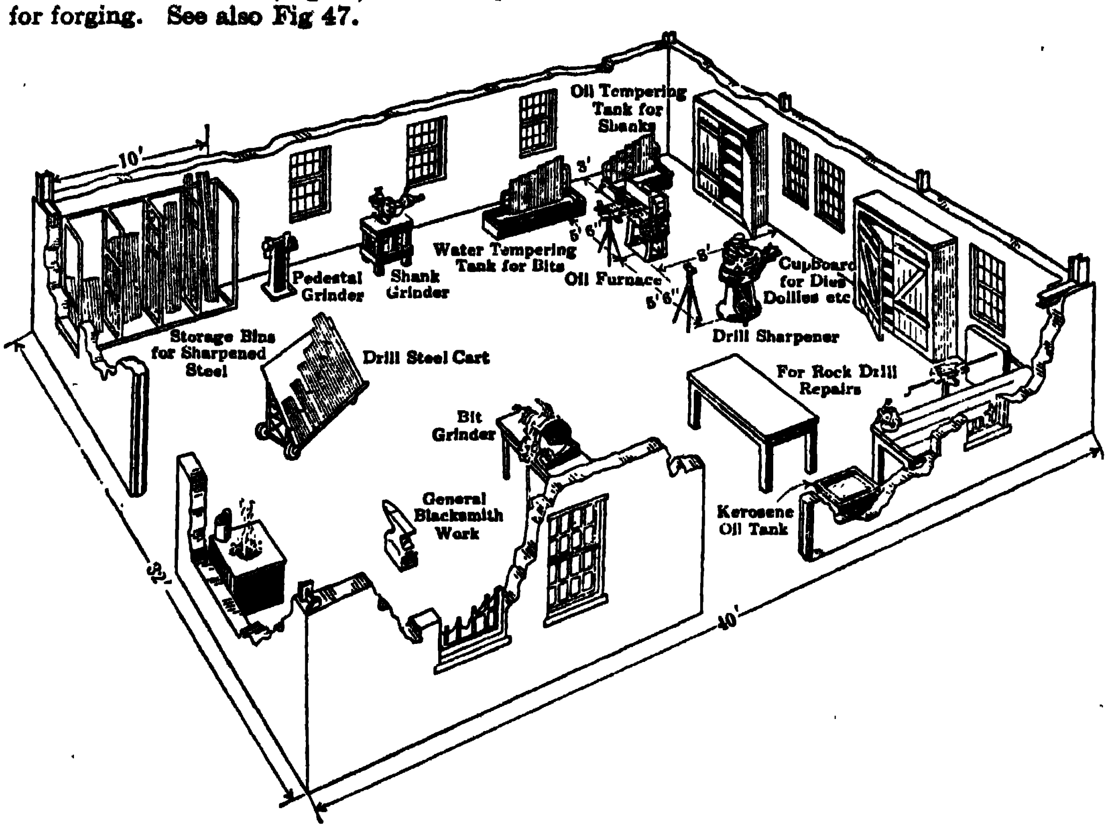

Fig 47. Diagram of Well Laid-out Mine Blacksmith Shop

13. PNEUMATIC QUARRY TOOLS

Channelers cut out blocks of stone without blasting. They can cut a continuous slot, at any angle from vert to horiz, by a gang of chisels, the entire machine moving back and forth along the slot at a speed that will keep the bottom smooth and even.

Power required. For operating by compressed air, the makers state that the air consumption when actually cutting is as follows for single-cyl channelers: 4 1/2-in cyl, 190 cu ft free air per min; 6 1/2-in, 230; 7-in, 300; 8-in, 400 cu ft per min. Duplex channeler requires 5–8% less than twice as much air as a simplex. A reheater reduces air consumption about 20%. Using steam, a 25 to 30-hp boiler serves a channeler having a 6 1/2–7-in cyl. Few air-operated machines are now used.

Rate of cutting depends on size of channeler and hardness of rock: 4 1/2-in cyl machines cut 60–75 sq ft per day in slate, 200 sq ft in soapstone; 6 1/2-in cyl machines cut 80–150 sq ft in marble, 260 sq ft in soapstone; 7-in cyl machines, 60–75 sq ft in tough sandstone, 130–210 sq ft in limestone; 8-in cyl machines, 60–76 sq ft per day in gneiss.

Channeling with drills (line drilling). A piston or hammer drill is mounted on a quarry bar, and drills a row of holes close together. The rock between holes is broken by a drill with broaching bit.

Stone surfacing (dressing) can be done with small hammer drills, so mounted as to move in a horiz plane over the block of stone.

14. COMPRESSED-AIR COAL CUTTERS (1)

These are widely used to replace hand work, for undercutting the face of coal, preparatory to breaking it by blasting or wedging. Objects: to economize cost of mining; to

decrease proportion of fines; to increase rate of production from a given extent of workings (1). Air-driven machines only are considered here; for elec cutters, see Sec 16.

Endless-chain cutters are furnished in longwall types for longwall mining (Fig 49) and in short-wall types for room-and-pillar mining. The bits are carried on an endless chain, driven by an air motor; the machine is fed forward by a chain or rope anchored at one end, and feeding into sprockets or winding on a drum in the machine itself.

Rotary-bar cutters are almost obsolete. They are used like shortwall machines, but have a toothed bar instead of an endless chain.

Pick machines are either unmounted or mounted on low wheels. The bit makes a cut 40–80 in deep. Unmounted hand picks are light-weight hammer drills, 15–18 in long and weighing 20–30 lb.

"Radialaxe" coal cutter is a rock drill, with bit rotation device, mounted on a column, and provided with worm gear, so that the machine may be swung radially in undercutting or shearing.

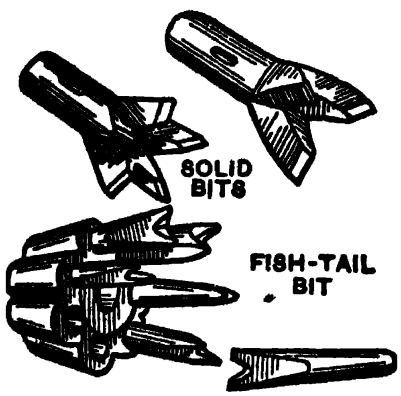

Fig 48. Bits for "Radialaxe" Coal Cutter

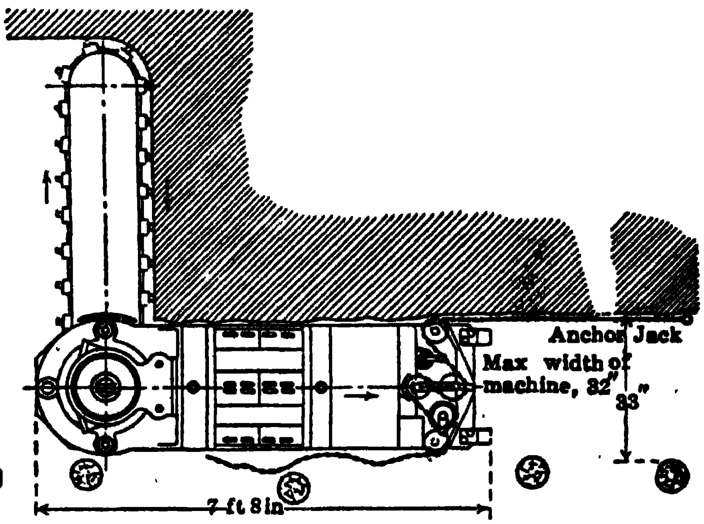

Fig 49. Sullivan Longwall Ironclad Coal Cutter

"Radialaxe" bits are of 2 forms (Fig 48). Solid bits, forged with 3 or 5 prongs, are sometimes used, but most bits are of the combination "fish-tail" type. All are easily forged and sharpened.

15. COMPRESSED-AIR HOISTS

Large air hoists for hoisting in mine shafts are dealt with in Sec 12.

Air "lifts" for raising heavy weights through small distances at slow speeds, as for cranes in iron works and machine shops, are made in several forms. SINGLE-CYLINDER TYPE consists of a long-stroke cyl, suspended vertically from a crane or cable, with the load hooked to lower end of piston rod. TELESCOPE TYPE, for low headroom, has 2 cyl, telescoping into each other. Oil or water, acted on by air press, may be used in both of the above, to prevent accidental lowering of the load through leakage of air, the oil being retained in the cyl by a stopcock, and passing into a reservoir for lowering.

Drum hoists are widely used for scraping, slushing, loading slides, handling timber in shafts, and pulling cars. They are driven by air, elec, or steam (Sec 16, 27). Engines designed for steam may be run by compressed air, but not economically. On replacing its boilers by a Diesel engine, an Ariz gold mine successfully converted its steam hoists to air operation. A reheater, heated by exhaust from the Diesel, was used between the compressor and hoist (27).

Air hoists are driven by a piston motor, turbine, or geared motor, with rated capacities of 750–18 000 lb. Cable speeds for slushing and scraping are 120–400 ft per min; for pulling cars, 25–100 ft per min. They are made with 1, 2 or 3 drums. Table 23 includes power required to hoist skip and rope, and to overcome engine friction which is taken at 20%. It is assumed that the skip weighs 0.5 as much as its contents, that the traction on a horiz mine track is 30 lb per ton and that there are 500 ft of wire rope. Engine is plain slide-valve, in good condition, and loaded to about full capacity. If not, and the air is throttled, more air is needed for same work.

Table 23. Air Required to Hoist 1 Ton (2 240 lb) on Slopes (Ingersoll-Rand Co)

Angle of slope to horiz, deg	Cu ft free air per min of actual hoisting, @ 350 ft per min rope speed	Cu ft free air per 100 ft of hoist	Angle of slope to horiz, deg	Cu ft free air per min of actual hoisting, @ 350 ft per min rope speed	Cu ft free air per 100 ft of hoist

25	400	114	75	880	250
30	470	134	90	900	257

16. COMPRESSED-AIR LOCOMOTIVES (1)

These were formerly widely used for mine haulage; now largely displaced by electric locomotives. **Note.** Sec 11 deals with all means of Underground Transport, including electric and gasolene locomotives (see also Sec 16). Sec 15 treats of compressed-air locomotives only.

General construction. There are 1 or 2 storage tanks, which, with piping, etc, are carried on a frame mounted on 4 or 6 driving wheels. The cyls are usually simple, sometimes compound. The high-press air of the storage tanks passes into a small auxiliary tank, where it is reduced to proper working press, before going to the cyls.

Air pressure in storage tanks, 700 to 1 200 lb. Cyl press: simple engine, 125–150 lb; compound engine, 200–250 lb. Intermediate press for compound cyls, 50–60 lb. TANK CAPACITY, for hauls of 1 to 1.5 mile, 50–150 cu ft. For long hauls, it is better to increase press, rather than size of tanks.

Tractive force of compressed-air locomotives may be found by: $T = (D^2 \times L \times 0.98\ P) \div d$: where T = tractive force, lb; D = diam of piston, in; L = stroke, in; P = initial press, lb; $0.98\ P$ = effective cyl press; d = diam of driving wheels.

17. PUMPING BY COMPRESSED AIR (1, 2)

General. Pumps designed for steam are often operated by compressed air, though rarely efficiently, due to: (*a*) difference in expansion curves of steam and air; (*b*) the frequently improper selection of cyl diam for the available air press.

Volume of air for pumps working without expansion. If V = vol of free air, cu ft per min; H = head under which pump works, ft; G = gal of water raised per min; P = receiver air press, lb; V_2 = vol of free air corresponding to 1 cu ft at press P; then $V = 0.093\ V_2\ (H \times G) \div P$. This formula is based on 100 ft piston speed, with 15% added volume of air to cover losses.

Table 24. Values of V_2 and $0.093\ V_2$, Mean Press per Stroke, and Hp per Cu Ft Free Air

Air press P, lb	V_2	$0.093\ V_2$	Mean air press per stroke	Hp per cu ft free air	Air press P, lb	V_2	$0.093\ V_2$	Mean air press per stroke	Hp per cu ft free air
25	2.70	0.2511	17.01	0.0743	60	5.08	0.4724	30.75	0.1340
30	3.04	0.2827	19.40	0.0847	65	5.42	0.5040	32.32	0.1406
35	3.38	0.3143	21.60	0.0943	70	5.76	0.5357	33.83	0.1468
40	3.72	0.3459	23.66	0.1033	75	6.10	0.5673	35.27	0.1527
45	4.06	0.3776	25.59	0.1117	80	6.44	0.5989	36.64	0.1583
50	4.40	0.4092	27.39	0.1196	85	6.78	0.6305	....	....
55	4.74	0.4408	29.11	0.1270	90	7.12	0.6621	....	....

Example. Required the vol of free air per min to raise 200 gal of water 150 ft, gage press being 80 lb. From Table 24, $0.093\ V_2$ corresponding to 80 lb = 0.5989; hence, $V = 0.5989\ (200 \times 150) \div 80 = 224.4$ cu ft free air. Hp developed in using 224.4 cu ft free air at 80 lb is $224.4 \times 0.1583 = 35.6$ hp. At 40 lb gage press, $V = 0.3459\ (200 \times 150) \div 40 = 259.0$ cu ft free air, and $259.0 \times 0.1033 = 26.8$ hp. These examples show the advantage of using low-press air for simple pumps.

Since machine drills require air at high press, they generally control the design of the compressed-air plant. To get the best results, the press for the pumps must be reduced below that in the mains. A receiver should be placed between the reducing valve and the pumps, to drain the air, lessen probability of freezing, and to equalize the press (1).

Foot-gallons pumped per cu ft of free air range from say 135 to 155; efficiency is increased by stage compression, and by reheating (Art 9).

Table 25. Air Consumption of Reciprocating Pumps (2)

The table gives the press and vol of air for any size pump. Reasonable allowances have been made for losses due to clearance in pump and friction in the pipe

To find the vol of air required to pump a given quantity of water a given height, find the ratio of diam between water and air cylinders and multiply the gal of water by the figure found in the column for the required lift. The result is the number of cu ft free air. Press required on the pump is in the column directly opposite. For example: the ratio between cylinders being 2 to 1, required to pump 100 gal to a height of 250 ft. Opposite 250, at ratio 2 to 1, is the figure 2.66; 2.66 × 100 = 266 cu ft free air. Press required is 37.8 lb on the pump piston.

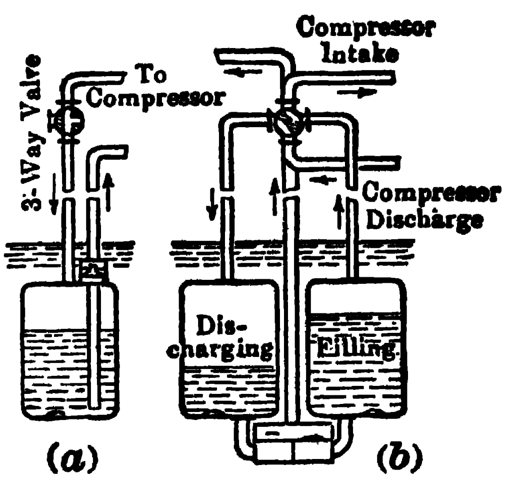

Fig 50. Direct Displacement Pump

Direct displacement pumps operate by displacement of a vol of water by an equal vol of air, the air press corresponding to height of lift. Air is used without expansion. SINGLE-CHAMBER PUMPS (Fig 50 *a*) are suited to low lifts. Compressed air entering the top of the chamber drives out the water, and when all is expelled, the air escapes through the 3-way valve. Then the water discharge valve closes automatically, and water enters the chamber through the bottom valve. The 3-way valve is operated by a float. DOUBLE-CHAMBER PUMPS (Fig 50 *b*). The chambers operate alternately, the action of the pump being practically constant. AIR REQUIRED. The press depends upon height of lift. Press per sq in per foot of head = 0.434 lb; hence, the height to which a given air press will raise water = gage press ÷ 0.434. 1 cu ft of water will be displaced by 1 cu ft of air at the required press, plus about 20% to cover losses. Effic of these pumps is about 25%, which compares favorably with effic of single-cyl direct-acting steam pumps.

Small, air-driven centrifugal pumps are available for pumping water from sumps, shafts and low places in the workings; capacities to 200 gal per min, against heads to 50 ft, single-stage, and 200 ft, two-stage.

Air-lift pump (See also Sec 13) (1, 2). The delivery pipe is partly submerged in the water to be raised. Compressed air is admitted to foot of the pipe. In a small diam pipe, the air forms piston-like layers, between masses of water; in a large one, air enters a number of ports or nozzles, mixing with water in form of bubbles. The water is raised partly by vis viva of compressed air, but chiefly by aëration and consequent reduction of sp gr of rising column. This is not an efficient method of raising water, if considered from a power basis only, but in its proper field it does unique service.

Submergence is depth below surface of water at which compressed air is admitted; PER CENT OF SUBMERGENCE is ratio of submergence to total length of delivery pipe; it must be greater for low than for high lifts. For best effic, range is about 66% for 20-ft lift (vert distance from surface of water to point of disch), to 41% for 500-ft lift; aver, say 55–60%.

Construction. Generally, when the cross-section of the well is large enough, the outside air pipe system is used, in which the water discharge pipe and the air pipe are placed side by side (Fig 51, No 1 and 2). Where well space is limited, the air pipe is inside the water discharge pipe (Fig 52, No 4 and 5). Fig 52, No 3 shows a typical footpiece.

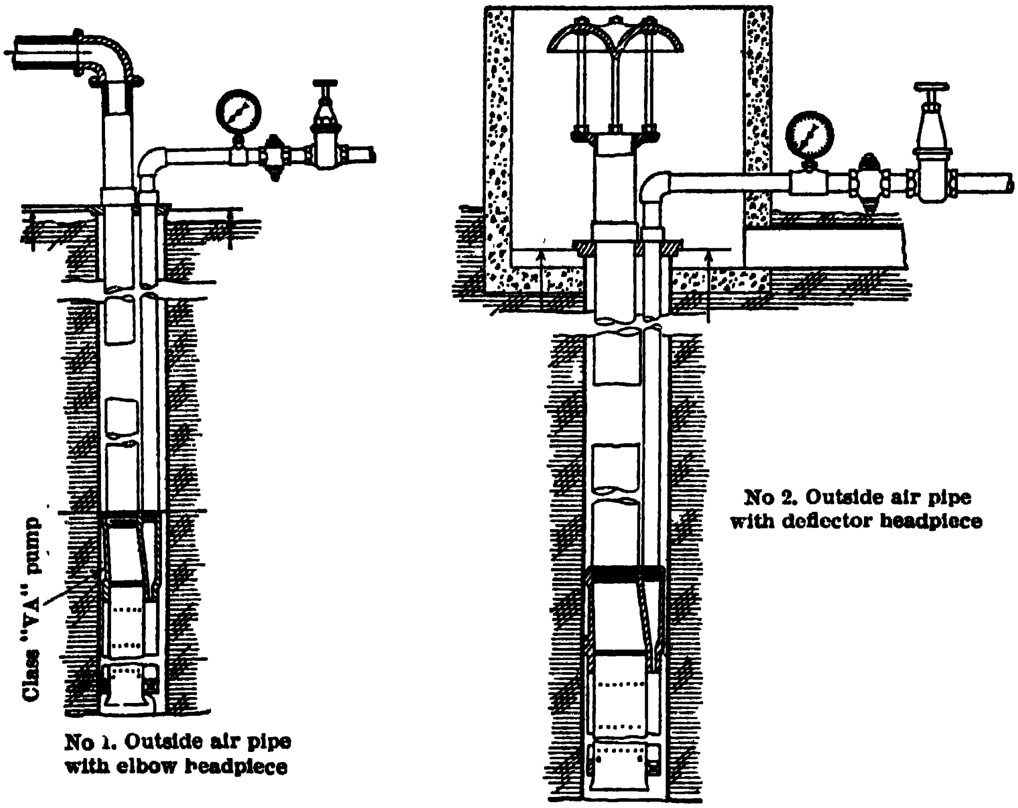

Fig 51. Air-lift Wells with Outside Air Pipes

Efficiency of the air lift (60, 61). Causes of loss: (*a*) slippage due to relative motion between air bubbles and water; (*b*) friction of the mixed air and water in discharge pipe; (*c*) friction in flow of water before air is admitted; (*d*) kinetic energy absorbed, due to veloc of discharge. High discharge veloc tends to low slippage loss. Friction in the discharge pipe varies directly with square of veloc, slippage varying inversely with veloc. Losses (*a*) and (*b*) are difficult to measure; (*c*) and (*d*) are more or less under control. For economy, the veloc of discharge should be such as to minimize (*a*) and (*b*). Important variables affecting performance of the air-lift are: percentage of submergence, lift, vol water discharged, vol and press of air.

Air-lift calculations (1, 62, 63). Essential factors: Va = cu ft free air per 1 gal water; h = total vert lift, ft; H = submergence, ft; C = constant (effic of system) (Table 26). Submergence governs the press required, which is greater for starting than for running. The air-lift differs from other pumps in that the press required to raise a column of water depends on submergence (H), not on lift (h); H being actual head against which air press acts. To find starting air press, multiply starting submergence by 0.434. Following formula closely approximates results of practice:

$$Va = \frac{h}{C \log \dfrac{H + 34}{34}}$$

For liquids other than water, the general formula becomes:

$$Va = \frac{h \times \text{sp gr}}{C \log \dfrac{(H + 34) \times \text{sp gr}}{34 \times \text{sp gr}}}$$

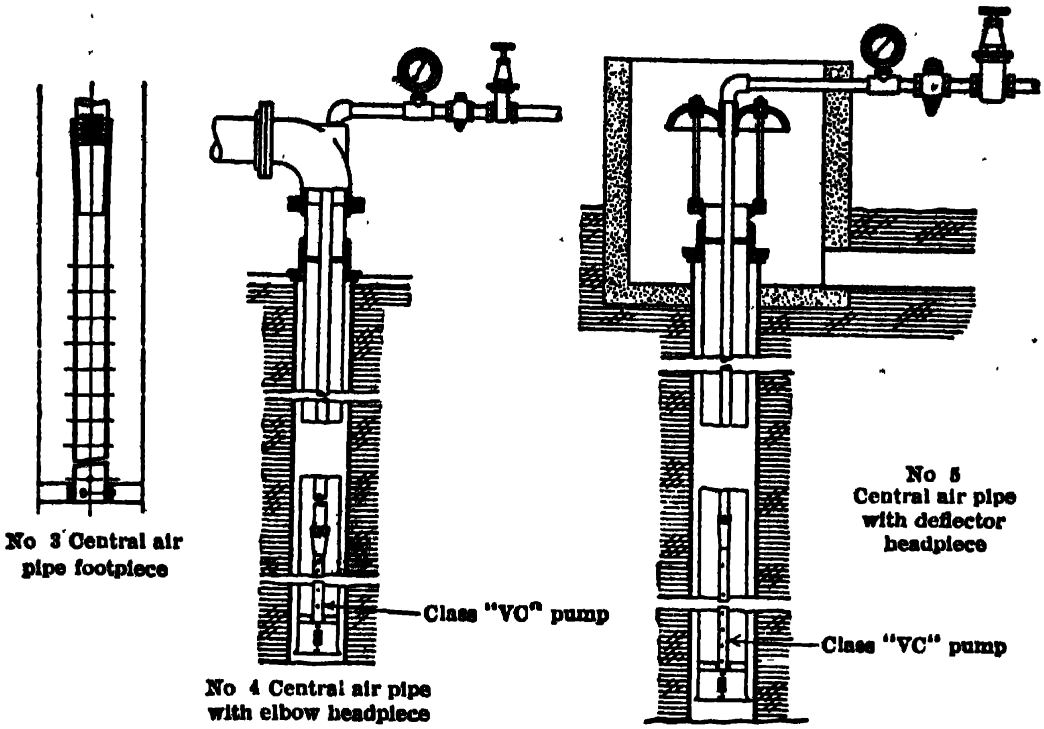

Fig 52. Air-lift Wells with Central Air Pipes

Values of C (Table 26) are based on best ratio of submergence to lift. As this can not always be secured, constants based on customary and best submergences are given in Table 27, for use in above general formulas. Actual pumping- or water-level in a well is seldom known in advance. It is customary to assume lift and submergence, based on experience, and pipe the well accordingly. When working conditions are arrived at, the submergence is adjusted by raising or lowering the pipes until best results appear.

Table 26. Values for constant C

Submergence, %	Value of C	
	Outside air line	Inside air line
75	366	330
70	358	322
65	348	306
60	335	285
55	318	262
50	296	238
45	272	214
40	246	185
35	216	162

Size of discharge pipe. $d = 13.54\sqrt{\frac{Q}{v}}$, in which d = inside diam of pipe, in; Q = vol of mixture of air and water, cu ft per min; v = veloc of mixture in pipe, ft per min.

With pipe of uniform diam, best discharge veloc of the mixed air and water, for lifts from 40 to 200 ft, varies from 2 000 ft per min at 35% submergence, to 700 ft per min at 70% submergence. With tapered pipe, best discharge veloc is 1 400 ft per min at 35% submergence, and 550 ft per min at 70% submergence. Best veloc for the mixed water and air at the bottom of the discharge pipe is 800 ft per min at 35% submergence, and 450 ft per min at 70% submergence.

Table 27. Submergences

Lift, ft	Customary allowable submergence, %	Best submergence, %
20 –125	50–70	65–70
125–175	40–65	60–65
175–250	40–60	55–60
250–350	37–55	50–55
350–650	37–50	45–50
650–750	35–45	40–45

Starting pressure, $P_s = 0.434\ H_m$, in which P_s = starting press, lb per sq in; H_m = starting submergence, ft.

Working pressure, $P_w = 0.434\ H_s + P_f$, in which P_w = working press, lb per sq in; H_s = working submergence, ft; P_f = friction drop in air line from compressor to footpiece, lb per sq in.

Compound air-lift is mainly used in shallow shaft sumps. When the depth allows about 25% submergence, water may be lifted halfway in one pipe and allowed to run back to the bottom of another at same depth as the first. This permits 50% submergence for a third pipe, in which

water is raised to point of discharge. In a deep shaft, Bendigo, Australia, water was raised in a series of lifts, a total of 1 385 ft, by air at 60 to 80 lb press (1).

Table 28. Cost of Pumping with Air-lift (from different sources, 1915)

Output, gal per min	Lift, ft	Cost of coal	Cost per 1 000 gal, ¢	Output, gal per min	Lift, ft	Cost of coal	Cost per 1 000 gal, ¢

2 000	75	....	4.50	100	60	2	4.50
2 000	50	....	3.50	....	......	....	....

Air-lift for water-works. The strainer openings should be of such size as to admit fine material into the well, whence it can be pumped, and exclude coarser particles, which form a natural gravel filter outside (Fig 53). Back-blowing, applicable to all wells, requires sealing the top of well casing. By closing the discharge pipe, air is forced through the footpiece, and, driving the water

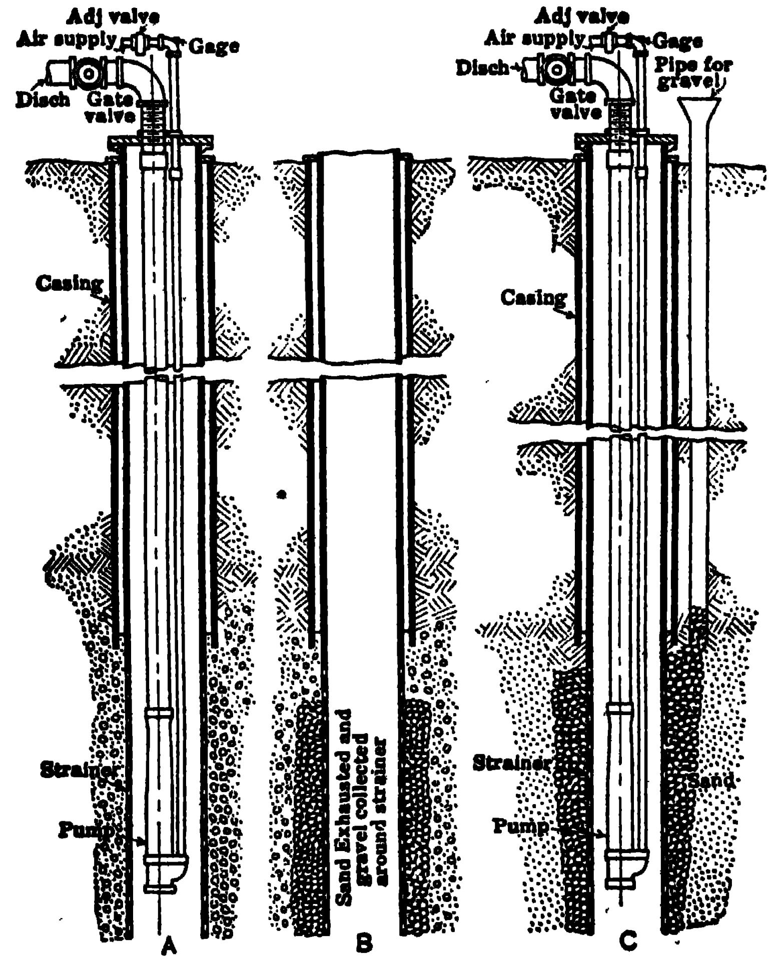

Fig 53. Well Construction under Different Conditions of Water-bearing Sand

through the strainer floats the finer sand. Then, by opening the discharge, the flow resumes its course and carries some of the sand with it. The operation is repeated as necessary, discharging the sand at the surface.

Fig 53 shows 3 modes of equipping wells: *A* has a proper strainer for a stratum of sand and gravel; *B* shows gravel collected around the strainer after the finer sand has been pumped out. The gravel strainer, which forms outside, increases the inflow area, keeps the strainer openings clear, and increases output. *C* shows a water-bearing stratum of fine sand, into which gravel is introduced through auxiliary holes, drilled nearby and terminating in the sand, so that when the sand is removed by back-blowing, the gravel enters around the strainer as before.

Air-lift in conjunction with mine pumps (65) is convenient as an auxiliary for drainage. By a suitable connection, live air is turned into the pump column, which thus becomes an air-lift. Exhaust air from a pump has been used for the same purpose, enabling the pump to work under a greater

head. The air-lift will unwater shafts to within a few ft of the bottom, after which its discharge pipe serves as the permanent pump column.

Improvised air-lifts (66) can readily be made with materials on hand at any plant, by inserting a small air pipe in any cased well. Footpiece is made by drilling holes, or cutting slits with hack-saw, in the capped end of the pipe. A small drill hole in the bottom of the cap will let out sand that may work its way in.

Unwatering mines with air-lift. For this the air-lift is especially well adapted, because: (*a*) its capac can be made very large; (*b*) as the water level in the mine is lowered, the air and disch pipes can be extended more readily than the usual forms of pumps can be moved to new positions.

I. Glen Alden Coal Co, Scranton, Pa (67). The Lackawanna River broke into the mine, flooding a pumproom containing five 5 000-gal electric pumps to a depth of 14–16 ft. Three air-lifts were installed, the first 2 discharging through 16-in pipes, the third through a 12-in pipe. When the water in the pumproom was lowered, some of the mine pumps were started before the air-lifts were completely installed. Both pumps and air-lifts operated 3.5 months. It was estimated that the air-lifts raised 660 000 000 gal, discharging 2 360 gal per min. Initial submergence, 77%; final submergence, about 20%; air press about 45 lb.

II. An inclined shaft, Idaho-Maryland Mine, Cal (68), unused since 1914, was unwatered in 1920. Discharge pipe comprised 900 ft 10-in oil casing, 200 ft 12-in machine-wound wooden pipe, and 1 200 ft 4-in air pipe. Compressor capac, 2 200 cu ft free air per min. Clamps for supporting the pipe were placed every 100 ft, and 2 1-in wire ropes were used for lowering. Dip of shaft to about 850 ft, 70°. At 700 ft, the pipe stuck, and water was lowered to 400-ft level, where a plunger pump was installed. By air-lifting to this level, the trouble point was reached, after which the pipe was extended to 1 013 ft, the 800-level was unwatered, and a pump there installed. From 800 ft down, unwatering proceeded to 953 ft, at which point the air-lift could just handle the inflow. Three compressed-air plunger pumps took 2 weeks to lower the water 47 ft to the 1 000-ft level.

The main air-lift unwatered the mine to a point 560 ft on the slope (519 ft vert), in about 1 month. Max capac attained, 1 450 gal per min, with 49% submergence and 97 lb air press. Capac dropped to 250 gal per min with 60-lb air and 18.3% submergence. Near bottom of the 10-in pipe, shaft flattened to 62.5° and then to 49.5°. For the portion from 560 to 886 ft (282 ft vert), capac varied from 1 500 gal per min with 77 lb of air to 200 gal with 50 lb air; submergence, 19%. From 886 to 1 068 ft, water was raised in a 10-in pipe. Having heavy submergence and small head, this lift had enormous capac; in one 24-hr period, the water was lowered 50 ft on the incline.

Elevating sands and slimes in concentrating and cyanide mills, and pumping solution in cyanide treatment, are special applications of the air-lift.

18. WORKING IN COMPRESSED AIR

Caisson disease, compressed-air illness, or air embolism, is caused by a too rapid decompression after exposure to high air pressure for a time. It is characterized by presence of free nitrogen in the tissues and body fluids, and by one or more of following symptoms: localized pain, vertigo, prostration, or symptoms referable to central nervous system (52). In selecting men for work in compressed air, the essentials are normal lungs, kidneys and heart; in the older men, blood pressure must not be high.

In the East River tunnels, N Y, where constant medical attendance was maintained, among 87 men over 50 years old, there were only 3 cases of compressed-air illness; indicating that, for sound men, the question of age may not be especially important. Men with moderate adipose tissue are not [illegible]ceptible than the aver individual, but corpulent men should be rejected.

Temperature and humidity apparently do not conduce to compressed-air illness, although humidity increases fatigue. During a period of very hot weather, a lock at one shaft of East River tunnel was exposed to the sun, causing intense heat inside the lock while men were decompressing. This did not tend to illness, but the men suffered from exhaustion after leaving the lock.

Hours of labor and working pressure. In the East River tunnels, N Y, no cases of illness occurred until 15 lb press was reached, although by that time there had been 188 496 decompressions. Table 29 shows that, for working press of 15–21 lb, there were only 16 cases in 621 342 decompressions, and as all were trivial, it appears safe to subject normal men to press up to 22 lb per sq in, for 8-hr shifts.

Lengths of shift in Table 29 are actual hr of labor at tunnel face; total time spent in compressed air, including decompression periods, was considerably longer.

Note that cases of illness reached their peak at 29 lb press, with 2 3-hr shifts. With the change, at 30 lb, to 2-hr shifts, the number of cases greatly decreased, but rose sharply at 34 lb. Had this change of shift been made at 29 lb, instead of 30, many of the 139 cases recorded at 29 lb would probably have been avoided. The benefit of the further change to 1.5-hr shifts, at 35–39 lb press, is clear. The relatively small number of decompressions above 34 lb did not furnish adequate data, though the percentage of cases was not large.

Table 30. Relative Cases of Illness in Subaqueous Tunnels of Penn R R and Pub Service Commission, N Y (52)

Tunnels	Decompressions	Press, lb	Cases No	Cases %

Pub Serv........	5 325	41	5	0.094
	8 456	42	12	0.142
	5 730	43	6	0.105
	4 702	44	1	0.021
	33 085	45	24	0.073

Tables 30, 31 cover a period of 1 month (Compressed Air Illness, Keays, 1909). In the Pennsylvania tunnel work, less insistent medical supervision is indicated.

Effect of gases in compressed-air illness (Sec 23, Art 5). Carbon monoxide (CO) is so dangerous that it should be kept at not more than about 0.01 of 1%. CO_2 seems to have no bearing on number of cases, except that it accelerates respiration, thereby causing more rapid saturation of the blood and tissues with nitrogen. During compression, the N absorbed by the blood increases approx 1% per each added atmosphere (14.7 lb). Haldane found that half saturation requires 15 min; nearly complete, 1 hr. Effort of labor hastens heart action and hence saturation.

Table 31. Hours of Labor, in Tunnels in Table 30

Pub Serv Comm tunnels					Penn tunnel				
Press, lb	Hr	Shifts			Press, lb	Hr	Shifts		
1–22	8	0.5 hr for lunch			1–31	8	0.5 hr for lunch		
		Hr on	Hr off	Hr on					
22–30	6	3	1	3

35–40	3	1.5	3	1.5	32–42	6	3	3	3
40–45	2	1	4	1					
45–50	1.5	0.75	5	0 75					

In decompression, the above process is reversed. Supersaturated body tissues give off N to the blood, which, after desaturation by the lungs, takes up more N from the tissues. This goes on until equilibrium is reached at normal atmos press. If decompression be too rapid to permit the blood to carry to the lungs all the N freed from tissues, or if the lungs can not rid the blood of excess gas, nitrogen bubbles (emboli) form in the tissues and circulatory system, causing severe pain. This is the present theory of the cause of caisson disease.

Symptoms. (*a*) Disturbances of central nervous system, due to pressure of the bubbles upon brain or spinal cord; (*b*) Unconsciousness or collapse, due to much gas distributed throughout the circulation; (*c*) Localization of pain depends on the particular tissues invaded by the bubbles; (*d*) Vertigo, due to bubbles in the middle ear, or to disturbances of nervous system; (*e*) Difficult breathing, due to bubbles forced through pulmonary arteries into the lungs (" chokes ").

Treatment. Cases of illness are usually relieved by recompression, but, if this be delayed in symptom (*a*), the nerve elements may be permanently injured. Symptom (*b*), with abdominal pain, may be serious, though prompt treatment should produce recovery. It is believed that illness could be limited to (*c*), if periods of labor are properly adjusted, and with sufficient time for decompression.

Analysis of cases of illness (52). In 1 361 461 decompressions in N Y Pub Serv Comm tunnel work, there were 680 cases, of which: 91.8% were of localized pain (see above); 6.5%, vertigo; 1.6%, nervous system. Only 1 case of localized pain (in abdomen, followed by collapse) was fatal. Of nervous cases, all but 2 recovered completely.

Care in entering compressed air. To prevent blocking of ear passages, men should " swallow " repeatedly; or, inflate the middle ear by firmly closing nostrils and mouth, and making a strong expiratory effort (Valsalva method). This equalizes internal press and opens the Eustachian tubes, unless the individual has cold in head. If equalization fails to take place, severe pain is caused by pressure on ear-drum, which may even produce rupture.

Precautions in " locking out." As a quick drop in press causes rapid fall in temp, men must be well clothed in the lock, to avoid chilling. While in the lock, they should exercise, to stimulate circulation, thus causing more rapid desaturation of N.

Medical air-lock is a steel cyl, 6 ft diam by 18.5 ft long; one end solidly closed, the other having a door opening inward. It is divided into 2 compartments with a door in the partition opening to inner compt, which contains a cot for use if necessary. The lock has elec lights and heater, telephone, clock, press gage, thermometer, and medical equipment. Press in either compt can be regulated from both inside and outside. Doors have bull's eye windows, for inspection from outside.

When a patient enters the lock, air press is rapidly raised to that in which he had been working. This compresses the bubbles of N in the tissues, which are again taken up by the circulation. Careful decompression follows in stages (details given below). In affections of spinal cord, ample time must be allowed for recompression; a second or even third recompression may be necessary.

Regulations of N Y State Labor Dept. Rule 1151 limits the number of working hours in any 24 hours, according to air press in working place, as follows:

(*a*) Not exceeding 22 lb press, 8 hr, with 30-min interval in open air; (*b*) 22–30 lb, 2 3-hr shifts, 1-hr interval; (*c*) 30–35 lb, 2 2-hr shifts, 2-hr interval; (*d*) 35–40 lb, 2 1.5-hr shifts, 3-hr interval; (*e*) 40–45 lb, 2 1-hr shifts, 4-hr interval; (*f*) 45–50 lb, 2 45-min shifts, 5-hr interval.

On passing out of the working place, Rule 1152 requires stage decompression, in which a drop of half the max press is at rate of 5 lb per min; the remainder, at uniform rates, varying according to working press, as follows: (*a*) for press below 15 lb, minimum decompression rate is 3 lb per min; (*b*) for 15–20 lb, 2 lb; (*c*) for 20–30 lb, 3 lb every 2 min; (*d*) over 30 lb, 1 lb per min.

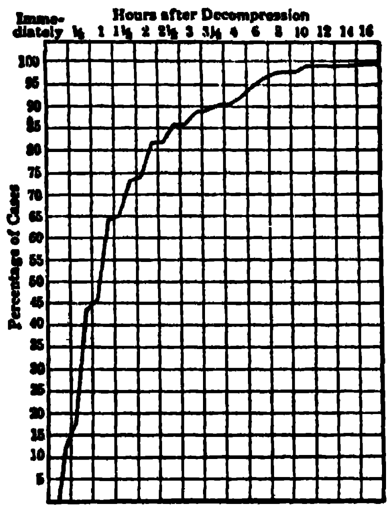

Fig 54
Relative to Time after Decompression Before Illness Began (52)

Rules 1153, 1171 and 1172 specify equipment of the decompression lock, and requirements as to sanitation, ventilation and medical attendance, which can not be detailed here.

19. MEASUREMENT OF COMPRESSED AIR (1, 2, 8, 9, 31)

This is desirable for determining the air consumption of a drill, quantity of air flowing through a pipe, and the compressor output. The appliances, time and experience necessary for accurate measurement are seldom available and their cost is rarely warranted. In most cases, an approx result only is obtained.

Direct-reading meters are simple, compact, and well suited to field use. Fig 55 shows a meter with the scale calibrated to read directly in cu ft free air per min, when measuring air at 80 lb per sq in. A table of multipliers is furnished with the meter, for other pressures. As the accuracy of this type of meter is affected by pulsating flow, small receivers should be placed in the line both before and after the meter, to minimize pulsations.

Water displacement meters (Fig 56) are accurate, but, due to their size, are suitable only for permanent installation.

Fig 56 shows a meter with 2 tanks, 2 ft diam by 4 to 5 ft high, connected at the bottom by a 3-in pipe, and about half filled with water. Each has a gage glass for observing the water level, and in top of each is a pipe and 4-way valve. When the valve is set as shown by the full line, water in right-hand tank is forced into the other by air press, and the air in the latter is driven out through the valve to the machine being tested. When the water level reaches a definite point at top of gage glass on left-hand tank, the valve is thrown to position shown by dotted lines. Then the process is reversed, the air in right-hand tank passing to the machine under test. The number of times each tank is emptied in a given period shows volume of compressed air used, expressed in cu ft free air by the formula, $P_1V_1 \div P = V$, in which P_1 = abs press of compressed air, V_1 = its vol, P and V = barom press and vol of free air.

Venturi meters are inserted in pipe lines for measuring the air. They cause a comparatively small press loss. They are usually fitted with a recording gage, the accuracy of

which is affected by pulsating flow. The following formula is by G. A. Goodenough:

$$Q = 1292\frac{D^2P_1}{\sqrt{T_1}}\sqrt{\left(\frac{P_2}{P_1}\right)^{1.434} - \left(\frac{P_2}{P_1}\right)^{1.717}}$$

in which Q = flow of air, cu ft per min, 68° F, 14.7 lb per sq in, and 40% relative humidity; P_1 = entrance press, lb per sq in abs; P_2 = throat press, lb per sq in abs; T_1 = entrance temp, abs; A = area of throat, sq in; D = throat diam, in; W = wt of air flowing per sec.

Orifice meters (Fig 57), with recording gage, are compact, easily installed and suitable for all usual pipe sizes. Their accuracy is effected by pulsating flow. The following formula is by S. A. Moss (*Trans* A S M E, Vol 50):

$$Q = \frac{19.16\,D^2\,C\,T_3}{P_3}\sqrt{\frac{(P_1 - P_2)P_2}{T_1}}$$

in which Q = cu ft free air flowing per min, at press P_3 and temp T_3; D = smallest diam of orifice, in; T_1 = abs temp, ° F, at upstream side of nozzle; T_3 = abs temp, ° F, at which vol of air delivered is expressed, usually atmospheric; P_1 = total abs press, lb per sq in, at upstream side of nozzle; P_2 = abs static press, lb per sq in, at downstream side of nozzle; P_3 = abs press, lb per sq in, at which vol of air delivered is expressed, usually atmospheric; C = coef of discharge, which must be known for each orifice. For well-rounded orifices, C varies between 0.95 and 0.99; for sharp-edged orifices, approx 0.6. Constants C are based on air containing 0.57% moisture by wt. The formula is accurate to within 2% when $P_2 - P_1$ is less than 10% of P_1.

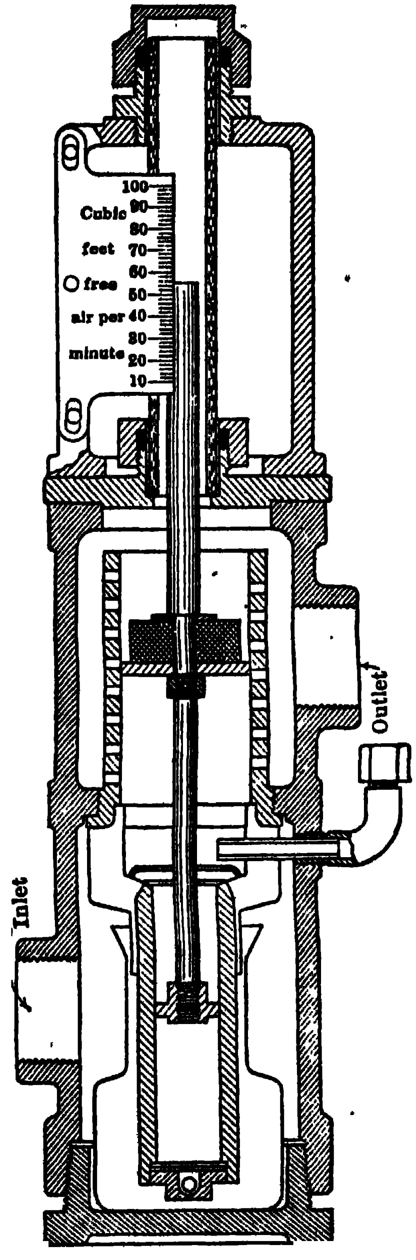

Fig 55. Direct-reading Air Meter (New Jersey Meter Co)

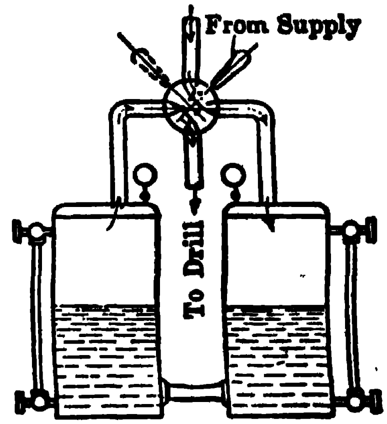

Fig 56. Displacement Tank Apparatus

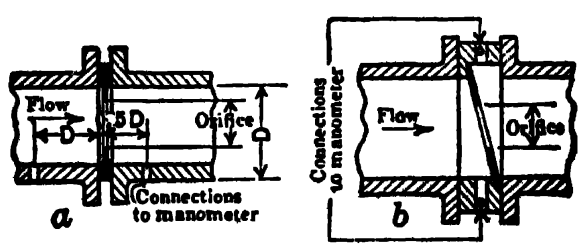

Fig 57. Orifice Meters for Pipe Lines

Non-pulsating flow, as produced by centrifugal compressors, can be more accurately measured. Properly calibrated Venturi and orifice meters give good results. On the Rand, where many centrifugal compressors are installed, a large number of meters of the "weighted-gate" type are used. In these a movable gate changes the size of orifice for different volumes of flow (1).

Measuring air-compressor output accurately requires considerable time and careful attention to the apparatus used. The procedure and precautions are outlined in "The

Test Code for Reciprocating Compressors," by the Amer Soc of Mech Engrs, and in the "Standards of the Compressed Air Institute," of the U S. The procedure outlined in these publications should be followed. The flowing air is measured through a low-press orifice, after the pulsations have been dampened in a receiver and nozzle tank. Fig 58 shows a typical set-up. The formula given above for orifice meters may be used. Fig 59 shows dimensions of standard nozzles for such tests.

Measuring leakage in air lines. A rough method is to find the percentage of compressor capac required to maintain press, when no air is being used. A meter in the main line can also be used to determine leakage. A more accurate method of testing leakage, with a low-press nozzle like that used in a compressor capac test, is shown in Fig 60 (49). Air flows from the receiver and through valve *A* to tank *B*, and then out through orifice *F*. At *D* is a water manometer *E*. Temp in the tank is taken by a thermometer at *C*. The orifice has a smooth, rounded inner surface, as in Fig 59.

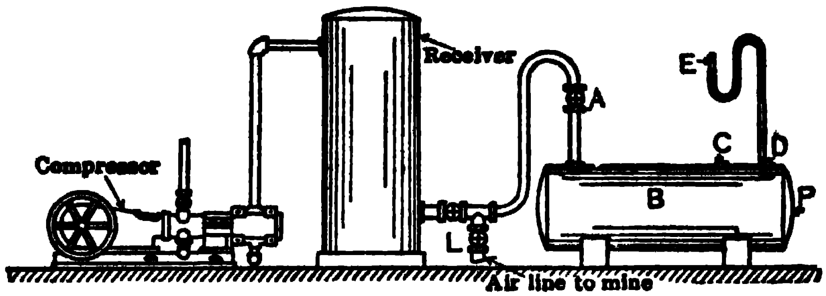

Fig 60. Apparatus for Testing Air Lines

To determine the leakage: Close valve *L* on air line. Regulate compressor so it will not unload at press at which test is to be made, and discharge all the air through orifice *F*. Adjust valve *A* until the compressor exactly holds the desired press. When press is constant, the meter shows the vol delivered at that press. Then, on opening valve *L*, the air line and meter are in parallel. Readjust valve *A* until receiver press is again constant at desired value. Compressor is now delivering same vol as when all air was discharged through *F*, with some leaks from air line, the rest going through *F*, where it is measured. Difference between first and second readings is the vol of leakage.

125	.494	1.98	7.90	31.6	126	284	506	790	1 138	1 549	2 023

Values are based on 100% coeff of flow. For well-rounded entrance orifice, multiply by 0.97; for sharp-edged orifice, multiply by 0.65; results are approx.

Loss of power due to leakage (50). At a mining plant tested, consisting of two 1 700-cu ft cross-comp non-condensing steam-driven compressors, supplying hoists, pumps and drills, one pump was operated by air continuously, for which purpose pressure was always maintained in the entire system.

Results of test: Aver compressor delivery during working periods, 1 950 cu ft per min; aver hp input, 340; flow of compressed air to supply leaks, 950 cu ft per min; hp to supply leaks, 157; total power cost per year, $18 200; power cost per year to supply leaks, $12 400; power cost to supply machines using the air, $5 800.

In another case, a pump of 200 gal capac ran 24 hr per day against a 30-ft head. For the pump only, the compressor input was 105 hp; whereas, with no leakage, the pump could be run by 13 hp. At a press of 70 lb sq in, 20 cu ft of air per min will escape through a $^1/_8$-in hole.

20. MISCELLANEOUS APPLICATIONS OF COMPRESSED AIR

Ore sticking in bins has been successfully freed by a compressed-air poke rod, consisting of a nozzle in the end of a pipe which is thrust into the bin. Wet slimy ore has also been freed by a series of 1 $^1/_4$- to 2-in pipes on the sides and bottoms of the bins, with $^1/_8$- to $^1/_4$-in orifices (13). A nozzle spraying a mixture of compressed air and castor oil from a line oiler has been used to remove dust from a mine heading after a blast. Castor oil does not create a fire hazard (14, 42).

Mine lamps are cleaned by compressed air at Alliance Colliery, Kasha, Pa, of Lehigh Nav Coal Co more quickly and thoroughly than by hand (15).

Mines at Kalgoorlie and Broken Hill, Australia, use compressed air to ventilate dead-end headings. A $^3/_{16}$-in jet in a 6-in Venturi induces 600 cu ft per min of air, which moves to the working face 500 ft away. With a 10-in Venturi, the air will travel 1 000 ft (18).

In the Hollinger Consol Gold Mines, Timmins, Ont, ethyl mercaptan is distributed through compressed-air mains to warn miners of fire in the workings or near a shaft (19).

In driving a sewage disposal tunnel, 11 ft 9 $^1/_2$ in diam, for the Minneapolis-St Paul Sanitary district, the heading-and-bench method was used. The face was undercut in sandstone by high-press air issuing from a 5-jet manifold, at end of a $^3/_4$-in pipe, and then advanced 4 or 5 ft with pick machines before another undercutting. No blasting was necessary (30).

SECTION 16

ELECTRIC POWER FOR MINE SERVICE

BY

GEORGE R. WOOD

ELECTRICAL ENGINEER

REVISED AND LARGELY REWRITTEN BY

CHARLES M. MEANS

CONSULTING ENGINEER, PITTSBURGH, PA

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

ELECTRIC POWER FOR MINE SERVICE

1. PURCHASED POWER

Electric power may be purchased from Public Service companies in most coal and metal mining regions, usually at a lower cost than by the operation of an isolated plant (1) and can be supplied to stationary motors at any required voltage. Direct current is required for traction haulage, coal cutters and storage battery charging. Rate schedules for alternating current usually include a demand charge, either expressed, or made a part of the energy charge, based upon integrated peaks of 5–15 minutes' duration, or on momentary peaks as created by hoists. Demand is usually expressed in k v a; energy, in kw-hr. Total cost varies from 0.9 to 3¢ per kw-hr. Power factor, load factor, delivered voltage and quantity used affect total cost.

2. CHOICE OF CURRENT AND VOLTAGE

Extent of territory to be served and density of load should determine voltage: 250 volt d c is preferable for underground use, because of safety; 500 volt is more effic in large mines or where loads are heavy (but certain states prohibit its use in new operations); 220, 440 and 2 200 volt a c can be applied to stationary motors and transformers; for lighting at shaft bottoms, and in pump and hoist rooms, a c at 110 volts. For underground a-c transmission, 2 200, 4 000 and 6 600 volts usually meet requirements, though higher voltages can be used if necessary.

3. POWER PLANT (see also Sec 40, 42)

Steam power is now rarely used at large metal mines, but has definite though limited application at coal mines where there is an abundance of waste fuel or unmarketable coal. Parts of certain coal seams contain impure bands that must be rejected, or that are not amenable to cleaning, but that can be burned under boilers with special firing equipment. In some districts there is a very limited market for the fines, and it may be more economical to burn at point of production. The boiler water problem can usually be solved in any

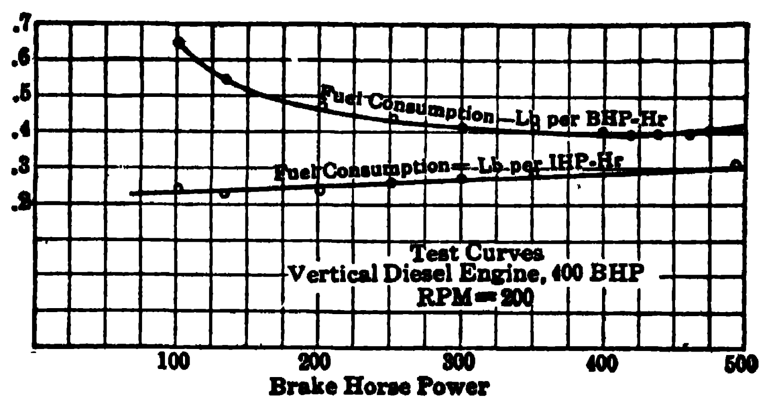

Fig 1. Test of Diesel Engine

district. Such plants can be economically connected electrically to existing utility circuits; cost, $60–$100 per kw of capacity.

Oil-burning engines are being widely installed where purchased power is not available. Engines of the Diesel type, now built from a few hp to 10 000 hp in single units, have been so perfected that they are as reliable as the steam engine with its boiler and auxiliaries. The modern oil engine will burn practically any liquid fuel, from kerosene to heavy tar oils, provided the latter are heated sufficiently to enable the fuel pumps to handle them. Fuel is burned directly in the cylinders, avoiding the well-known losses in the steam plant.

Total thermal effic of the oil engine is approx 34–36%, as against about 10% effic of boiler and steam engine. The builders usually guarantee an oil consumption of 0.41–0.5 lb per hp hr.

Ignition of the fuel oil is directly by heat of compression of the charge of air in the cyl, as the oil is sprayed into it. The atomised spray, coming into contact with the hot air, which is at about 500 lb press, has a temp of about 1 000° F. There is no explosion in the cyl; after ignition during the first part of the stroke, the oil-vapor expands and acts on the piston at nearly constant press until the exhaust port is opened (Sec 39, 40).

Commercial oil engines are: 4- and 2-cycle, single-acting; 4- and 2-cycle, double-acting. They are also designated, with reference to design of the piston, as: crosshead type, which is the more reliable for heavy duty and constant work; trunk type, which is longer, but requires lower headroom, and costs less. Oil engines are also classified as: AIR-INJECTION, which require an air compressor to atomise the fuel oil (the compressor power being usually from 8 to 10% of the engine power); SOLID-INJECTION, which have no compressor, the oil being injected into the cyl by a pump. The latter type is probably best for the smaller size engines (Sec 39).

Cost of a 500-hp oil engine, directly connected to an a-c generator, with exciter, switchboard, piping, auxiliaries, foundation, freight and erecting, delivered in central portion of U S, is \$80–\$90 per hp, depending upon type of engine, station equipment, and the cooling-water supply, which costs more if cooling towers are required, instead of allowing the water to go to waste.

Attendance required is less than for steam plant, since there are no boiler and yard crews, and no handling of ashes. Fuel can be stored in tanks by pumping or gravity flow from tank cars, with no loss or deterioration.

Conclusions. Oil engines are ideal for mining plants. They require small space, there are no standby losses, as all costs except fixed charges stop when engine is shut down, and should produce power for about 1.5–3¢ per kw-hr. (For more details as to sizes, costs, effic and thermodynamic operation of oil engines, see Sec 39.

4. SUB-STATIONS

Sub-stations: OUTDOOR SUB-STATIONS (not inclosed), for transforming a c to a higher or lower voltage and for controlling the various circuits. In general, they comprise transformers, oil switches and lightning arresters, mounted on a concrete foundation with a steel structure to support disconnecting switches, bus-bars and transmission circuits. For a small sub-station, the entire equipment can be mounted on wood poles. INDOOR SUB-STATIONS are usually small fireproof buildings, housing motor-generator sets (Sec 42, Art 6), rectifiers, or rotary converters (Sec 42, Art 11), with the necessary control for converting a c to d c for use underground. The d c is carried underground from these stations by suspending cables in shafts or boreholes. UNDERGROUND SUB-STATIONS are used to house step-down transformers, rectifiers, motor-generator sets and rotaries. Housing should be fireproof and adequately ventilated. When oil is used to cool transformers, or in switches and similar equipment, provision is made to entrain the oil in case of leakage. MERCURY ARC RECTIFIERS have advantages of high effic, high momentary overload capac and portability, and make them attractive conversion units for mine service. Two types, multiple anode and single anode (ignitron), are available. For installations inside the mine, the rectifier and auxiliaries are usually in 3 units, each mounted on its own 4-wheel truck. One truck carries rectifier, heat exchanger and vacuum pumps; another carries transformers (filled with non-combustible liquid dielectric to avoid need for fireproof vault) and an oil circuit-breaker; and the third, a direct-current automatic reclosing circuit-breaker, also relays and meters. As each truck is permanently wired as a unit, the entire sub-station equipment may readily be moved on the mine track after breaking a few electrical connections. Fig 2 shows COMPARATIVE EFFICIENCIES of the types of conversion equipment, any of which can be arranged for automatic operation.

Automatic control is successfully applied to all sub-station equipment, and its cost is fully warranted by saving in labor and increased reliability of operation.

Motor-generator sets should be used where there is variation in the a-c supply, or where it is desired to create over-compounding of d-c, to compensate for voltage drop due to line resistance. By increasing the excitation of the synchronous motor field, a leading power factor can be created that in many cases has considerable value (Sec 42).

Rotary converters have higher effic than motor-generator sets, and will stand severe momentary overloads without injury, but the d-c voltage varies with the a-c voltage. They operate at about unity power factor and give no correction to the system.

Commutating-pole type of rotary converter (Sec 42, Art 6) is especially adapted to mine service, because of its enormous overload capacity. For load factors of 30% and less, which are usual at mines, it is common to use sub-station apparatus which will

average half load and occasionally carry peaks of 50% overload. With commutating-pole rotaries, the machine may be operated near its rated capacity, carrying the peaks at overloads of 200%. This gives much higher all-day effic and satisfactory service, with a machine of half the usual size. These machines may be obtained as standard in sizes of

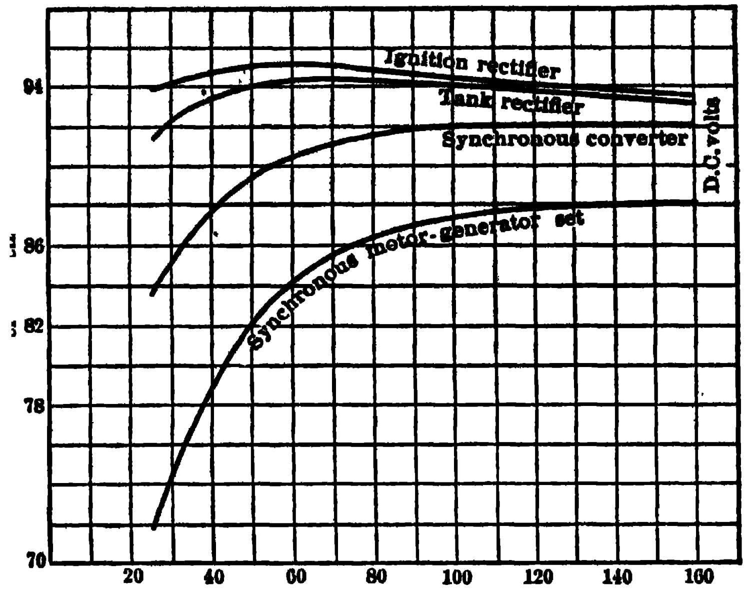

Fig 2. Efficiencies of Conversion Equipment

100 kw and up for 60 cycles and as small as 300 kw for 25 cycles. They are usually connected 6-phase and have remarkably good effic; the 150-kw, 60-cycle, 275-volt machine attaining 94.7% at 1.5 load, and 93.5% at 0.75 load.

5. TRANSMISSION LINES (see also Sec 42)

Calculation of d-c 2-wire circuits: if I = current in amperes, or watts ÷ volts; L = length of transmission, ft; V = volts lost in transmission; then circular mils in conductor = $(22 \times I \times L) \div V$.

For haulage work, where the track forms the return circuit, the rail capacity should be at least equal to that in trolley and feeders. Steel rails in general have 12 times the resistance of copper, and for 2 rails will be equal to 20 000 cir mils of copper per lb, per yd. Thus, a track of 40-lb rail will be equivalent to 800 000 cir mils. When capacities of wire and rail are unequal, the drop in each should be figured separately, using the formula $V = 11 \times I \times L \div$ cir mils, in which case V is the drop in half the circuit. If the load is distributed, L represents aver distance.

Table 1. Distances to which 100-kw 3-phase power can be transmitted at different potentials, assuming energy loss of 10% and a power factor of 85%. Distances are proportional to squares of voltages and inversely proportional to the kw

Amer wire gage	Area in circular mils	Voltages					
		2 000	3 000	4 000	5 000	6 000	8 000
		Distance of transmission in miles for various potentials at receiving end					
6	26 250	1.38	3.11	5.53	8.65	12.5	22.2
5	33 100	1.75	3.93	7.00	10.9	15.7	28.0
4	41 740	2.20	4.96	8.80	13.8	19.8	35.3
3	52 630	2.77	6.25	11.1	17.3	25.0	44.4
2	66 370	3.50	7.88	14.0	21.9	31.5	....
1	83 690	4.41	9.93	17.6	27.6	39.7	....
0	105 500	5.58	12.5	22.3	34.9	50.1	....
00	133 100	7.02	15.8	28.0	43.9	....	....
000	167 800	8.85	19.9	35.4	55.3	....	....

Calculation of short 3-phase transmission circuits, capacity neglected:

e_g = Volts, line to neutral at generator end; e_r = Volts, line to neutral at receiver end; $E = \sqrt{3}\,e$ = volts phase to phase; R = Resistance of one conductor, ohms; X = Reactance of one conductor, ohms; I = Current per phase; $= \frac{\text{Three-phase watts}}{\sqrt{3}\,E\,(p\text{-}f)}$; $p\text{-}f$ = power factor = $\cos\theta$; power loss = $3I^2R$; $e_g = \sqrt{(e_r\cos\theta + IR)^2 + (e_r\sin\theta + IX)^2}$. Cos θ and sin θ correspond to the power-factor angle at the receiver end. For leading power-factor, sin θ will be negative.

Permissible losses may be determined from standpoint of economy in transmission or from operating conditions. It is common practice to figure all d-c lines with a loss of say 10%; but large saving in transmission cost may be effected by considering that, as a general rule, for best economy the value of power lost should approximately equal the INTEREST charges on the conductor.

Example. Assume 500-kw aver load at 500 volts, delivered 1 000 ft with 5% loss. With power costing 2¢ per kw-hr, this loss amounts to $4 320 per year. The required copper, from above data, is 5 200 lb, which, at 15¢, will cost $780, and interest on this cost at 6% is $46.80. Total yearly cost of delivering this power is $4 367 per year, of which the interest charge is about 1%. It is evident that a much larger investment in copper with a reduced power loss would be more economical. For trial, assume 5 times as much copper, with 0.2 as much power loss. Interest charges will then be $234, power loss $864, and total transmission cost is $1 098, a saving of $3 269 per year. Evidently a saving of about $200 might be effected by still further reducing the loss to about 0.5%, but this would involve an investment of about $4 000 for added copper. On BASIS OF COST the investment in above cases would be large, as the copper required for least annual cost would be nearly 9 000 000 cir mils. An even larger installation would theoretically be justified were the power cost higher or copper cost lower; on the other hand, with power cost halved, the size of conductors would be halved.

From OPERATING POINT OF VIEW, it is advisable to allow not more than 33% drop at max load, which permits satisfactory operation of mining machinery under the worst conditions, and at lower loads conditions will be greatly improved. This appears an excessive drop, but voltmeter records at a large number of mines show max drop of 50% and over. With 10-hr load factors of 20 to 30%, this max loss represents an aver loss of 6.6 to 10%. With potentials of 300 to 600 volts at the mine openings, the minimum voltages underground will be 200 to 400, which will give satisfactory operation of machinery designed for 220 and 500 volts. The low cost of power, usual in coal mining, makes a large copper investment inadvisable.

With a-c transmissions, full-rated voltage should be maintained, since output and torque of induction motors vary as the square of the applied voltage. With step-down transformers and where reduced voltage taps may be used, line drops of 10 to 15% may be advisable; but, in general, and particularly with synchronous converters, it is best to design transmission lines for not over 5% drop at rated capacity, which should be taken as the max 15-min integrated peak. Where this is not known the continuous rating of primary apparatus connected may be used.

Construction. Location of transmission lines for either d c or a c should be considered relative to accessibility, economy, and safety.

Accessibility for inspection and repairs is of first importance, and if conditions permit location near a road, it pays to make a considerable detour, as it will facilitate finding sources of trouble. In case of ground or short circuit, a repairman can cover the ground in 0.2 to 0.5 the time if on horseback or with automobile. In many cases, particularly in coal-mining districts, a mile or more added length of line will give advantages worth many times the first cost. If such location is not available, lines should be straight as possible; should have clearance of at least twice the line spacing over or under any other lines; and through towns or villages should be kept high (30 to 40 ft), because if low, short circuits and groundings may be caused by objects thrown over the wire.

Poles and cross-arms (Sec 42, Art 14). Steel cross-arms and pins are best, as the life of wood arms is short, unless treated, in which case the cost will approach or exceed that of steel. The Bo-arrow and similar constructions are light, strong, cheap, and do not require gaining and weakening a wooden pole. Steel poles or towers are common for long high-voltage lines, with spans of 200 to 500 ft. For ordinary mining work, wood poles are satisfactory for spans of 100 to 125 ft, where wires are not larger than No 0.

To a point 1 ft above ground, the butts of wood poles should be treated with creosote or other preservative. All joints and wherever poles are drilled or cut should be similarly treated. Where brush or grass fires are expected, place concrete around pole to height of 2 ft, or protect base with rock, or, if conditions justify, use steel poles.

Lightning arresters (Sec 42, Art 13), for protection of sub-stations, should be made up of capacitors and suitable station or line-type arresters.

Ground wires are an efficient protection for transmission lines, and if several are used, partially surrounding the lines, they afford complete defense against lightning, though arresters will still be necessary to prevent trouble from arcing grounds. Pole lines usually have a single ground wire, supported from the pole top on a bayonet or ridge iron.

In moist climates or where exposed to fumes and gases, as from coke ovens or smelters, ground wires should be of copper; elsewhere they may be of galvanized steel strand, double dipped, 3/8 or 7/16-in diam, and should be tied with wire of the same material, NEVER COPPER WITH STEEL. Good groundings may be made at power plants, as to water pipes, etc; but at sub-stations and on transmission lines it is often necessary to drive iron pipes into the ground, or to bury copper ground-plates. Galvanized iron pipes, 0.75 to 1-in diam, driven 6 to 8 ft in earth, will have 15 to 20 ohms resistance. Where good grounds can not be obtained for a considerable distance, larger and better ones should be provided where possible at each end of such section (2).

6. UNDERGROUND WIRING

Underground circuits not exceeding 550 volts use insulated or bare wire, supported on insulated fittings. Wires may be supported directly on hangers or insulators attached to roof or sides of passageway, or may be attached to timbers supporting the roof, but in such manner as will allow timbers to be changed without disturbing the electrical circuit. In all cases wires must be kept free from contact with roof, sides or timbers, whether insulated or not.

Circuits exceeding 550 volts are insulated for proper voltage, and protected by armor (metallic or nonmetallic), or carried in iron conduit; metallic armor or conduit to be grounded. For circuits of 2 300 volts a c and higher, cables are available without metal armor. Individual conductors are shielded by 5-mil tape, with bare grounding conductors in contact with the tape. In case of insulation failure, grounding conductors carry fault to ground. Circuits are mechanically protected by burying in trenches in floor or sides of passageway.

Table 2. Current-carrying Capacity of Bare Copper Conductors Used in Mines

Conductor, B & S gage	Current capac, amperes	Conductor, circ mils	Current capac, amperes	Conductor, circ mils	Current capac, amperes
10	80	250 000	690	750 000	1 520

Trolley wires may be supported from roof, walls, timbers, or pipe, as conditions require, and are strung 4 to 6 in outside the gage line, on the side opposite to safety or manholes, room necks, or chutes (Sec 23). MINIMUM HEIGHT is about 6 in clearance above the locomotive frame; general range, 32 to 56 in; max height, usually 7 ft. Where the wire is less than 6 ft above rail, it must be protected at all cross-headings, on partings and switches, or wherever men or mules are required or permitted to cross underneath or work near it. This protection consists in placing the wire in an inverted trough of wood or other material, so that sides project at least 2 in below wire, or by cutting a groove in the roof, so that the wire is supported 2 in above roof level. Wooden troughs may be supported on roof bolts, or held by trolley wire suspensions, spaced not over 10 ft apart. Special fittings have been devised for clamping, insulating, supporting, and stretching trolley wire underground, as shown in catalogs of makers. As much of the underground trolley wire is not permanently located, soldered ears, frogs, etc, are not used.

Trolley lines should be sectionalized, so that any grounded section may be isolated and repaired without interference with other sections. It is usual to install SECTION INSULATORS for each cross or panel heading of the mine, their number and location being determined by local conditions. Where roof is very bad, it may be desirable to sectionalize every room heading or branch.

Bonding rails is done by welded, compressed and pin-terminal bonds. WELDED BONDS have a direct weld between the copper wire and steel terminal which is welded to the rail;

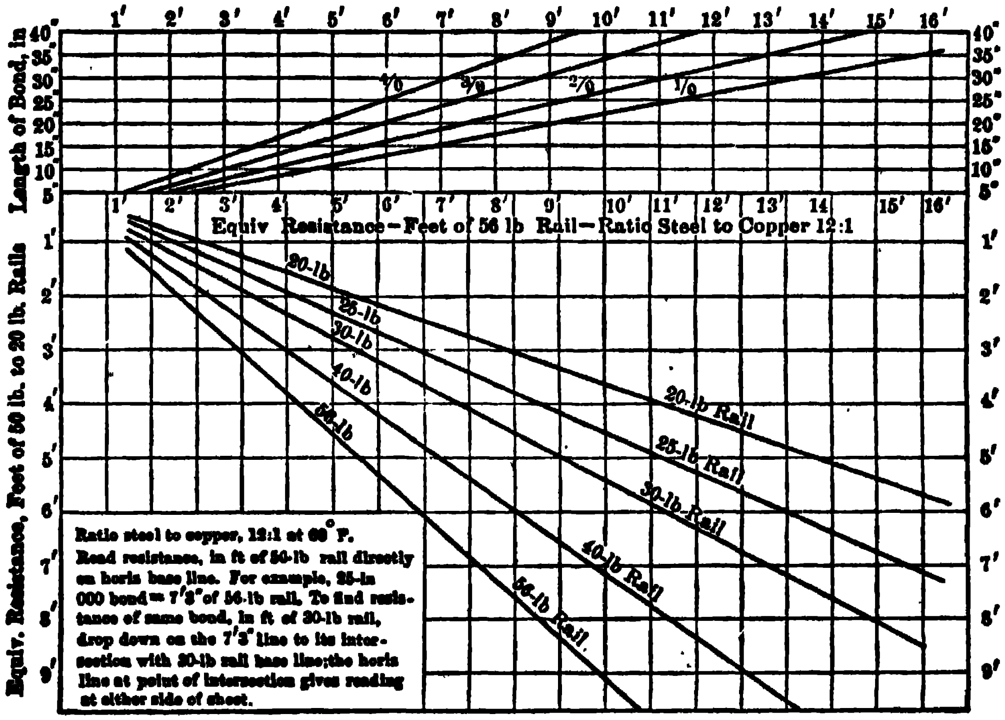

Fig 3. Rail Bond Resistance Chart

they are easy to apply and give permanency of contact; any form of arc-welding apparatus can be used. Welded bonds have a contact area equal approx to 6 times nominal capacity of the bond. COMPRESSED-TERMINAL or PIN-TERMINAL BONDS are either concealed under the splice bar or are outside of it. CONCEALED BONDS can be used satisfactorily only where the rail is 60 lb and over, as with lighter rail there is insufficient room between splice bar and rail to avoid cramping and cutting the bond. The copper stud of the pin-terminal bond should be same size as the hole in rail. A small hole is drilled in stud, and after stud is placed in the rail, a drift pin is driven through, expanding the stud to a tight fit. Following the drift pin a short, tapered steel pin is driven and remains in the stud, maintaining contact with the rail. With the compressed-terminal bond, the stud should be expanded in the rail by a screw or hydraulic compressor, and enough pressure applied to cause the copper stud to flow into and make intimate contact with the rail metal. A head is formed on each side of the hole, sealing it against moisture and maintaining contact of the bond. The compressed-terminal bond is the most efficient, with lower resistance throughout a long life, but the pin-terminal type is more easily applied and with intelligent

application gives excellent results in mining work. EARTH RESISTANCE in coal and metal mines is usually very low, because of acid water, and in many mines a large part of return current travels through the earth. This causes ELECTROLYSIS of rails, pipes, etc, which can be reduced or eliminated by good bonding of track, with return feeders if required, and by bonding track rails to air or water piping at intervals of say 500 ft (Fig 3).

Capacity of bonds should be 0.5 that of trolley and feeders, but not less than 500 circular mils per ampere should be allowed, based on aver load. Area of steel rails, sq in, = 0.1 the wt per yd, and conductivity is about $^1/_{12}$ that of copper. 1 sq in = 1 250 000 circular mils (nearly), and a short cut from lb per yd to equivalent circular mils of copper is: 1 lb per yd equals 10 000 mils. THERMIT RAIL WELDING is applicable to heavy, much used underground tracks, eliminating use of bonds and bonding troubles; reduces track maintenance and gives a smooth track. This follows the practice of street railway tracks embedded in paving.

Mine telephone wiring must have special attention, because, on account of the small sizes required, the conductors are mechanically weak and subject to breakage and trouble.

Where phones are near shaft bottoms or pit mouths, it is true economy to install wires or cables in an acid-waterproof, strong and flexible, non-metallic conduit. Along entries and gangways, where a conduit would be too expensive, rubber-insulated wire should be used. This must be supported on insulators and kept clear of coal, rock or timbers, as carefully as though it were bare, since insulation can not be depended upon underground. METALLIC CIRCUIT should be used for telephone service, to avoid noise and interference from power circuits, and lines must either be transposed frequently or TWISTED-PAIR used.

Signal systems. For these the same precautions as above should be observed and, for bare signal wires along haulage roads, potentials should not exceed 30 volts.

7. ELECTRIC HOISTING (see Sec 12 for general subject of hoisting)

Electric hoisting is more economical than steam, except where fuel is cheap and cost of power high (3). Where a c is available, either purchased or produced at the mine's central plant, hoisting by electricity eliminates boiler plant and the stand-by losses attendant upon the use of steam. Choice of TYPE OF HOIST is largely influenced by power requirements and conditions under which power is furnished. Slight changes in duty cycle will greatly modify power requirements. A cycle consisting entirely of acceleration and retardation is inherently wasteful with any type of hoist. Fig 4 shows hoist diagrams for various duty cycles, ranging from 2 to 10 sec acceleration to full speed, for a hoisting period of 17 sec, with conical drum. The fig shows effect of too rapid or too slow acceleration. The quantity $\sqrt{\text{Mean}^2}$ hp ("root mean square hp") is obtained by multiplying the square of the current input in each cycle period by the number of sec duration of the period, adding these and dividing by total elapsed time (sec), and extracting the square root (Bib 3, p 323).

Types of hoist drive (4) commonly used are: (*a*) INDUCTION MOTOR, geared to drum; (*b*) D-C MOTOR, direct-coupled to drum, with variable voltage supply from an independent motor-generator set; (*c*) D-C DRIVE, same as above, with flywheel type motor-generator set, supplying variable d-c voltage. Type (*a*) is lowest in first cost, with effic equal to or greater than type (*b*), and is usually recommended in sizes up to 600 hp, under power conditions where heavy starting peaks are not prohibitive or penalized. Type (*b*) has the advantage of ease and certainty of control (5), adjustable hoisting speed and elimination of gears. Reduced speed will reduce peaks while developing a mine, when hoisting men, and in similar service. It is more expensive than type (*a*), and has the disadvantage of requiring the operation of 2 separate machines, *viz*, the motor-generator set and the hoist. Motor-generator set may include an additional generator for mine use, to which part of the stand-by loss may be charged. Type (*c*) is suitable only for large hoists, where the power contract heavily penalizes peak loads, as the effic is 10 to 12% less than that of type (*b*). The effect of the flywheel is to cut down peaks of the load curve, and theoretically permits uniform input to the induction motor driving the hoist generator. Stand-by losses are still larger than those of type (*b*), approximating 2 kw per ton of flywheel wt, and it is not possible to reduce this charge by driving another generator (6).

Fig 5 shows typical diagram, line *AB* representing aver power input to the hoist motor. For complete elimination of peak loads the flywheel must, within each complete cycle, deliver power in hp-sec, corresponding to area of diagram above the aver line.

Fig 6 is a diagram for obtaining effective wt of flywheels. The example shown by the heavy lines assumes 20% drop in speed to deliver 25 000 hp-sec, with radius of gyration assumed as 4 ft, with set running initially at 600 rev per min, and shows that an effective wt of 39 000 lb will be required. Use of conical drums often improves the load curve by reducing the acceleration peak

and compensating for wt of rope, which is a large factor in deep shafts (Sec 12). Elec shaft hoisting is chiefly an elec problem, and design of drums will depend on the most economical duty cycle.

Control of induction-motor hoists may be by liquid rheostat or magnetic contactors. **Liquid rheostat** consists of a tank, filled with electrolyte (as soda or salt water) arranged to carry electrodes, usually triangular or trapezoidal. Electrodes are preferably fixed in

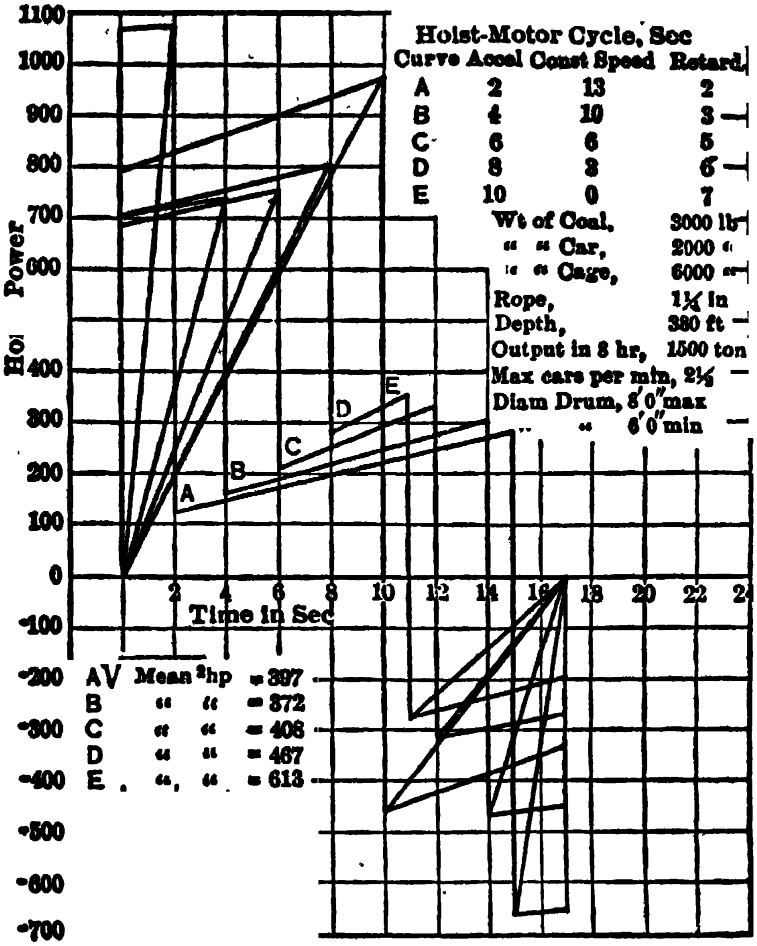

Fig 4. Electric Hoist Diagrams

position, and the electrolyte, circulated by a small pump, rises and falls in the tank. Electrodes are connected in the wound rotor secondary circuits, and motor torque and speed vary with the submerged area of electrodes. As the secondary circuit must not be opened, the electrode tips remain submerged. The primary switch of the motor is inter-locked with a lever operating a weir; the first movement of this lever closes the primary circuit, and further movement raises the weir controlling overflow of the electrolyte, allowing the liquid to rise on the electrodes. Assuming the weir to be raised at once to its full height, the rise of electrolyte on the plates, and consequently the rate of ACCELERATION of the motor, depend on the capacity of the circulating pump, thus providing a smooth and certain control of acceleration (7). This type of rheostat is preferable, because of low first cost and upkeep, and smooth acceleration.

Resistance of ordinary hydrant water, per sq ft cross-sec and 1 ft in length, is approx 100 ohms. Table 4, A, gives resistance when containing commercial table salt; Table 4, B, gives resistance when containing commercial H_2SO_4.

Table 4. Data for Liquid Rheostats

Table A		Table B	
% Salt by wt	Resist, ohms	% Acid by wt	Resist, ohms
0.23	7.84	0.174	4.12
0.46	4.65	0.435	1.75
0.70	3.12	0.724	1.10
0.93	2.38	0.985	0.85
1.16	1.90	.....	....
1.39	1.48	.....	....

For liquid rheostats without forced circulation, use from 600 to 1 000 cu in of solution per kw absorbed. Plates or electrodes should have an area of 1 sq in per ampere.

Contactor control consists of a series of magnetic contactors, arranged with current-limit control, so that the contactors close automatically in succession as the current falls

to a predetermined point. Time control may also be used where the cycle of operation is such as will permit it, and may possess advantages not present with current-limiting contactors. Position of a MASTER CONTROLLER determines the number of contactors which may close, and operator may thus start more slowly, but can not exceed the fixed limit of acceleration.

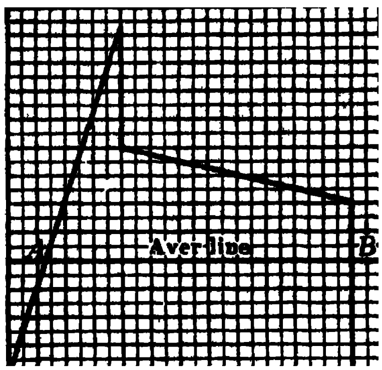

Fig 5. Hoist Diagram, Showing Aver for the Cycle

Control of d-c hoist motors by field control of variable-voltage generator is by rheostat in generator field, which is separately excited. Generator is of interpole type, and readily commutates current from 0 to max voltage, positive or negative, while running at a constant speed. Hoist-motor field is separately excited, so that its speed varies directly as impressed voltage. Same mode of control is used for ILGNER SYSTEM, with addition of a slip regulator in the induction motor circuit, allowing the set to slow down when heavily loaded, thus drawing energy from flywheel for all loads above a fixed capacity (Sec 12).

Slip regulator in a simple form consists of a liquid rheostat, in series with main induction-motor secondary, with electrodes raised by a small induction motor in series with main motor primary current, usually through series transformers. These electrodes are counterbalanced, so that, with normal current in main motor, they are completely submerged with minimum resistance in main-motor secondary. When line current exceeds predetermined amount, the torque of the small regulator motor is correspondingly increased, lifting the electrodes and thereby

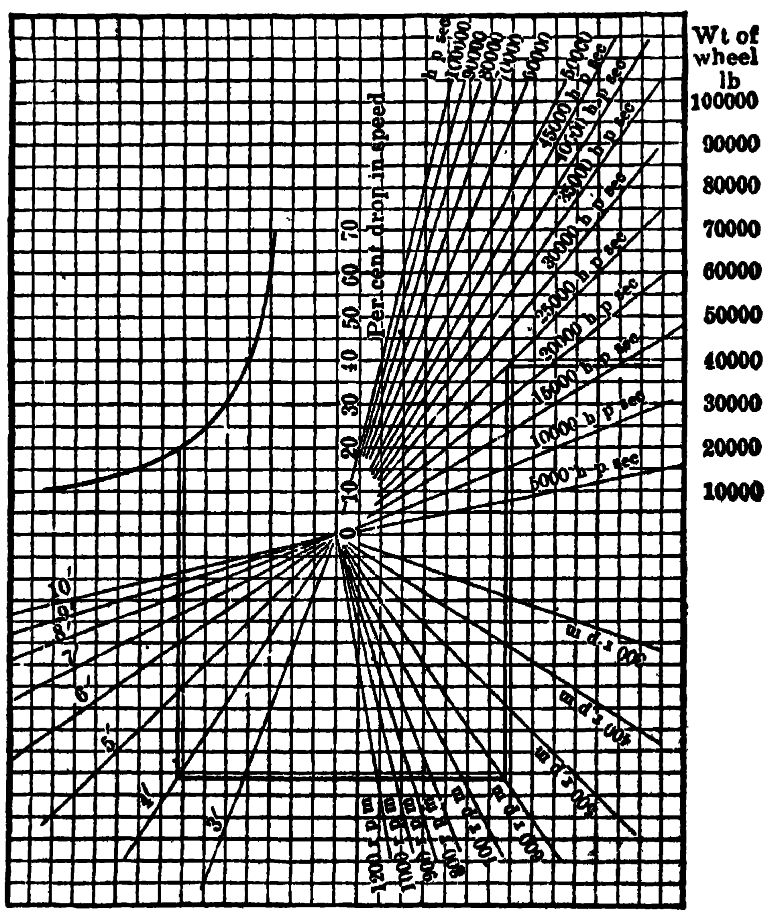

Fig 6. Diagram for Obtaining Effective Wt of a Flywheel

increasing the secondary resistance of main motor, slowing it down and allowing flywheel to deliver energy to the d-c generator.

Safety requirements demand that electric shaft hoists be provided with an approved device to prevent overwinding (Sec 12). Where men are hoisted, additional provision

must be made to prevent overwinding at their special landings, if any. In such case, there is also a visual signal to indicate at all man landings that the overwind device is set for hoisting men; and it must not be possible to operate the hoisting signal lights without setting the man-landing overwind device. Besides the main brakes, shaft hoists must have a hand brake, capable of keeping the drum under control of the operator. If the power supply fails in case of overwinding or overspeeding, an automatic trip or release applies this brake, which must be able to hold the max unbalanced load. If any contingency causes an emergency application of the brake, power is shut off from the motor.

The hoist must not be maneuvered unless all equipment, including protective devices, is in normal working condition. Should the legal rate of speed be exceeded when men are on the cage, the hoist is automatically brought to a stop. For a hoist designed to operate in balance, the driving motor must have sufficient power to raise full loads of men in a max unbalanced condition, in case of emergency. Electrical safety devices must be tested at the beginning of each shift; a record of such tests being made and signed by an authorized person, and kept on file at the mine.

Automatic control is most readily applied to D-C HOISTS with field control, since at any position of the controller speed is practically constant, even with varying load. It follows that an interlock may be arranged, which will maintain the speed in a definite relation to the position of the cage in the shaft. Hence, both acceleration and retardation may be automatic, and an overwind is impossible; and in case of overbalance or rapid retardation, current will be returned to the line. With INDUCTION-MOTOR HOIST, the speed at all resistance points varies with the load. Against overwinding, some centrifugal device should be used, in connection with a limit switch to open the circuit and apply the brakes, if the speed at certain points is not suitably reduced. If the landing is approached at proper speed, the device will not operate, but if the proper speed is exceeded at any one of a number of points, the current will be cut off and brakes applied.

Slope hoists are particularly adapted to electric drive, which eliminates losses of the steam hoist when idle, while lowering unbalanced, waiting for trips or on account of accidents; it gives uniform torque for starting, and maintains uniform speed with varying loads (as on variable grades). Motor-driven hoists may be located at any desirable point underground, where it might not be economical or possible to operate otherwise. Nearly all slope hoists have either single or double reduction gearing; the former is preferred, particularly since the perfection of the double-helical gear.

Small geared hoists are largely employed in local dips in collieries. With rope pull of 500 lb and equipped with 3-hp motor, these have been standardized by several makers, at prices approximating $400, or somewhat less. Using track sheaves, a single hoist may serve 2 or more dip headings or rooms. Some extensive bituminous mines use large numbers of these convenient hoists.

8. ROPE HAULAGE AND CONVEYERS

Endless and tail-rope haulages (Sec 11) are readily adapted to electric drive, although endless rope, with rope speeds of about 3 to 4 miles per hr, requires large gear reduction. The greater flexibility of locomotive haulage has eliminated rope haulages except where grades are very heavy. In such cases the use of motor drive permits location of haulage engines at any point, outside or underground.

Car hauls, conveyers, and elevators are almost always motor driven (see Sec 27). The proper type of motor must be selected to suit the character of work; whether induction a-c or shunt, compound or series-wound d-c motors are chosen, depends on the speed and torque characteristics of load. Enclosed and ventilated motors should be selected for dusty or wet service. Since the motors are run continuously without attendance, full overload and no-voltage protection and preferably current-limit starters should be provided.

Sometimes, as with retarding conveyers, power is required for starting, after which mechanical or regenerative braking is necessary. Frequently it is desirable to install emergency control, so that in case of trouble the conveyer or car-haul may be instantly stopped from any one of a number of points. A small switch short-circuits the trip coil on a no-voltage release, opening circuit breaker. The motor thus stopped can not be started until this switch is opened.

9. ELECTRIC LOCOMOTIVES (for "Underground Haulage," see Sec 11)

Standard mine locomotive (Fig 7) has a heavy steel frame, on journal springs over axles, gear-driven by series-wound motors, which are supported partly from axles and partly from frame. A rheostatic control, usually with series-parallel connections, and C-I grid resistances, serves for starting and running in either direction. Contactor con-

trol with master controller is used on the larger locomotives. Hand or compressed air brakes, sand boxes, valves, trolley and headlights are all of special mine types.

Details. Frames may be of C I, riveted steel plates, solid steel slabs, or cast-steel bar type. Riveted-plate and slab frames are unbreakable, as in collision. Cast bar-steel frame has the advantage of affording ready access to brakes, sand rigging, and other apparatus, and gives best ventilation. Bearings, for journals, axle linings through motors, and armature shafts, must be carefully designed to exclude dust and sand, and to give good service with minimum attention. Journal bearings are of bronze, easily removable when weight is taken off, and lubricated by waste-packed oil cellars. Axle-bearing linings may be of bronze or babbit, lubricated in the same way. Armature bearings are preferably ball bearings, though bronze-lined waste-packed bearings are also successful. It is highly important that the wear on these bearings be minimized, because wear shifts the air gap, affects commutation and gear mesh, and may destroy the armature by rubbing the pole faces. Well-designed and constructed ball bearings have eliminated such troubles almost completely on small locomotives, and are becoming standard practice on large ones of 75 hp and over. The limited space on narrow-gage locomotives makes ball bearings desirable. Motors for mine locomotives vary but little in general design from standard railway motors, though because of the lower voltages used, the coils, commutators, and brushes are often heavier for the same hp. Coils should be form-wound, interchangeable, impregnated, and baked, making them practically waterproof and increasing the conduction of heat from the copper conductor. The usual narrow track gages require very compact motors, making it increasingly difficult to obtain sufficient heat-radiating surface. Good commutation is difficult to obtain on account of

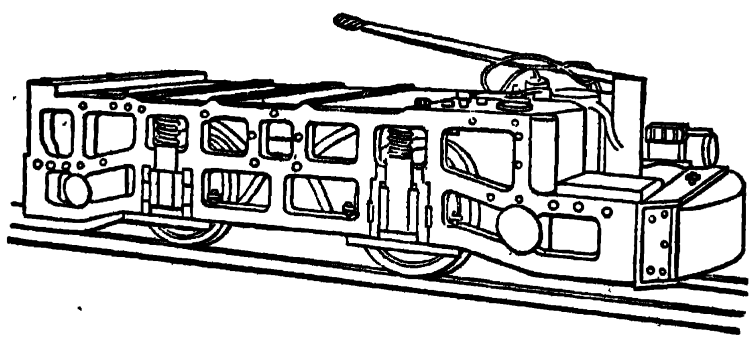

Fig 7. Electric Mine Locomotive

rough track, many frogs and switches, and severe peak loads, both on starting trips and on heavy grades. Commutating-pole motors are very advantageous, eliminating sparking due to overloads and minimizing effect of jar and vibration on commutator and brushes. They also have a higher continuous rating, due to lower magnetic densities in armature core and pole face. Where gear faces are reduced on very narrow gages, special heat-treated alloy steels may be used, and would be an advantage in standard practice. Controllers for most locomotives below 10 ton are of the magnetic blowout type, with separate interlocked cylinders for speed control and reversing; 10-ton locos or larger are of the contactor type. Most controllers have both series and parallel connections on reverse cylinders, but series connection is of no special value except for very light work, as motors will not operate satisfactorily in series unless mechanically connected, as with side-rods. Some large controllers use double contacts, with separate blowout magnets for each resistance and running point.

Resistances for speed control are practically all of the C-I grid type. Grids are strong, elastic, and easily replaced. Resistances should be placed at the ends of locomotives, where ventilation is good, and not above or near motors or cables.

Successful operation of electric locomotives depends primarily on motor rating per ton of wt; also on type of wheel, wt of rail, amount of sand used, etc.

Drawbar pull (Table 5). Maximum available for starting depends on the wt of locomotive, and in extreme cases, with sharp sand, is as high as 50% of the wt; ordinarily, say, 40%. Without sand a coeffic of adhesion of 25% may be estimated for steel wheels, or 20% for chilled C-I wheels.

Usual rating for adhesion is 25%, and motors are available which will exert this drawbar pull at rated speed for 1 hr with a temp rise of 75° C. This so-called railway rating is satisfactory where length of haul is short and grades not excessive, so that sand is unnecessary except on starting, and approximates 10 hp per ton, at 8 miles per hr. On long hauls (over 1 mile) with adverse grades requiring much sand and where motors can not

Table 5. Locomotive Drawbar Pull and Haulage Capacities

Figures are for locomotives with steel wheels; for C-I wheels, take 80% of values in table

cool off between trips, the standard 1-hr capacity will not suffice. In such cases, the motor rating for continuous service is specified, and should not be less than 6 hp per ton. CONTINUOUS RATING of enclosed, series motors, as used on locomotives, ranges between 35 and 48% of the 1-hr rating. FORCED VENTILATION, by separate fan outside the casing, increases this by 60 to 85%. Chief objection is that sand, dust, or moisture may be drawn or forced into the motor windings, but, by taking in air at top and discharging it at bottom of motor casing, this difficulty is largely avoided. In mines of large output, with narrow-gage tracks and limited height of gangways, ventilated motors are necessary, and experiments made on the above lines show reduction in temp rise, as in Table 6.

Table 6. Forced Ventilation for Haulage Motors

Wt of motor, tons	Trips	Aver no cars	Length haul, ft	Temp, deg C, without fan		Temp, deg C, with fan		Mine temp	Remarks
				Com	Wind'gs	Com	Wind'gs		
24	14	72	12 000	111	104	76	72	14°	Air inlet at gear end
30	10	100	15 000	124	106	64	70	14°	Air inlet over commutator

Use of sand increases the tractive resistance of mine cars from 20 to 100%; the smallest possible quantity of the best quality obtainable should be used.

Cost of locomotives of same wt and rating is fairly uniform among the different builders. Following are examples of common sizes:

4 ton...........	$3 160	8 ton...........	$4 230	13 ton..........	$6 300
6 ton...........	3 850	10 ton.	565	15 ton...........	7 290

These prices are for chilled-iron wheels; add $152–$182 for steel-tired, and $90–$152 for rolled-steel wheels. Add $490 for cable-reel gathering locomotive, and $400 for crab-reel type (see below).

Gathering locomotives are of the same general type as main-line haulage locomotives, with the addition of a trailing-cable or rope, which permits the locomotive to enter rooms or headings where no trolley wire is strung. These locomotives require much less headroom than mules, and a locomotive with 2 men will gather from 2 to 5 times as many cars as 1 mule with driver, the advantage being greatest where grades are worst. Where the vein is only 3 to 4.5 ft thick the saving is great, because for mule haulage the top must be taken down or bottom lifted to make headroom. Gathering locomotives should handle 85 to 150 cars per day, or even more where several cars may be placed at once in each room or stope. Haulage should be planned so that cars are delivered and removed regularly; it is usually necessary to arrange headings in pairs so that on one trip empties may be placed in one and loaded cars taken from the other, rather than to handle empties and loaded cars in the same heading.

Cable-reel type has a 2-conductor twin or concentric trailing cable, attached to the trolley and to rail at the room neck, and paid out as the locomotive travels into the room, the cable as reeled out lying on the floor. A single-conductor cable is sometimes used, with the room track forming the return circuit. On returning, the cable is again wound on the reel, a tension of 10 to 20 lb being maintained to prevent over-running and cutting the cable. In some types the reel is driven by a friction clutch from the locomotive axle, but a later form drives the reel by a small series-wound motor, with resistance for continuous connection across the line, maintaining uniform tension like a spring of infinite length. Cables may be overrun and injured by the friction-clutch type, should braking cause wheels to skid, or by the motor type should the current fail. Cable-reel type may be used for pushing empty cars or pulling loaded cars up grade.

Traction-cable or crab type carries a small and very compact motor-driven hoist. In operation, the "spragger" or trip-rider pulls the wire rope into the room, couples it to car, and motorman winds up rope, pulling car out to locomotive on heading. One or more loaded cars may thus be hauled up grades too steep for locomotives. This type may be used where grades are against loaded cars only; in special cases, locomotives carry both forms of reel.

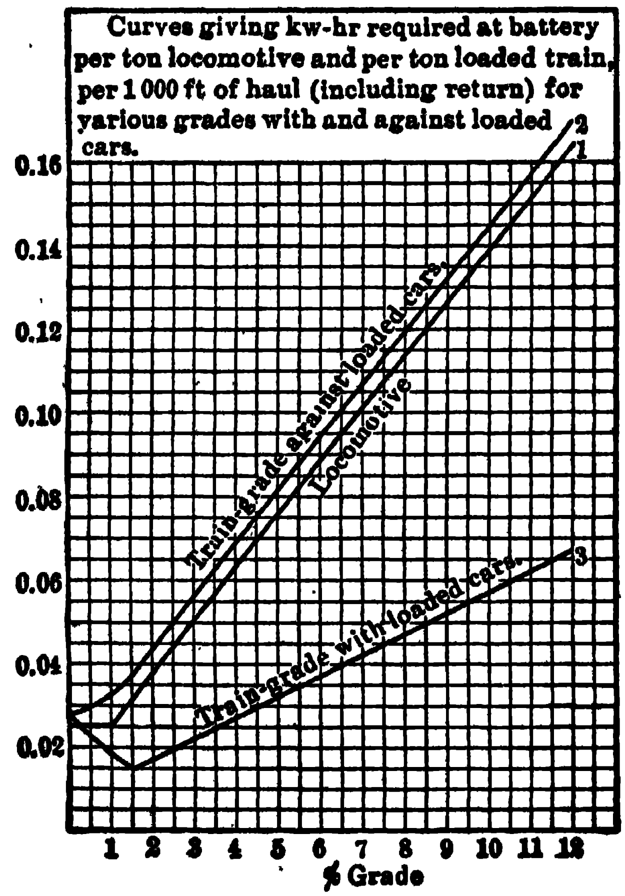

Fig 8. Battery Capac for Storage-battery Locomotive

Storage-battery locomotives, for light main-line haulage and for gathering service, are made in a number of sizes and types, and are guaranteed for specific installations. Battery equipment forms a large part of the locomotive wt, and the frame, motors, and other parts are as light as is consistent with strength. High-speed automobile-type motors are commonly used, with double-reduction or worm gearing, the voltage used ranging from 80 to 100, with a few at 150 volts and higher (16). BATTERIES are of 2 types, the acid or lead type, or the alkaline nickel-iron. Each has advantages for specific installations, but the alkaline battery is 30% lighter, and is more rugged, while the lead type is about 15% more efficient and is 30% cheaper in first cost.

Calculation of battery capacity for a given installation. Fig 8 contains 3 curves: 1, for the locomotive; 2, for the train, with grade against the load; 3, for the train on a grade with load. The curves are based on frictional resistance of 30 lb per ton on level track, plus 20 lb for each per cent of grade. Effic of locomotive and motor equipment is assumed to be 60%. These curves can be used for calculating battery capacity for any kind of duty; given the wt of loaded train, number of cars per train, grade, haulage distance, and wt of locomotive. The proper wt of locomotive, which must be sufficient to haul the max load on specified grades, is selected from Table 7, which gives max drawbar pull (lb) and haulage capac (tons) for a given wt of locomotive equipped with steel wheels. Track friction, 30 lb per ton and resistance of 20 lb per ton for each per cent of grade.

Calculation of battery capacity for a gathering locomotive. It is convenient to divide the length of haul into 3 parts: distance from side track to first room on entry; distance on entry in front of rooms; max depth of room (total depth is used in calculation to allow for switching, etc.).

Example. Assume the locomotive must gather 120 cars in 8 hr, delivering each empty car to the face. Trains are of 10 cars, making total number of trips 12. Wt of loaded car, 5 200 lb; length of haul from side track to first room, 600 ft; depth of room, 250 ft; length of haul on entry

8	4 000	133	3 840	77	3 680	53	3 520	39	3 360	30	3 200	25

in front of rooms, 400 ft. Rooms are level and grade on entry is 1.5% against the load. Distance the locomotive travels, and distance the train is hauled on different parts of a trip, are given in tabular form:

	Equiv length of haul, ft	
	Loco	Loaded train
Side track to first room..	600	600
On entry in front of rooms	400	400 + 2 = 200
In rooms................		10 × 250 = 2 500

Loaded train weighs.... $\frac{5\,200 \times 10}{2000} = 26$ tons

Assume locomotive weighs 5 tons. Kw-hr required: to haul 1 ton of locomotive 1 000 ft on level, 0.025; to haul 1 ton of locomotive 1 000 ft on 1.5% grade, 0.031; to haul 1 ton of loaded train 1 000 ft on level track, 0.026; to haul 1 ton of loaded train 1 000 ft on 1.5% grade, 0.037.

Kw-hr required for each part of haul over which LOCOMOTIVE travels = (distance (ft) ÷ 1 000) × loco wt × kw-hr (read from curve). Per trip for level track, (2 500 ÷ 1 000) × 5 × 0.025 = 0.312. Per trip for 1.5% grade, (1 000 ÷ 1 000) × 5 × 0.031 = 0.155.

Kw-hr required for each part of haul over which TRAIN travels = (distance (ft) ÷ 1 000) × tons of loaded train × kw-hr (read from curve). Per trip on level track, (250 ÷ 1 000) × 26 × 0.026 = 0.17. Per trip on 1.5% grade, (800 ÷ 1 000) × 26 × 0.037 = 0.77. Total kw-hr per trip: locomotive, 0.467; train, 0.952; or 1.419. Hence, total for 12 trips = 17 kw-hr.

Table 8. Kw-hr Capacity at Normal Discharge Rates

(Normal battery charge for standard locomotives)

Alkaline		Lead	
Type	Kw-hr	Type	Kw-hr
63 A–4	11.3	48 MV 9	11.9
63 A–6	16.0	48 MV 11	14.8
63 A–8	22.6	48 MV 13	17.9
126–A–4	22.6	48 MV 15	20.8
....	.....	96 MV 9	23.8

To allow for decreased capacity of battery when discharging at a high rate, as required in gathering service, switching extra cars, pulling empties and loads on track, hauling locomotives from charging station to working place, and running with brake partly set, the kw-hr obtained by calculation is multiplied by 1.35, to give the capacity at normal discharge rate, which in this case is 23 kw-hr. Consult Table 8 for battery capacities.

Note that for above example the nearest battery capacity with least number of cells is 63 A-8 alkaline, or 48 MV 15 lead. Either will need at least 1.5-hr boosting charge, whenever the battery has been in use for 4 hr, in which case alkaline battery will have 15% greater capacity, and lead 25% greater capacity than given in table. Example shows how Fig 8 is used when calculating battery capacity required for gathering, and it is evident that this method can be used for any kind of installation on any kind of haul.

10. ELECTRIC-DRIVEN PUMPS (for "Mine Drainage," see Sec 13)

Piston and plunger pumps are being superseded by centrifugal pumps for every use underground, because of lower first cost, less room required and less maintenance. Electric drive is now almost exclusively used for centrifugal mine pumps. Details are given in Sec 13, Art 10.

Main underground centrifugals usually have cast-iron casings and bronze runners; or bronze casings with chrome-iron runners, or entirely of chrome, depending on character of the mine water. These pumps are designed for specific heads, stages being added as head increases. For PRIMING centrifugal pumps no foot valve is required in the suction, but a check valve in the discharge is essential. With automatic control, a float switch or electrode is customary for starting and stopping. A time clock or remote control can be used. A relay will stop pump when three attempts have been made to start it; a suitable signal indicates when this occurs. In case steam, compressed air or water under pressure is available for priming, the vacuum pump can be dispensed with. It is essential that all air in the pump or suction line be exhausted before the pump will start.

Submerged pumps, requiring no priming device, are sometimes useful; but, due to their cost, they are generally limited to relatively small units, say not over 20 ft in length. For UNWATERING MINES, the cost of BORE-HOLE PUMPS may be fully warranted. They consist of a vertical motor mounted on the surface on top of the discharge, with a shaft extending to a pump at the bottom. Where the water is acid, protection of exposed parts is expensive. Such pumps, having capacities to 5 000 gal per min against heads of 600 ft, are built by the Sterling Pump Co, Hamilton, Ohio, and other makers. Fig 9 shows a submersible pump, made by the Byron Jackson Co, Los Angeles, Calif, the motor of which is mounted at the bottom inside the casing, power being carried to it by a power cable and copper oil tube carried outside the discharge pipe to the surface. It can be installed in a crooked slope, shaft or bore hole, and turned at any angle at the bottom. Sizes are from 10 to 10 000 gal per min.

Gathering pumps, discharging into main sumps, usually require 3-10 hp motors, arranged for "across-the-line" starting, and are connected to the trolley system or feeder lines. They can be provided with a float switch for starting and stopping.

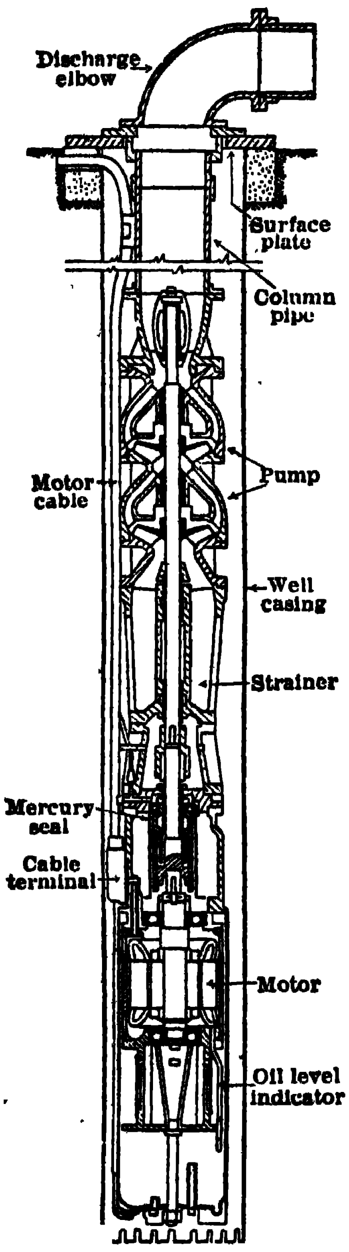

Fig 9. Submersible Electric-driven Centrifugal Pump

11. ELECTRIC COAL CUTTERS (for compressed-air cutters, see Sec 15, Art 14 and Bib 9)

Principal types: shortwall, longwall, turret or top cutter, and universal cutter, the earlier chain-breast type having given way to the shortwall machine. In 1939, the tendency is toward larger capacity motors, to meet the demands of double or triple shifting. For some special applications, motors of 100 hp (intermittent rating) are employed. Contactor control, with thermal and magnetic overload protective features, is in general use (20–25).

Shortwall machine (Fig 10) has no stationary guide frame, and for moving is mounted on a truck, propelled by gearing connected to the cutter motor. It carries a reel holding 200–500 ft of trailing cable. The cutter head is a narrow rectangle, with driving sprocket at one end and an idler at the other. By rope or chain feed, the machine pulls itself into the coal face to the length of cutter bar and then travels sidewise, cutting close to the floor and sliding on it. The machine can also cut at a determined height above the floor. In mines worked with conveyer systems, the truck is not generally used, as the machine remains in place until the mining is completed there. A recent departure from heavy designs in shortwall machines is the Sullivan "Buddy," with 15-hp motor. Being designed for conveyer mining, it has no cable reel or truck.

Longwall machine (Fig 11) resembles the shortwall, but has a longer and narrower body, with the cutter bar at right angles to the frame. Little used in this country at present, but its use is likely to increase in thin seams.

Turret or top cutter (Fig 12) is generally track-mounted, with two motors, one propelling the machine, the other driving the cutter chain. It is now less used than formerly. The cutter bar operates in a horiz plane, with limited vert adjustment for variations in height of seam, or dirt bands to be cut out. This machine is also available with cutter bar arranged to cut at or near bottom of the seam. One design of turret machine is not track-mounted, but moves across the coal face in essentially the same manner as the shortwall machine.

Universal or track-mounted cutter (Fig 13). The cutter bar is adjustable for working at any desired angle and height, thus permitting shearing, or top, center, or bottom cutting to be made as conditions require.

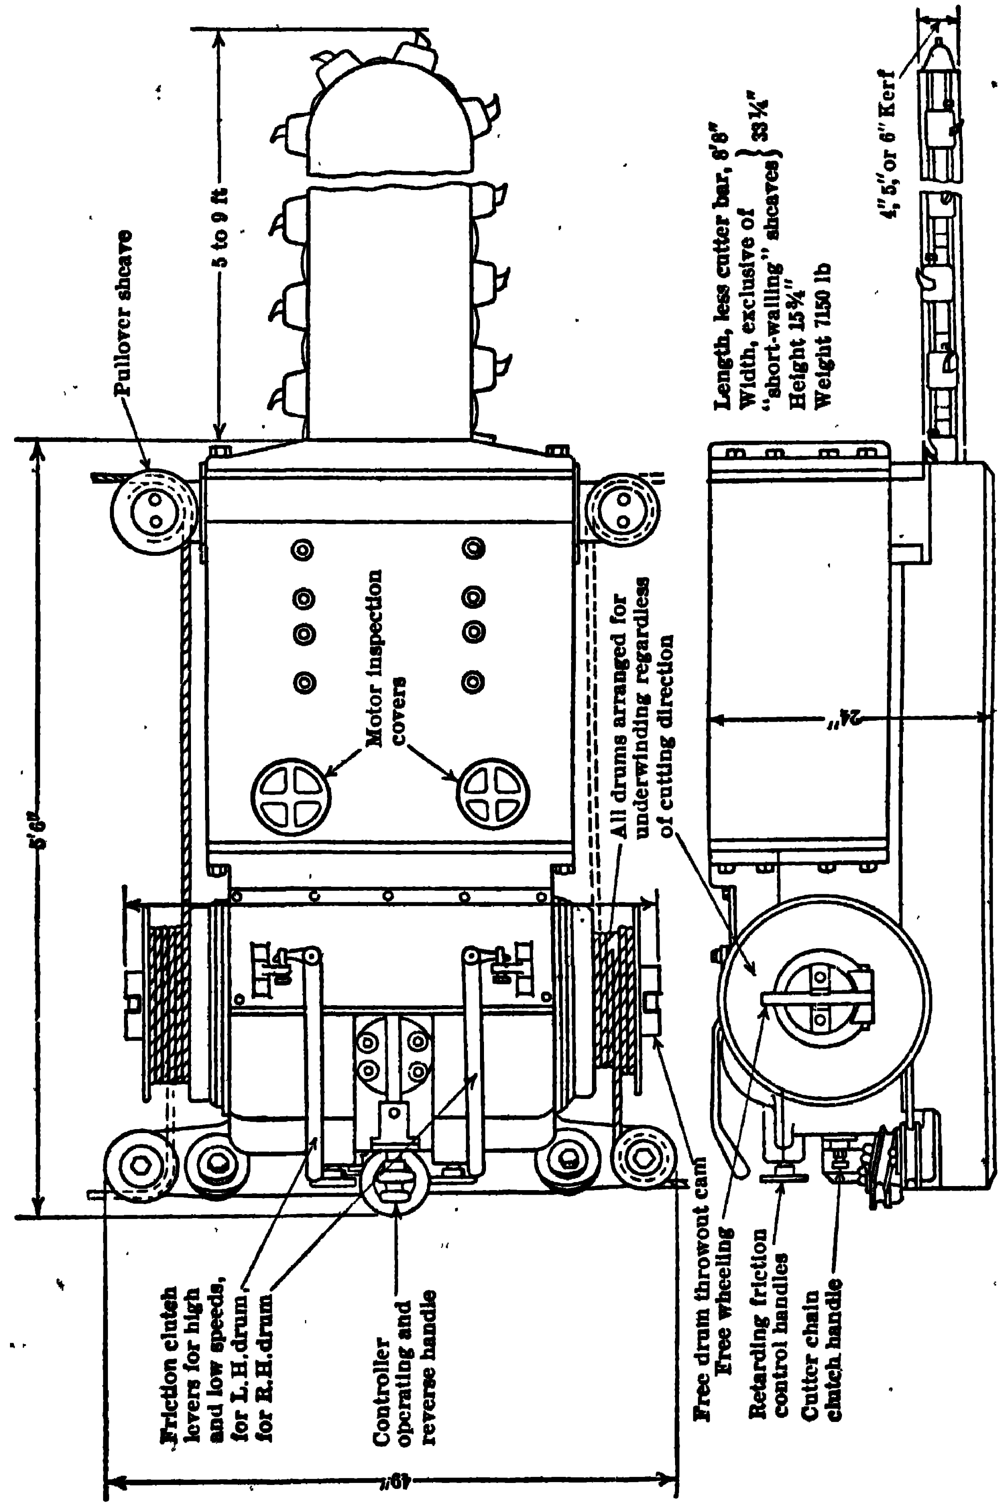

Fig 10. Sullivan Shortwall Coal Cutter (representative of all standard makes)

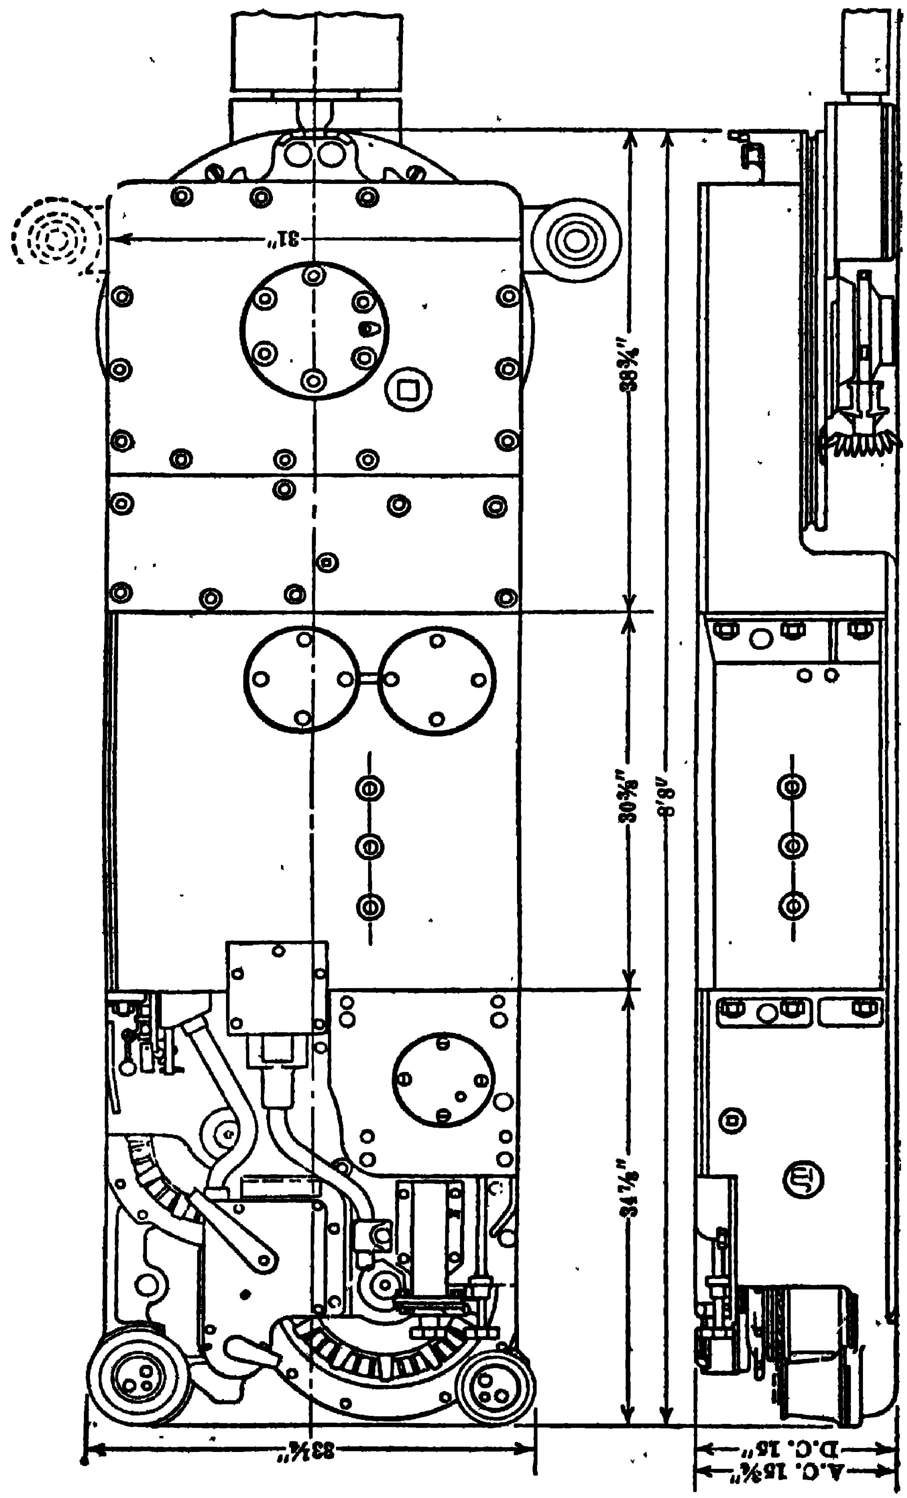

Fig 11. Jeffrey Longwall Coal Cutter

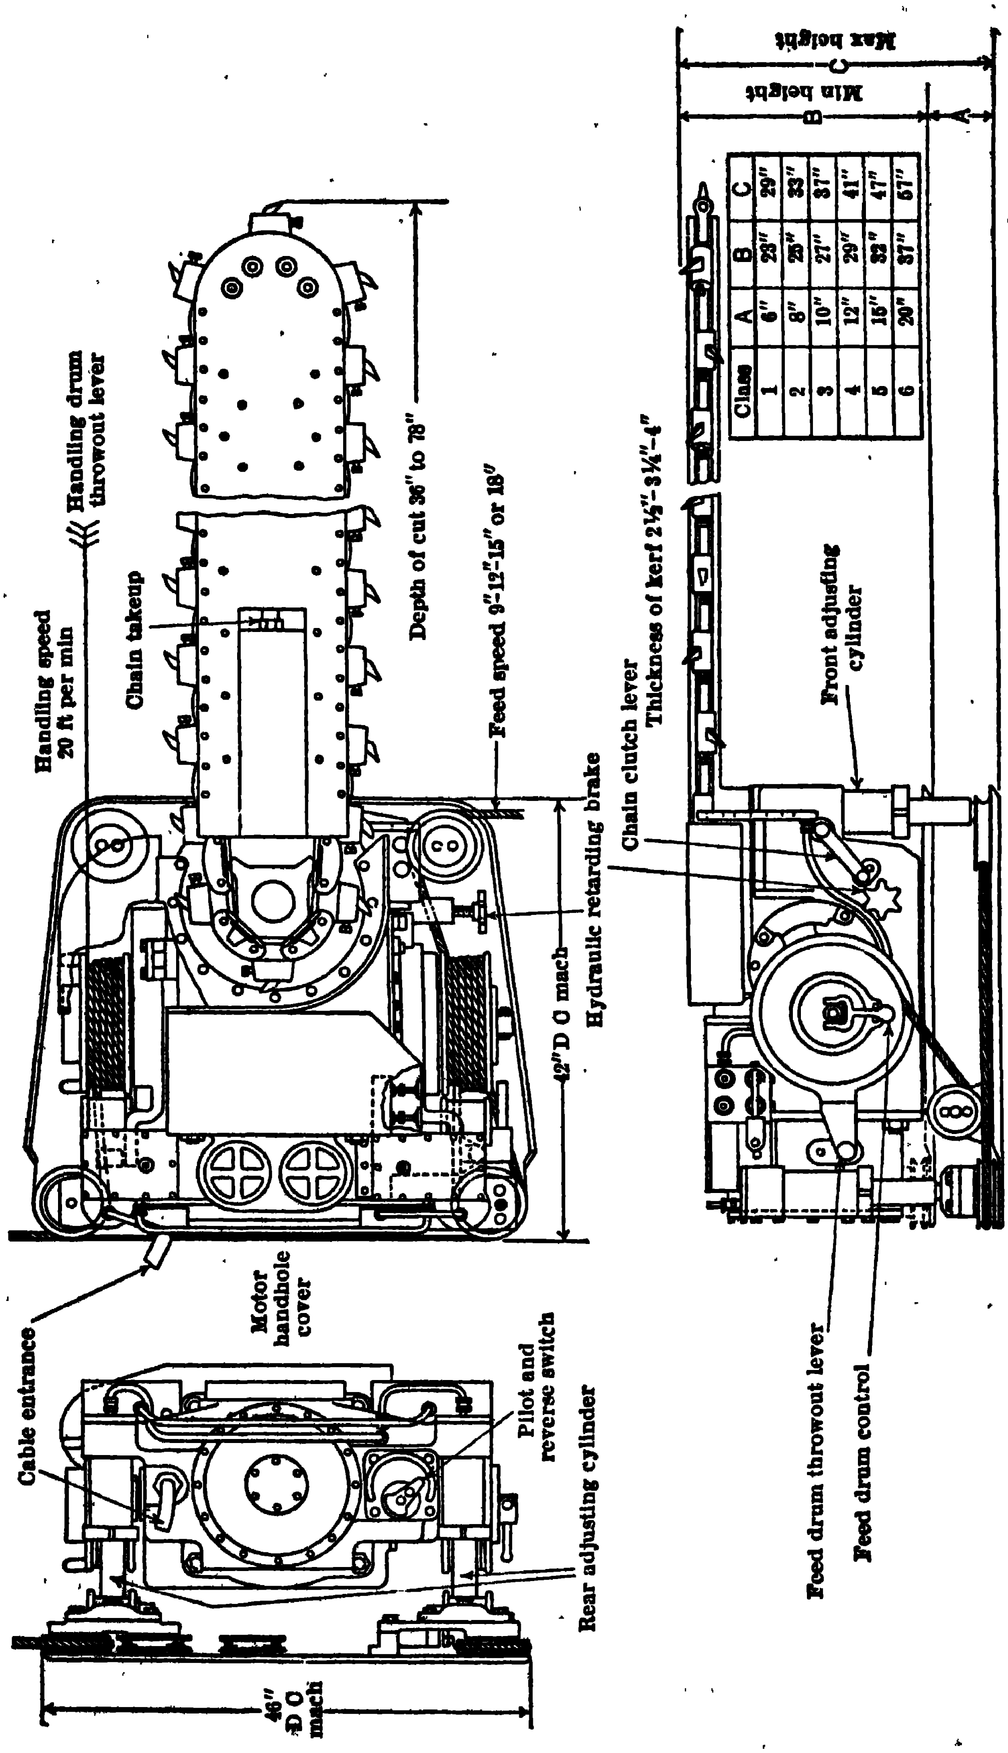

Fig 12. Sullivan Floor-type, Turret, or Top Cutter (9B)

Coal cutters in general have one or more motors, to a max of about 100 hp. Present tendency is to increase the power, because of continual service in machine mines. The current is usually a c at 250–500 volts, but d c can be used.

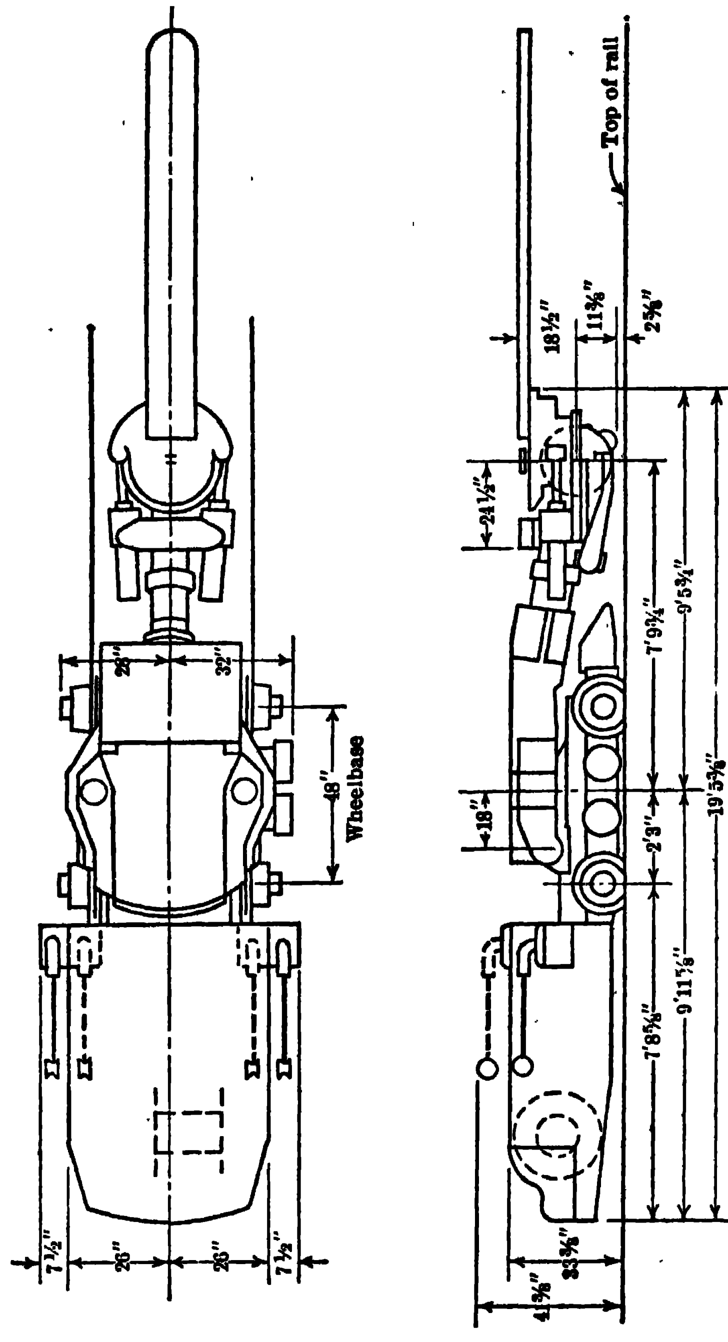

Fig 13. Jeffrey Track Coal Cutter, Universal Type, Bottom, Top, or Center Cuts, or for Shearing

12. MINE LIGHTING BY ELECTRICITY (see also Sec 23)

Lighting of mine buildings, offices, stores, shops and dwellings, should be at low current potentials, preferably not over 125 volts, to reduce fire risk and shock hazard. This involves the use of a c current, with distribution at standard voltage of 2 200 and step-down transformers of suitable capacity at centers of distribution. Large buildings, as storehouses, should have 3-wire systems at 110–220 volts, to reduce wiring costs. Dwellings may be grouped in blocks of 10 to 20 or more, supplied from a single transformer.

Underground lighting of haulageways is done by connecting 275-volt lamps singly or in groups in parallel to the mine d c trolley and feeder circuits, except for 500-volt trolley systems, in which case 110, 125 or 275-volt lamps may be connected in series as required.

At SHAFT BOTTOMS and similar areas of important activity, where a c circuits serve pumps and hoists, a small step-down transformer may be used to reduce 2 200 volts to 110, or 110-volt lamps used in series for 220 and 440-volt a c circuits.

Miners' storage-battery cap lamps (see Sec 23) are widely used in nearly all mines. They are generally installed on a rental basis, under which the miner is assessed 6 to 8¢ per shift, the mine operator paying 65 to 85¢ per month to cover parts and servicing. There are two types: (*a*) Wheat lamp, having a 2-cell lead-acid storage battery, and (*b*) Edison lamp, with 2 or 3-cell alkaline batteries. Both lamps are highly efficient and have the approval of the U S Bur of Mines for use in gaseous mines. The Wheat lamp complete weighs 3.6–4.5 lb, depending on the model; the Edison 4–5.4 lb. Makers also supply lamps fitted with handles, for officials and others in inspection service. Special lamps, with red globes for trip or tail light duty, can be had with either storage or dry cell batteries. Flash lamps, having dry cells, are now made in permissible types.

13. UNDERGROUND MECHANICAL LOADERS

These comprise a large variety of equipment, nearly all of which is operated electrically. Full details of construction and applications are given in Sec 27.

14. ELECTRIC-DRIVEN FANS AND BLOWERS

Electric drive is now used almost exclusively for all kinds of mine ventilators. Constant speed motors are best adapted to this service, though variable speed is sometimes used. Details of fans and blowers are given in Sec 14.

15. MISCELLANEOUS ELECTRICAL DEVICES

Block-signal systems (Fig 14), with red, green or yellow lights, for control of main-line haulage are available with manual or automatic operation, for both of which current is taken from trolley circuits. Only one motor at a time can enter a single-track line. Signals reduce waiting time at sidings, making faster and more effic haulage. Manual operation involves opening and closing the circuits by hand; automatic systems are usually operated by relays, receiving current by the passage of the trolley wheel or glider (see also Sec 11, 23).

Rock-dust distributers of various sizes and capacities are available. Fig 15 is an example. One type has a 20-hp motor, with push-button control, which drives feed screw, agitator, and a high pressure blower capable of distributing 60–100 lb of dust per minute through 500 ft of 3-in hose, or through a fan-shaped nozzle. A recent design has 2 motors, one driving the blower, the other the agitator and feed screws. Rock dust distributers are not self propelling, but are usually moved by a cable-reel or storage-battery locomotive; or the distributer can be connected direct to the trolley wire with a trolley tap and rail clamp. For the general subject of rock-dusting see Sec 23.

Photo-electric cells (electric eyes) and relays are applied in and about mines to promote safety and efficiency by automatic control or operation of equipment for: (*a*) opening and closing of doors for passage of locomotives and cars; (*b*) throwing of track switches; (*c*) operating block-signal systems that protect main-line haulage; (*d*) giving warning of approach of locomotives and cars; (*e*) counting cars in trips; (*f*) checking number of men entering or leaving mines; (*g*) insuring proper spotting of mine cars on cages; (*h*) weighing cleaning plant rejected material.

Methane detectors use the Wheatstone bridge principle of measuring elec resistance, to indicate the amount of methane present in mine atmos by measuring the change in resistance of a heated platinum filament. A miner's cap-lamp battery or dry cells supply the current for operating these devices (for details, see Sec 23).

Mine fan signal systems. One device consists of a contact attachment to the fan shaft, which interrupts a circuit to one or more incandescent lamps. The rate of flickering gives a visual indication of the fan speed. Another device employs an air vane in the fan housing. When the fan stops, or the speed drops too low, the decrease in air pressure causes the vane to drop and close contacts to complete the circuit to an audible signal. A propeller-driven generator is connected to a voltmeter, with scale calibrated in rpm.

16. TYPES OF ELECTRIC MOTORS FOR MINE SERVICE

The following tables of sizes and prices of motors are condensed from catalogues of the General Electric Co, dated Jan 1, 1939. Prices of other makers correspond closely with these tabulations.

a, Type K only. *b*, Type KF only. *c*, for Type K; $338 for Type KF. *Motor only.

Explosion-proof motors for hazardous gas conditions are tested and listed by the Underwriters' Laboratories, and must be specified for this service, that they may bear the Underwriters' Label which indicates factory inspection by Underwriters' representatives.

The motors listed in Tables 10 and 11 are in quite general use. In ordering, consult the General Electric Co's catalogue of Jan 1, 1939, which also contains details of the starting devices, both manual and magnetic.

For mine service, the use of these motors is usually limited to sizes larger than 25 hp.

All are open-type, 60-cycle, polyphase motors, rated 40 C, when operated on 50 cycles at listed voltages, will operate without injurious heating, not exceeding 50 C rise; sixty-cycle horsepower ratings and prices apply; synchronous speeds will be 5/6 of those at 60 cycles. * Motor only.

Table 13 lists synchronous motors, which have limited application where power factor correction is required. Usually in mines, synchronous motor-generator sets are employed for this purpose. To increase their use, rotaries or rectifiers may be advantageous.

Direct-current, constant speed motors are widely employed for operating coal-cutters, underground mechanical conveyers and loaders. Sizes smaller than those listed in Table 14 (from $^1/_{20}$ hp to $7^1/_2$ hp) are also made and are useful for general service.

The foregoing tables of different types and sizes of elec motors, with their list prices, are intended to be illustrative only, in aiding engineers to make preliminary estimates of mine plant. As already stated, sizes having other horsepowers, speeds and voltage are also manufactured.

Besides the types listed in the tables, there are variable-speed motors, geared motors, induction motor-generator sets, and direct-current generators and exciters, most of which have rather limited fields of use for mine service. For information regarding them, apply to the makers.

LEVELING AND CONTOURS

TOPOGRAPHIC, AERIAL, MINERAL AND RAILROAD SURVEYING

SURVEYING AND DRAFTING INSTRUMENTS

1. TAPES AND RODS

Steel tapes are commonly 25, 50, 75, 100, 200, 300, or 500 ft long. To 100 ft, they are usually thin steel ribbons; the longer tapes are thicker and narrower, to lessen liability of kinking and to stand rougher usage. The lighter tapes are graduated throughout in feet, tenths, and hundredths; the heavier are usually marked by notched sleeves, etchings, or brass rivets at every 1-, 5-, 10-, or 20-ft point, with last foot on each end divided into tenths or hundredths. When 5-, 10-, or 20-ft points alone are marked, the last 5, 10, or 20 ft is usually graduated at every foot.

Some 200 or 300-ft tapes are made 201 ft or 301 ft long, the added foot graduated into tenths or hundredths. In most lighter tapes the zero-point is at end of ring, in some at the end of the steel ribbon, while in others it is 0.2 or 0.3 ft from end. The heavier tapes have a handle for each end, the zero and other end of the graduations then being marked on the ribbon. Bronze tapes are made for use in wet places, such as mines. Metric tapes are in lengths of 10, 15, 20, 25, 30, and 50 m; many being graduated in feet and inches on reverse side. Common lengths of light metric tapes are 15 and 30 m, the heavier, 25, 50 and 100 m long. Most long tapes are on reels, which should be of ample size, for a wet and dirty tape fills a larger reel than a clean one, and long tapes for surface surveying at mines are also often used underground, where they become wet and dirty. INVAR TAPES are for very accurate work. Due to temperature changes, their length changes only about 1/25 as much as ordinary steel tape. U S Gov't uses 15 kg tension for 50-meter Invar tapes. They are not made at present in the U S, but 100-ft Invar tapes are obtainable.

Steel tapes fitted with thermometer for temperature corrections, and with spring balance handle for measuring amount of pull, are used chiefly in city surveying. Broken tapes can be mended by riveting on back of tape a piece of old tape of same width; complete tape-mending kits are sold for this purpose. Tapes graduated in feet and inches are used particularly in building construction.

Cloth and metallic tapes are common; the former stretch readily and are useless for surveying. A metallic tape is of cloth with fine brass wires woven into it to prevent stretching. These are usually graduated into feet, tenths, and half-tenths, and made in lengths of 25 to 100 ft; sometimes with feet divided into inches. A 50-ft metallic tape may be in error as much as 0.5 ft, owing to rough usage and alternate wetting and drying; hence it should be used only for rough work.

The cost of a 100-ft tape and box is from \$5 to \$20. The heavier tapes, exclusive of reels, cost \$5 to \$12 per 100 ft, and can be obtained up to 1 000 ft; the ordinary reels for long tapes cost \$3 to \$20; certain special reels for mine surveying cost as high as \$25. Metallic tapes 50 ft long cost \$3 to \$4. Bronze tapes are a little more expensive than ordinary steel tapes.

Pocket steel tapes from 3 ft up are for accurate measuring when long tapes, marked only at the 5-, 10-, or 20-ft points, are used. Lengths: 3, 5, 6, 8, 10 ft; 1, 1.5, 2, 2.5 meters. To CONVERT MEASUREMENTS recorded in tenths and hundredths of a foot into inches and fractions, the following equivalents may be used:

Decimal of foot	= 0.01	0.08	0.17	0.25	0.50	0.75
Inches	= 1/8 −	1 −	2 +	3	6	9

If these values are memorized, decimals of a foot may be quickly transposed into inches, for example: 0.72 ft = 0.75 ft − 0.03 ft = 9 in − 3/8 in = 8 5/8 in.

Odometer is an instrument attached to a wheel of a vehicle, to record number of revolutions made by wheel in traversing between two points; rev × circumf = distance.

Pedometer is an instrument to record the distance traversed by a person carrying it; it is adjustable for different lengths of pace.

Stadia method of measuring distance (see Art 22).

Leveling rods are of two types, TARGET and SELF-READING; former is read by rodman, latter by levelman. Commonest forms of target rods are the Boston, the New York, and the Philadelphia; the Philadelphia can be used also as a self-reading rod (Fig 1). Most rods are made of 2 or more sections, so that they may be extended. Target of Boston rod is permanently fastened to one strip of the rod; this requires that for readings higher

than the unextended rod the rod must be inverted, which introduces an error if foot of rod is worn so that the target is not in correct place with reference to the zero of vernier scale. The other target rods are always used right-side up and have movable targets. The New York rod has a vernier for reading to a thousandth of a foot (Art 2); most Philadelphia rods have a scale resembling a vernier, which gives the hundredths and makes it easy to estimate thousandths, thus serving every purpose of a vernier. All these rods are usually 6 or 7.5 ft long and are extensible for readings up to 11 or 13 ft. They are also made 3 ft long, with extension to 5 ft, and 5 ft long with extension to 9 ft, for use underground.

A self-reading rod has graduations (usually every hundredth of a foot) painted on its face, so that it can be read through telescope by the levelman. The figures and graduations on face of rod are usually of a definite pattern, thus aiding levelman to read hundredths and estimate half-hundredths of a foot. Self-reading rod for ordinary work has many advantages over target rod. A rod equipped with clamps having screw-heads, which lie close to rod and are protected by a metal guard, is preferable to a rod with outstanding screws, especially if rod is to be shipped from place to place. Ordinary leveling rods cost $10 to $20.

One-piece 12-ft rods are accurate and cheap, but not readily portable. They have hardwood edges, extending slightly beyond face of rod, to protect edges and face.

Stadia (or telemeter) **rods** are usually of soft pine, with a face 3 to 4 in wide, on which distinctive diagrams are painted, to be clearly distinguished at distances of 1 000 ft or more. For stadia sights not greater than 300 ft, the ordinary Philadelphia rod is suitable; for sights up to about 600 ft, either the first or second rod shown in Fig 2 is suitable; for longer sights the third rod in Fig 2 is best. Many surveyors make their own stadia rods, because those sold have too narrow a face, with too many figures and graduations, and are not marked with clear, distinctively shaped diagrams. For ease in transportation, stadia rods are frequently in two parts, hinged at about the 7-ft mark; if hinged, it is well to provide a hard-wood cleat for back of rod, to strengthen hinged joint. In Fig 2 two of the rods have cross-hairs marked on them, to show how they are read (Art 22 and 23).

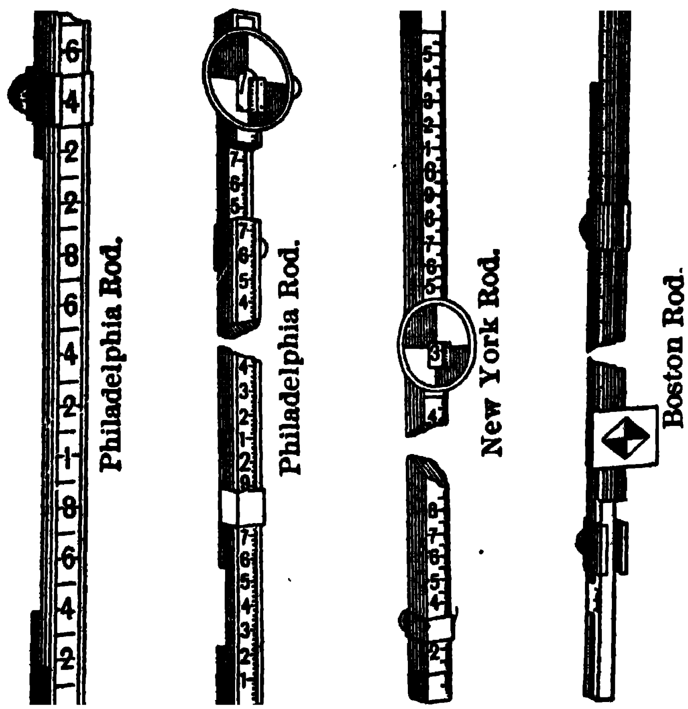

Fig 1. Leveling Rods

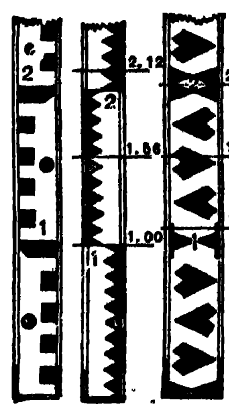

Fig 2. Stadia Rods

2. VERNIERS

Vernier is used for determining fractional part of smallest division of a scale more accurately than it can be estimated by eye. The simplest form (used on some leveling rods) is shown in Fig 3, where one unit on rod is divided into 10 equal parts. The entire length of vernier equals space occupied by 9 divisions of scale; if then the vernier length be subdivided into 10 equal parts, one division on vernier will be $^9/_{10}$ as large as one division on scale. If the index (zero-point of vernier) in Fig 3 is at 3 on the scale, then distance

ab must be $^1/_{10}$ of one of scale divisions, and *cd* is $^2/_{10}$ of a scale division. If vernier be raised until *a* comes opposite *b*, then reading will be 301; if *c* comes opposite *d*, the reading is 302. Hence, in the case of a decimal vernier, the number of that line on vernier which coincides with any line on scale gives the number of tenths of the smallest division on scale by which the index point lies beyond the last preceding scale division. For example, reading at right of Fig 3 is 326.

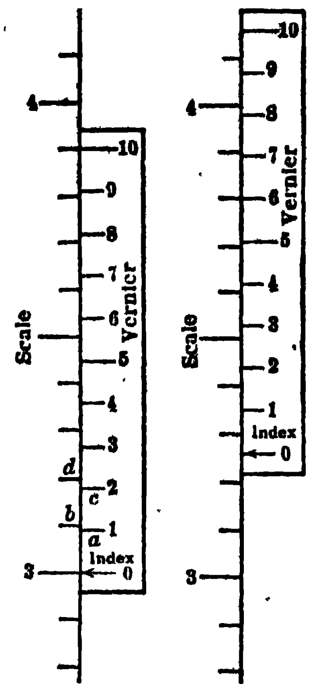

Fig 3. Leveling Rod Vernier

Transit verniers are usually double, one on each side of the index, so that angles can be measured either clockwise or counter-clockwise. Against the horiz circle of ordinary transit there are usually four verniers, in pairs (Art 4). A 1-min instrument has its horiz circle divided in half-degrees and there are 30 divisions on the vernier; a 30-sec instrument has circle divided to 20 min, with 40 divisions on vernier; a 20-sec instrument has circle divided to 20 min, with 60 divisions on vernier; and a 10-sec instrument has circle divided to 10 min, with 60 divisions on vernier.

The vernier of a 1-min instrument is constructed by dividing into 30 equal parts the space occupied by 29 half-degrees on circle; the difference between one division on circle and one of vernier is therefore 1 min of arc. A pair of verniers is thus constructed on both sides of a zero-point (or index). If the pair of verniers is then placed so that their common zero-point coincides with one of the divisions, say 0° point on circle, then the 30-min line on each vernier will also coincide with the 14° 30′ line on circle, and the first lines on either side of zero of vernier will fail to coincide with the corresponding lines on circle by 1 min, the second line on either side of the zero of the vernier will fail to coincide with its nearest mark on circle by 2 min, and so on. If now the vernier be moved so that the next line to its zero-point coincides with its nearest line on circle, one vernier will read 1 min and the other 29 min; and the reading will be either 0° 01′ or 359° 59′, depending upon whether angle is read clockwise or counter-clockwise. Therefore, to read an angle on a transit, note the last division on circle beyond which vernier index has passed; then follow along vernier in same direction to the first line which coincides with any line on circle, and add the number of this line to circle reading. Thus, Fig 4 represents a 1-min horiz circle with double vernier, which reads (remembering that it is the vernier that moves) 350° 44′ clockwise, or 9° 16′ counter-clockwise.

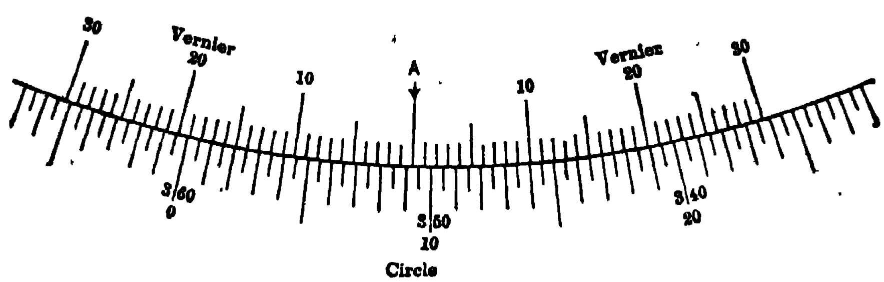

Fig 4. Horizontal Circle, with Double Vernier

Single verniers are used with the horiz circle of some instruments, on which a double vernier would be in the way of the telescope standards; for example, on a 20-sec transit a single vernier corresponds in length to about 20° of arc. A single vernier has two zero-points, one at each end, and is numbered to read from either end. To measure an angle, one or other vernier index-point is set at 0° of the circle, depending upon the direction in which angle is to be measured.

Folded vernier is a short, single vernier, sometimes used with vert circles of transits and plane tables. It is designed to shorten the single vernier to half its ordinary length, so that it can be placed between legs of the standards. The index point is the middle division; the numbering goes from middle to left end, and then begins again at right end and runs to middle. Similar numbers run in reverse direction, starting at middle and running to right. In reading such a vernier, if a coincidence is not reached between middle and farther end, return to the other end of vernier and continue in same direction, toward the center, until coincidence is found.

Retrograde verniers are those in which vernier divisions are longer than circle divisions. They are found only on old surveying instruments. In the ordinary verniers described above, a vernier division is always smaller than a circle division; these are called DIRECT VERNIERS.

3. THE COMPASS

Surveyor's compass is used to determine the MAGNETIC BEARING of a line, that is, the horizontal angle between the line and a magnetic needle. The needle is balanced on a pivot in center of a circular box, the edge of which is usually graduated in half-degrees and is numbered from 0° to 90° in both directions from N and S ends of compass-box; the needle swings freely in a horiz plane. Attached to the compass-box, in exact line with its N and S points, are two vert sights (sometimes a telescope) used for pointing the instrument. The compass is connected to a tripod by ball-and-socket joint, which is clamped after instrument has been made horiz by two spirit levels attached to frame. The frame has a spindle which fits into the ball-and-socket joint, so that after instrument has been leveled it can be swung around in a horiz plane. A small counterweight is attached to S end of needle (in the northern hemisphere) to prevent needle from dipping and thus rubbing against glass top of compass-box. For compasses used in mines, and their limitations, see Sec 18, Art 4.

To use the compass, first set it up at the point, level it, let the needle down on its pivot, then point the sights along the line of which the bearing is required. Since the needle points north, and the box turns under it, the letters E and W on the box are commonly reversed from their natural position so that the reading of needle will give the proper quadrant directly. The BEARING of a line, sometimes called the FORWARD BEARING, is the angle it makes with needle when looking along line AB from A toward B. The bearing of same line, looking from B toward A, is called the REVERSE BEARING. To obtain the bearing of a line, always read N end of the needle if N end of the box is toward the station of which the bearing is desired; when S end of box is toward that station, read S end of needle (the one to which counterbalance is attached in the northern hemisphere). If wrong end of needle be read, the bearing noted will be the reverse bearing. For difference between MAGNETIC and TRUE BEARING see Art 10.

Precautions. When not in use, needle should be kept raised from pivot by the screw and lever provided for that purpose, to avoid dulling pivot-point. Before reading bearing, be sure the needle has been let down on its pivot, and tap the glass lightly over end of needle, to be sure it is not touching under side of glass. If needle appears to cling to the cover, the glass has probably become electrified; that can be corrected by placing a moistened finger on the glass. The clinging of the needle to the glass may also be due to carelessness in leveling the compass, to loss of magnetism, or to shifting of counterweight. In using compass, take care that no iron or steel is near instrument, to attract needle from true position. (Steel tape, pins, ax, pocket-knife, or steel in eyeglass frames are sources of error.) Electric currents affect needle so seriously that a compass is of little use in cities, or in underground elec haulage ways, for obtaining even an approx magnetic meridian. Some compasses have a movable inner circle, on which the declination can be laid off; care should be taken that this circle is set at 0° if declination is not to be laid off (Art 10).

It is good practice to take both forward and reverse bearings of all important lines, because of liability of needle to be deflected from magnetic meridian by presence of ferruginous rocks or other iron material; this deflection is called LOCAL ATTRACTION. If the bearing of AB, taken from Sta A, and the bearing of BA, from Sta B, do not agree, local attraction exists at either A or B. To determine at which station it is present, take bearing of BC with compass at B, and then with compass at C determine bearing of CB. If these agree, local attraction is indicated at A but not at B.

Adjustments of compass. (*a*) The bubbles are adjusted in same manner as those on horiz plate of a transit (Art 4). (*b*) Straightening needle and centering pivot-point, the need for which is detected by noting whether S end reads 180° from N end; failure to do so may be due to a bent needle or a bent pivot-point, or both. A bend in needle may be detected by reading S end of needle when N end points at some selected graduation, and then reading N end when S end points at same graduation. Bend the needle at the middle, where metal is soft, until ends read the same in either position (though not necessarily reading 180° apart at either trial). The pivot may be centered by finding (by trial) the position of max difference between end readings in different parts of circle and bending pivot until any two end readings agree. (*c*) Re-magnetizing the needle; by rubbing it with a bar magnet from middle outward to ends, applying N end of magnet for the S end of needle, and *vice versa.*

The pocket compass is a hand instrument for obtaining roughly the bearing of a line. There are two kinds, PLAIN and PRISMATIC. Former is much like surveyor's compass, except that it usually has no sights. In prismatic compass the graduations, instead of being on compass-box, may be on a card fastened to needle (like a mariner's compass) and moving with it. This compass is generally provided with sights; bearing is read by

means of a prism, or folding mirror, at same instant that compass is sighted along line. Pocket compasses for surveying range in price from $10 to $60, the latter being small, delicately constructed compasses, to carry in pocket for use with a tripod. The ordinary surveyor's compass costs from $25 to $75, including tripod.

In using the **Brunton pocket transit**, the observer sees simultaneously the compass and the object sighted. This is accomplished by a hinged mirror, which reflects the line of sight upward, toward observer. A CLINOMETER (Art 5) is attached, for measuring the inclination of line of sight.

4. TRANSIT AND ITS ADJUSTMENTS

Engineer's transit (sectional view, Fig 5) has two spindles, one fitting inside the other, to each of which is fastened a horiz circular plate; the outer spindle is attached to lower plate, on which is a graduated circle, and inner spindle carries upper plate, to which the verniers and standards holding telescope are attached. The motion of these horiz plates is controlled by clamps and tangent screws. On upper plate are two spirit-levels; the plates are leveled by 4 (sometimes 3) leveling screws, working between base and lower plate. Transits having telescope bubble and vert arc are called ENGINEER'S (OR SURVEYOR'S) TRANSITS; a plain transit lacks these attachments.

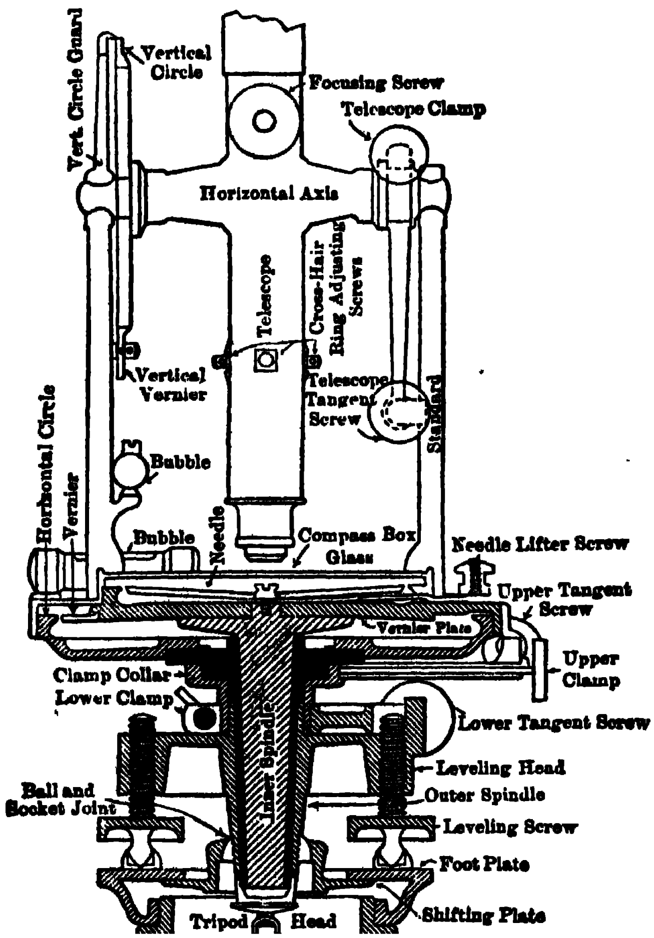

Fig 5. Engineer's Transit (Sectional View)

Telescope has a compound objective, and an eye-piece composed of 4 lenses, if instrument is an erecting transit, two lenses if inverting; an inverting instrument gives much better illuminated field. Between objective and eye-piece is the cross-hair ring, held in its concentric position by four opposing screws tapped into the ring, the heads being outside the telescope tube.

Special attachments are: (*a*) Dark eye-piece for observing sun. (*b*) Diagonal or prismatic eye-piece for sighting high altitudes. (*c*) Reflector attached to telescope for illuminating cross-hairs when working in dark. (*d*) Gradienter screw for measuring rates of grade directly. (*e*) Stadia hairs, which are two extra horiz cross-hairs for measuring distances by stadia. (*f*) Solar attachment for determining meridian by observation on the sun.

Precautions in care of transit. Neither tripod legs nor their shoes should be allowed to become loose. In taking instrument out of its box, always lift it by placing the hands beneath leveling base. When about to move transit from one point to another, be sure that the 4 leveling screws are properly bearing, that needle is lifted, and that clamps are set just firmly enough so that any slight shock will allow motion. Carry a waterproof bag at all times to protect instrument from rain or dust. When transit must stand out in rain, the cap should be put over object glass and eye-piece closed; if water gets into telescope, take out eye-piece, cover open end of the telescope tube with a cloth, and allow it to dry out. Any parts that have been wet should be wiped dry, especially vert arc, but be careful not to touch edges of arcs; always avoid placing the hands on exposed graduations, as they will tarnish the metal. In cleaning lenses, use fine camel-hair brush; for screw threads, use stiff toothbrush and apply a very little watch oil after cleaning, wiping

off exposed screws after oiling. Carry transit in a box when traveling on a vehicle. When shipping, always enclose transit in its case, with all clamps tightened, pack paper about it, and enclose case in another box packed with excelsior. Cover tripod threads with wooden or metal cap when shipping.

Adjustments of the transit are: (*a*) to make plane of plate bubbles perpendicular to vert axis of instrument; (*b*) to make line of sight perpendicular to horiz axis; (*c*) to make horiz axis perpendicular to vert axis of instrument.

(*a*) **Bubble tubes.** Bring plate bubbles to centers of respective tubes by turning leveling screws. Turn 180° and correct half of apparent error by turning capstan screws of bubble tubes. Adjust each bubble independently.

(*b*) **Line of sight.** First, adjust vert cross-hair to lie in plane perpendicular to horiz axis. Set up and level the instrument. Sight the vert hair on a well-defined point, clamp both plates, and move telescope up and down. If the point does not appear to travel along vert cross-hair, loosen screws holding cross-hair ring, and by tapping lightly on one screw, rotate ring until above condition is fulfilled. Then tighten screws and proceed with second part of adjustment as follows: Sight telescope at point A (200 to 300 ft away), and clamp vert axis; invert telescope on its horiz axis and set a point B at about same elev as A, in line of sight, and about same distance from instrument as A. Loosen clamp, turn horizontally and sight A again; clamp horiz motion, invert telescope on horiz axis and if line of sight falls on B it is in adjustment. If not, set point C in line of sight beside point B. Mark or note a point D one-fourth the distance between C and B, measured from C. To adjust, move cross-hair ring until D is intersected, by loosening screw on one side of telescope and tightening opposite one. If transit has an erecting eye-piece, move ring in direction D to C; if an inverting eye-piece, move ring in direction C to D.

(*c*) **Telescope standards.** Set up and level the transit. Sight on some high point A and clamp vert axis. Lower the telescope and set point B in line of sight about level with telescope. Reverse telescope, turn instrument 180° horizontally, sight again on A and clamp. Lower telescope until point B is visible, and mark point C in line of sight and at same height as B. If C does not fall on B, raise or lower adjustable end of horiz axis by the capstan-headed screw under it. Bring adjusting screw into position by a right-hand turn; otherwise the block on which horiz axis rests may stick and not follow the screw. Then tighten capstan screws just enough to avoid looseness of the bearing.

If an instrument is badly out of adjustment, it is better to bring it gradually into adjustment as a whole, rather than to attempt to adjust completely one part at a time. Then the adjustment of one part will not disturb preceding adjustments, parts are not subjected to strains, and instrument will remain longer in adjustment.

Telescope bubble (see "peg" adjustment, explained in Art 5).

Vernier of the vert circle should read 0° when telescope bubble is in center of its tube. If not, loosen screws holding vernier and tap lightly until the zeros coincide. This adjustment eliminates what is called the INDEX ERROR in measuring vert angles, provided line of sight is in adjustment parallel to bubble tube.

Objective slide should move parallel to line of sight. Adjust line of sight as described under (*b*) above, but use very distant objects; then repeat same adjustment using points close by; if an error is observed in this last test, it indicates that the objective slide does not move parallel to line of sight. Adjustment is made by moving adjusting screws of objective slide apparently to increase the error by one-quarter of observed error. Then test adjustment of line of sight again on distant points. The adjustments of objective slide, centering eye-piece tube, and centering the circles, are usually done by instrument makers.

To eliminate effects of errors in adjustment, so as to obtain accurate results, the instrument must be used as follows: To avoid errors in plate bubbles, turn 180° horizontally and bring bubbles half-way back to the middle by the leveling screws. Errors in line of sight and horiz axis are avoided by sighting telescope first in its direct and then in its reversed position, and taking the mean of the results, when running lines or measuring angles. Errors of eccentricity are eliminated by taking mean of readings of two opposite verniers, and errors of graduation of the circle are nearly eliminated by reading the angle in different parts of circle or by measuring the angle by repetition. When only one vernier is read in determining an angle, take care to read the one that was set at 0°.

Transits cost from $125 to $500. They weigh 5 to 15 lb, exclusive of tripods, which weigh 7 to 12 lb. Accurate results can be obtained with the lighter transits having 3 1/2- to 4 1/2-in horiz circle. It is advisable not to use too light a tripod with light-weight instruments, on account of wind. Stiff-leg tripods cost $15 to $25 and extension-leg tripods, $20 to $35.

5. THE LEVEL AND ITS ADJUSTMENTS

Engineer's level is a telescope to which a delicate spirit-level is attached parallel to line of sight, so that, when bubble is in center, the line of sight is horiz. The two common types are the Y- and the dumpy-levels. In both the telescope is mounted on a vert axis, about which telescope can swing horizontally, and is leveled by 4 leveling screws.

Y-level has its spirit-level attached to telescope, which rests in two Y-shaped supports, fastened to a horiz bar rigidly connected to vert axis. The telescope can be taken out of the Ys, turned end for end, and replaced, when testing bubble for adjustment.

Dumpy-level has its vert axis, horiz bar, and supports for telescope, all cast in one piece, to which spirit-level is attached. The dumpy-level will stand much rougher usage than the Y-level, has fewer wearing parts, and permits fully as precise work. Practically the only advantage the Y-level has over dumpy-level is that the adjustment of line of sight can be a little more conveniently tested.

Locke hand level is a metal tube with plain glass covers at ends and a small spirit-level on top. When looking through the tube an image of the bubble is seen in one-half of tube, being reflected by a prism. In other half of tube, the landscape is viewed. When bubble is in center, the observer can note where the horiz line, which appears in center of bubble tube, cuts a leveling rod (Art 19).

Clinometer is similar to a hand level, except that the bubble is attached to an arm, free to move in a vert plane; used for measuring slopes by sighting telescope along inclined line, moving the arc until bubble is centered, and then reading angle of inclination.

Adjustments of the Y-level are: (*a*) To make horiz cross-hair truly horiz and to make line of sight coincide with axis of the pivots, or be parallel to it; (*b*) to make line of sight and axis of bubble tube parallel; (*c*) to make axis of bubble tube perpendicular to vert axis.

(*a*) **Line of sight.** First make horiz cross-hair horiz, when instrument is level. This is tested after leveling, by sighting on a point and noting whether the cross-hair appears to remain on the point, as telescope is slowly rotated on its vert axis. Adjustment is made, if necessary, by rotating the cross-hair ring, as described under second adjustment of transit. When this is done, loosen clips which hold telescope in the Ys. Set a fine mark on a wall in the intersection of the cross-hairs, and clamp the vert axis. Rotate telescope 180° about its own axis. Correct half apparent error by the screws of cross-hair ring, adjusting first one hair and then the other.

(*b*) **Bubble adjustment by indirect method.** Bring bubble to center of its tube and clamp vert axis. Rotate telescope in the Ys a few degrees on its horiz axis; if bubble moves, correct entire error by the capstan screws at one end of bubble tube. Then clamp telescope over a pair of leveling screws and bring bubble into center of tube; lift telescope from Ys, turn it end for end, and replace in Ys without jarring the instrument. Correct half apparent error by the vert adjusting screw of bubble tube.

(*c*) **Adjustment of Ys.** Level the instrument, then bring bubble exactly to middle, over a pair of leveling screws. Turn telescope 180° on its vert axis and correct half apparent error by adjusting screw of the Y support. Since the bubble is brought to center of tube at each reading of the rod, this last adjustment in no way affects accuracy of leveling, but is a convenience.

Adjustments of dumpy-level are the same in purpose as for Y-level, but are, owing to construction of instrument, done in a different order and in some cases by different procedure. They are: (*a*) to make horiz cross-hair truly horiz when instrument is level; (*b*) to make axis of bubble tube perpendicular to vert axis; (*c*) to make line of sight parallel to axis of bubble.

(*a*) **Cross-hairs** are adjusted as described in paragraph *a* above.

(*b*) **Bubble tube.** Level the instrument and carefully center the bubble over a pair of leveling screws. Turn telescope 180° horizontally and correct half apparent error in the bubble by adjusting screws of level tube.

(*c*) **Line of sight by direct or "peg" method.** Select points *A* and *B*, 200 ft or more apart. Set up level beside *A*, so that when a rod is held on *A* the eye-piece will just clear the rod. Look through the large end of telescope at the rod and take reading opposite center of field of sight. Point telescope toward *B* and read the rod in usual manner, being sure that bubble is in the middle of tube. Then set up level at *B* and repeat above operation. These observations give two independent determinations of difference in elev between the two points; the true difference in elev is the mean of the two differences. (Same result can be obtained from a single setting of level, at a point exactly midway between *A* and *B*.) Leaving instrument at *B*, set rod at *A*, with target set to read height of instrument above *B*, plus or minus the true difference in elev between *A* and *B*. If line of sight is then brought to intersect the rod target, it will define a level line. The bubble being in center

of its tube, the line of sight is now brought to intersect target by moving cross-hair ring by its adjusting screws. Example:

Instrument at Sta A		Instrument at Sta B	
Rod reading on Sta A	= 4.243	Rod reading on Sta B	= 4.618
Rod reading on Sta B	= 5.724	Rod reading on Sta A	= 3.177
Diff in elev of A and B	= 1.481	Diff in elev of B and A	= 1.441

Mean of two differences = $^1/_2$ (1.481 + 1.441) = 1.461, the true difference in elev.

Instrument at B is now 4.618 above the station. Rod reading on Sta A should be 4.618 − 1.461 = 3.157, to give a level sight.

This peg adjustment may be applied to line of sight of the Y-level, except that in this case, after target at A has been set at correct elev to define a level line, the line of sight is made to bisect target by the leveling screws and then bubble is brought to mid-position by its adjusting screws. This method is also used for adjusting the hand level. In applying it for transits, the adjustment may be made by moving either cross-hair ring or one end of level tube. If cross-hair is moved, the adjustment of line of collimation must be tested; if bubble tube is moved, the vert arc vernier must be adjusted.

To eliminate effect of errors, in adjustment of line of sight of bubble tube, or of the Ys, the observer must be sure that bubble is in center of tube at instant rod is read, and that backsights and foresights are about equal in length.

Precise levels, designed for running long lines of bench levels, are usually equipped with three leveling screws, an inverting telescope of high power, stadia hairs, very sensitive bubble to be read by a mirror simultaneously with the rod, and a slow-motion screw for leveling (Art 18).

Leveling instruments cost from $100 (architect's levels, with horiz circle) to $250; precise levels cost from $400 upward; hand levels, about $8.

6. DRAFTING INSTRUMENTS

Only a few of the more uncommon drafting instruments are here described.

Planimeter is for determining area of an irregular plane figure. The method is to follow perimeter of figure with the tracing point of planimeter, reading recording wheel at beginning and end of process; the difference in readings gives area expressed in a certain unit. They are also called integrators.

Amsler polar planimeter, the most common form, has two arms, one of fixed length and the other adjustable, the length of latter being set to give any desired unit of measurement, as indicated by scale marked on arm by maker. At end of fixed arm is a weighted needle point, called the anchor point, which is pressed into the paper to hold instrument in a fixed position. The tracing point is at end of adjustable arm. The planimeter thus rests on three points, anchor point, tracer, and recording wheel. To measure an area, press anchor point into the paper outside area to be measured, and in such position that the tracer can follow around entire perimeter of area. Before proceeding further, run tracer around perimeter and note whether recording wheel, during this process, runs over any creased or irregular part of drawing paper; if so, change position of anchor to avoid it. Start tracer from a definite point in perimeter, preferably such a point that the two arms will be about at right angles to each other. Read the scales on disk, wheel, and vernier, obtaining four digits in the reading, the first from the disk, the next two from wheel, and the fourth from vernier. Move tracer carefully around perimeter until starting point is reached, when the disk, wheel, and vernier scales are again read. The difference of the two readings gives area in the unit at which length of adjustable arm is set. Check the area by another determination, with anchor point in some other position, so that recording wheel will travel over a different path on the paper; for in its first trip there might have been some irregularity in paper, or dirt on it, which caused wheel to slip and not accurately record all the path over which it traveled. If unit of measurement recorded by planimeter is unknown, find it by running planimeter around any known area. If area is so large that anchor point can not be set outside its limits, divide it into segments, determining area of each separately; or anchor may be placed inside the area, provided the area of a CORRECTION CIRCLE is added to result, which value is given by maker. Results correct to within 1% may easily be obtained with this instrument.

Some planimeters are made with both arms of fixed length, thereby giving all results in one unit. These cost $15 to $30, whereas those with adjustable arm cost from $30 to $60.

Rolling planimeter has a tracing point at end of an adjustable pivoted arm, which is fastened to a frame supported on two rollers. The whole instrument is rolled forward and backward in a straight line, while the tracing point traverses outline of area. A precision within 0.1% is easily reached with this instrument, provided corrections are

made to allow for shrinkage or swelling of drawing paper which may have occurred after drawing was made. These instruments cost $125 to $175.

Pantograph is an instrument for copying a plan to the same or a different scale; used principally for enlarging or reducing a plan having many irregular lines, such as a topographic map with contours. It is a jointed framework of several pieces of wood or metal, assembled to form a parallelogram. It rests upon three points, one of which, *A*, is fixed, while the other two, *B* and *C*, are movable. There are other bearing points, but they simply support the instrument and are not essential to its principle. The two movable points *B* and *C* are in such positions that they will trace exactly similar figures and by varying position of these points on their respective arms, the relative scales of the figures traced by them can be adjusted. The essential condition which the instrument must fulfil before it is ready for use is that *A*, *B*, and *C* shall lie in a straight line, and that each point shall be attached to one of three different sides (or sides produced) of the parallelogram. Any one of the three points can be the fixed point. These instruments are usually provided with scales on the arms, indicating proper settings for various reductions or enlargements. Because of lost motion in joints, very accurate results can not, as a rule, be reached, but the best metal pantographs are sufficiently accurate for most topographical maps; more care must be taken in the use of the instrument for enlarging than for reducing. Cost ranges from $1 to $300; reliable work requires use of a pantograph costing $100 or more. An instrument called the EIDOGRAPH, costing about $125, has been made for the same purpose as a pantograph.

7. DRAWING AND BLUEPRINT PAPERS

Drawing papers for working plans are of all grades, from manila detail paper, at about 13¢ per yd, to well-seasoned, muslin-mounted paper, which is affected but slightly by changes in humidity, costing $2.00 to $5.00 per yd, depending on width and quality. Mounted paper comes in 10-, 20-, and 30-yd rolls, in widths of 36, 42, 58, 62, and 72 in. The best grades of drawing papers can also be obtained in sheets, either plain or mounted; common sizes: Demy, 15 by 20 in; Medium, 17 by 22; Royal, 19 by 24; Double Royal, 24 by 36; Imperial, 22 by 30; Double Elephant, 27 by 40; Antiquarian, 31 by 53 in.

Transparent paper is used largely for studies and for temporary copies of plans. For more permanent copies tracing cloth is used; there is a growing use of bond papers for permanent tracings. Tracing paper comes in sheets of same standard sizes as mounted paper; also in 10-, 20-, and 50-yd rolls and in widths 24, 27, 30, 36, 40, 42, 48, and 54 in, costing 5 to 25¢ per yd.

Tracing cloth is a uniform quality of finely woven linen, coated with a preparation to make it transparent. It is made in 24-yd rolls, in widths 30, 36, 42, 48, and 54 in, and costs $1 to $2.50 per yd. Most tracing cloth has to be rubbed with powdered chalk or specially prepared pumice before it will take ink. It has a smooth and a rough side; most draftsmen prefer the rough side, because it takes ink and pencil lines more readily, and will not show erasures so plainly, when process prints are made from it.

Cross-section and profile papers can be procured with colored lines, both on heavy paper and on transparent paper or cloth; also mounted on muslin or linen. Cross-section paper is printed in orange, green, red, and blue, in sheets 16 by 20 in, 17 by 22 in, 15 by 42 in, and 40 by 50 cm; also on smaller sheets called "coordinate paper," for rectangular or polar coordinates, and for logarithmic scale and isometric drawings. Cross-section papers are also made in 20- and 50-yd rolls with the engraving, 20, 24, and 30 in wide, and in metric units 50 cm and 75 cm wide. Profile papers are printed in green, orange, and red, in three scales, called Plates *A*, *B*, and *C*. *A* has 4 spaces horizontally to the inch and 20 vertically; *B*, 4 horizontally and 30 vertically; *C*, 5 horizontally and 25 vertically. These are mostly manufactured in 20- and 50-yd rolls, with the engraving 5, 9, 10, and 20 in wide, and cost 15 to 25¢ per yd on paper, 90¢ to $1.25 per yd mounted on cloth, and $1 to $1.35 per yd on tracing cloth.

Blueprint paper is the most common of process papers. It is a white paper, coated on one side with a solution which is sensitive to light. When fresh it has a yellowish green color; if it has a green, dark green, or blue color, it is old and will not give clear white lines. The more permanent blueprints are made on coated cloth. Good rag stock paper gives whiter lines than wood pulp paper.

Prepared blueprint paper and cloth is made in 10- and 50-yd rolls, in widths 24, 30, 36, 42, and 54 in; paper costs 15 to 25¢ and cloth 60¢ to $1.50 per yd, according to width.

In making a print, expose the tracing (with blueprint paper under it) in a printing frame a length of time depending on sensitiveness of paper and brilliancy of light. Then wash paper thoroughly in water, to remove all chemicals. Don't let the tracing become wet, for wet spots can not be eradicated from tracing cloth. In most large cities are concerns engaged in making blueprints,

supplying prints at from 3 to 5¢ per sq ft. Blueprints always shrink to a smaller size than the tracing; linear shrinkage usually varies from 0.5 to 2%, depending upon quality of paper. To write white lines on a blueprint, use solution of bicarb soda or Chinese white water color, applied with ordinary clean pen.

Brown process paper is a thin sensitized paper for making a NEGATIVE print from a tracing. The negative is then used to make prints having either blue or brown lines on white ground. This double process yields prints which are shrunk 2% or more from the original drawing. The process requires a bath in hyposulphite of soda, as well as a washing in water. Prints from brown process negatives can be made to produce lines almost as black and perfect as the original drawings. Negatives cost 5¢ per sq ft.

Direct black and white process prints give black lines on white background. Prints from this process do not shrink. Cost is about double the cost of blueprints. There is also a direct process blackprint paper and cloth, of German manufacture, used the same as blueprint paper. It requires washing in water only.

Photostat prints. Drawings are photographed on a sensitive paper, which is washed in fixing bath and dried. First print from an ink drawing on white paper has white lines on dark brown background. If this is again photographed, there will be brown lines on white background. The latter effect is obtainable directly from a blueprint by a first photograph. Most photostat machines reduce or enlarge only about 2 diameters; but the process can be repeated until the required scale is obtained. Since photostats shrink considerably and more or less unevenly in drying, a graphical scale should be put on the drawings. Cost of photostats, 7–10¢ per sq ft.

8. PLOTTING TRAVERSES

By protractor and scale. The courses of a traverse should be plotted by a more exact method than may be used for plotting details; but the latter can usually be plotted safely by protractor and scale. A closed traverse must necessarily close on the plan; any error of closure on plot therefore indicates error in scaling a distance or in laying off an angle. The bearing of any line of traverse can be computed from bearing of some other line, assumed to be correct, by means of the intermediate deflection angles; thus any line can be extended until it meets the plotted meridian, and its direction can be checked independently. Such checks are absolutely necessary if traverse is not a closed circuit.

Rectangular coordinate method is useful in plotting, especially when the area of a closed traverse has to be determined, because same computations required for finding the area can be used for plotting. First, compute latitude and departure of each course in traverse; then the total latitude and total departure (or longitude) of each point. N latitude and E departure are called plus, S latitude and W departure being minus (Art 12). If a meridian through the most westerly point and an east and west line through most southerly point be chosen for axes, there will be no negative coordinates. The total latitude of any point is the algebraic sum of all the latitudes of preceding courses, beginning with the most southerly point, and similarly for the total departure (or longitude), beginning with the most westerly point. In the case of a closed polygon, construct a rectangle of which the height equals difference in latitude of most northerly and southerly points, and the width equals difference in longitude of most westerly and easterly points. This rectangle should be plotted very accurately by straight-edge and reliable triangles, or constructed by beam compass, and checked by scaling the diagonals. To plot any point, lay off its total latitude on both the easterly and westerly sides of rectangle, measuring from southerly side; the point will lie on a line connecting these two points. Along this line scale off from westerly side of rectangle the total departure of the station, thus determining position of point. The other points are similarly plotted. To check a plot of this character, scale lengths of the traverse lines. Lines running nearly parallel to the axes should be checked by some other method, preferably the tangent method, explained below.

Fig 6 shows computations and coordinate method of plotting the same traverse of which the area is computed in Art 12; total latitudes and departures used in this plot are computed from balanced latitudes and departures in example in Art 12. Advantages of this method are: each point is plotted independently of others; all plotting is done by scale only; and plotting can be readily checked.

To apply the coordinate method of plotting to a traverse which does not close, draw two series of coordinate lines accurately spaced and intersecting at right angles; number these lines northward and eastward from origin of coordinates, the latter being chosen preferably at or beyond extreme southwest corner of traverse. Coordinates of the stations are computed from the unbalanced latitude differences and departures, and plotted as described above. In relatively unimportant work an unclosed traverse may sometimes be plotted by the chord or the tangent method, avoiding computation of coordinates.

Tangent method consists in laying off the deflections of a traverse by plotting the natural tangents of the angles. First compute bearings of all the courses on the basis of deflection angles. Then obtain algebraic sum of all the deflection angles, and add it to the bearing of first course; if result checks bearing of final course, the bearing computations are correct. Next plot the traverse roughly with scale and protractor, to determine its shape and extent; this is for purpose of starting first course on final drawing, at such point and direction that the drawing will be centered properly on the sheet. Then proceed to plot as follows (Fig 7). Draw through starting point A a line representing the meridian, in such manner that first course AB will run in desired direction. Construct a right triangle with A as the vertex, Ab the base, and cb the natural tangent of bearing of AB, measured in same unit as Ab; Ab should be of ample length, say 10 in, because from this base line the entire traverse is projected. Draw Ad through c and scale off AB. From Bd erect another perpendicular ef equal to tangent of the deflection angle at B, and then scale BC. Similarly plot courses CD, DE, and so on. Check every third or fourth course, as DE, by transferring the meridian to pass through D; then construct a right triangle Ddh, scale gh, and compare it with tangent of calculated bearing of DE. If error in bearing is 10 min or less, scale off on gh the tangent of calculated bearing, and draw DE through this new point, so that error in direction of DE will not be carried further along the traverse; if error found is greater than 10 min, repeat previous plotting, beginning at last checked course, and find error. A scale reading 10 ft to the inch is convenient for constructing legs of right triangles. When deflection angle much exceeds 45°, it is more accurate to plot the complement of deflection angle rather than angle itself, in which case a perpendicular is erected at station point and used as base of right triangle.

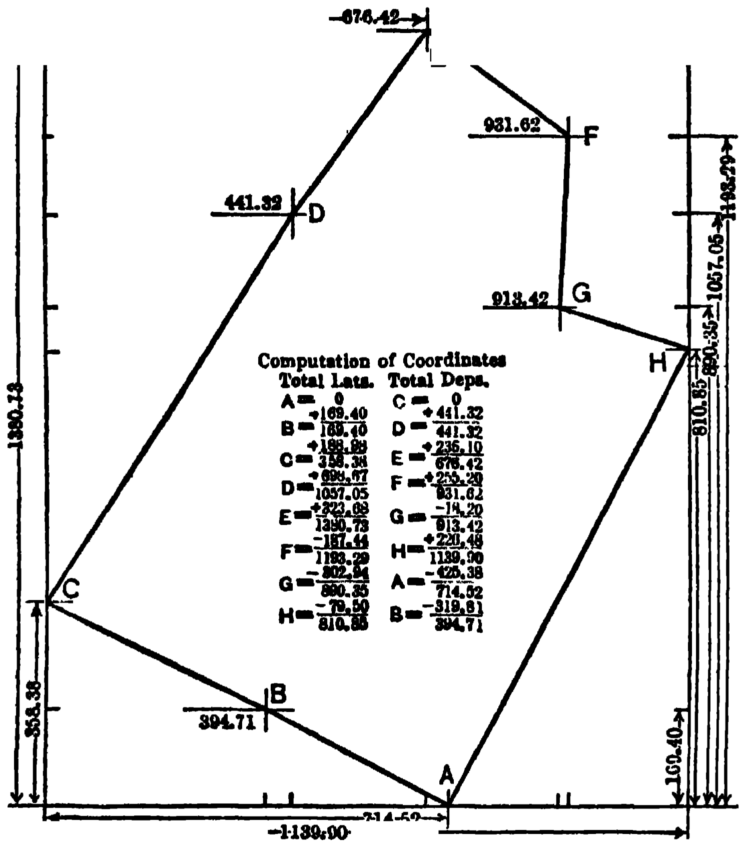

Fig 6. Coordinate Method of Plotting Closed Traverse

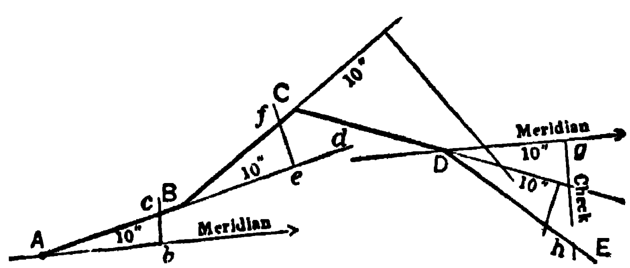

Fig 7. Tangent Method of Plotting Traverse

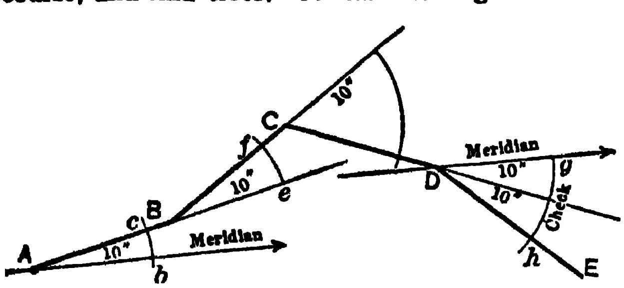

Fig 8. Chord Method of Plotting Traverse

Chord method consists in laying off deflection angles of a traverse by plotting chords of arcs which will subtend the angles. Fig 8 represents same traverse as Fig 7, but plotted here by chord method. Draw Ab representing meridian; draw bc with 10-in radius, and

scale from b the chord distance bc, which equals 10 times twice the sine of half of the deflection angle. Ac is drawn through c, and AB scaled. Then draw arc ef with 10-in radius, and plot deflection angle at B by scaling chord ef equal to 20 times the sine of half the angle, draw BC through f and scale BC. Similarly all of the angles are plotted. Check every third or fourth course, as DE, by transferring the meridian through D; draw arc gh, scale chord gh, divide it by 20 to obtain sine of angle; find the corresponding angle, double it, and obtain calculated bearing. If it is in error 10 min or less, correct it by plotting chord corresponding to calculated bearing, and draw DE in corrected position; if the error is greater than 10 min, re-plot and correct error. If deflection angle is greater than 90°, lay off 90° of it by a triangle and the rest by method of chords. In looking up twice the sine of half the angle, for plotting chords, the necessity for multiplying by 20 can be avoided by plotting natural sine of half the angle directly as a chord, with a scale of 10 ft to the inch, while the radius is measured with a 20-ft scale.

For maps of large areas, such as a state or a portion of a country, it is not sufficiently accurate to draw meridians and parallels of latitude as forming rectangles. The most common form of projection used is the POLYCONIC, in which the surface of a sphere representing the earth is developed on a series of cones tangent to parallels of latitude. In the U S Coast Survey, Special Publication No 5, is a table giving the x and y coordinates of points of intersection of meridians and parallels, for plotting parallels of latitude and meridian lines for this kind of projection.

9. FINISHING THE PLAN

Every plan should have a complete title written or lettered in pencil when drawing is begun, so that it can readily be identified. If plan is a land map, a meridian should be shown, and designated whether true or magnetic. State names of abutting owners, and limits of their property. Insert all essential dimensions in their proper places. In case of a land plan, the area is usually expressed in square feet or acres and is lettered in middle of the parcel; lengths of sides are printed at middle of each line, and bearings of each side, or angles between them, should be given; also section corners, stone bounds, iron pipes, or other physical boundaries which may exist are represented by abbreviations, such as S B for stone bound, I P for iron pipe, sp for spike, and stk for stake. It is the practice of many surveyors to omit from plan the calculated bearings of lines, or angles; this custom can not be too severely condemned. It is good practice to letter in some inconspicuous place, preferably near border, a reference to the notebook containing survey from which the plan was plotted, and initials of draftsman. If any leveling has been done in connection with the plan, the location and elevation of bench-marks should be described in a note, or plotted on map, preferably both.

On working drawings, and sometimes on finished plans, the traverse lines of the survey are drawn, usually as fine, colored, full lines; the stations being indicated either by very small circles, the centers of which mark the exact points, or by short lines drawn through the points in such manner as to bisect angles. Triangulation stations are represented by equilateral triangles, stadia location stations by small squares, and other auxiliary stations by circles. The elevation of bench-marks is frequently represented by a small cross and figures, thus, B M × 72.63.

The boundaries of a property and the physical features, such as streets or buildings, are usually drawn as full black lines. Shore lines are drawn in black or Prussian blue, and should, as a rule, be the heaviest lines on the plan, unless they are a very unimportant feature. Whenever colors are to be used, better results can always be obtained with water colors than with bottled inks. Red drawing ink gives very unsatisfactory results; in a few years it spreads and gradually fades away, leaving the tracing discolored. The following colors are commonly used by surveyors: burnt sienna, raw sienna, yellow ochre, scarlet vermilion, carmine, sepia, cadmium yellow, chrome yellow, gamboge, Hooker's green, Prussian blue, and indigo. All of these, except gamboge, may be used on tracing cloth without danger of running, but if process prints are to be made from the tracing, Prussian blue and indigo will not print well. Some colors which do not give good prints may be made to do so by adding a little Chinese white or cadmium yellow to give them body, but not enough to change the color. A most satisfactory way to color a plan is to shade the line or areas by colored pencil on back of tracing. Before using the color, rub places where it is to be applied with a pencil eraser and after color has been applied rub it down with a cloth to produce a uniform shading. On blueprints, for a red line, use scarlet vermilion; for yellow, Winsor & Newton's chrome yellow "Winchester."

Lettering on a drawing should, as a rule, read from bottom of plan, that is, all words and figures should read from left to right when the plan lies with its title horizontal; lettering running perpendicular to bottom should read from bottom upward. Roman or

Gothic letters are appropriate on maps for published reports, or where a neatly finished appearance is desirable, but, since most plans are prepared chiefly for utility, the Reinhardt style is applicable for all lettering except possibly main title of map.

Reinhardt lettering is rapidly executed, presents a workman-like appearance, and is used more than any other (Fig 9). For fine lettering, such as Roman, No 170 Gillott pens are suitable. Some draftsmen prefer a little coarser pen, such as Gillott's No 303, and a still coarser pen, Gillott's No 604 EF, will be found suitable for the finer letters of single-stroke work, as for numbering contours or for the smaller dimensions on a map. For still heavier lines, King's No 9 Nonpareil (similar to stub pen) is serviceable. For heavier lines than these, and particularly for executing the Reinhardt style, the Paysant patent pens are good; they come in sets of graded size, costing say $1.50 per pen, including holder. No 6 and 7 Paysant gives about right weight of line for notes on tracing cloth, while No 4 pen will give a line heavy enough for the main line of a title. These pens make lines which have somewhat rounded ends, so it is necessary for neat results, when making the heavier letters, to square up the corners with an ordinary fine pen, as Gillott's No 170. The slot of a Paysant pen should not be cleaned with a cloth because lint attaches to slot; it should be cleaned

Fig 9. Style Sheet for Lettering

with a small piece of tough paper, and then wiped with a cloth. The so-called ball-point pens are also used to some extent for single-stroke work.

Title should comprise: brief description of drawing, owner's name, location of property, scale, date of survey, surveyor's name and address. It should be so laid out that the most important information is on the most prominent line. The lines of title should be centered, arranged in compact form, but not crowded. It is advisable to letter first the most important or longest line. In other lines, when two words occur on same line separated by a considerable space, first letter right-hand word and then start left-hand word at same distance from center line of title as is the end right-hand word. The size of title should conform to size of plan. Never waste time on a fancy title; it is hard to read and as most draftsmen are not familiar with such alphabets, the results are apt to be poor. Put title in lower right-hand corner of a plan, so that it can be read by turning up the corner of sheets that lie above it in a drawer. In some offices, titles are set up in type and printed on plan. A rolled plan should have a brief title on back, at both ends, so it will be visible when sheet has been rolled in either direction. A graphical scale should be drawn on plans that are to be reproduced photographically.

Notes are an essential part of most plans; they are usually lettered in Reinhardt style. Border lines are not necessary on construction drawings, but on finished drawings and maps a single firm line, drawn 1/2 to 1 in from edge of sheet, gives a good appearance. A fine line just inside of a heavier one makes a good border line; many draftsmen make border lines too heavy.

Meridian should be represented on all maps as a full arrow, if it be a true meridian, or as a half-arrow, if it represent the magnetic meridian, the half-arrow head being on same side as the declination. Make arrows of simple design, and not too conspicuous in size or breadth of lines. It is good practice to show both the true and the magnetic meridian, and to indicate on latter the declination existing at place and time of survey. Do not let a meridian line cut any other lines of a drawing.

To clean a drawing use sponge eraser, art gum, or dry bread crumbs. For tracings, gasolene or benzene will remove pencil marks without affecting ink lines, but it takes the life out of the tracing and makes it turn yellow with age; it also causes a tracing to collect dirt more readily. A tracing upon which lettering has been stamped must not be cleaned with gasolene.

On working plans requiring accurate scaling, it is advisable to plot, at the outset, two long scales

at right angles to each other, by which to measure amount of shrinkage or swelling of the paper, and to make allowance for it in subsequent plotting or scaling from the plan.

Tracings from blueprints or from penciled working drawings can be made by laying them on a drawing table having a glass top, and placing table where plenty of light will fall under it, or else placing electric lights under the table.

Conventional signs are used to represent topography and other common details. A few of the most common are shown in Fig 10. They are used mostly on topographic maps and are produced

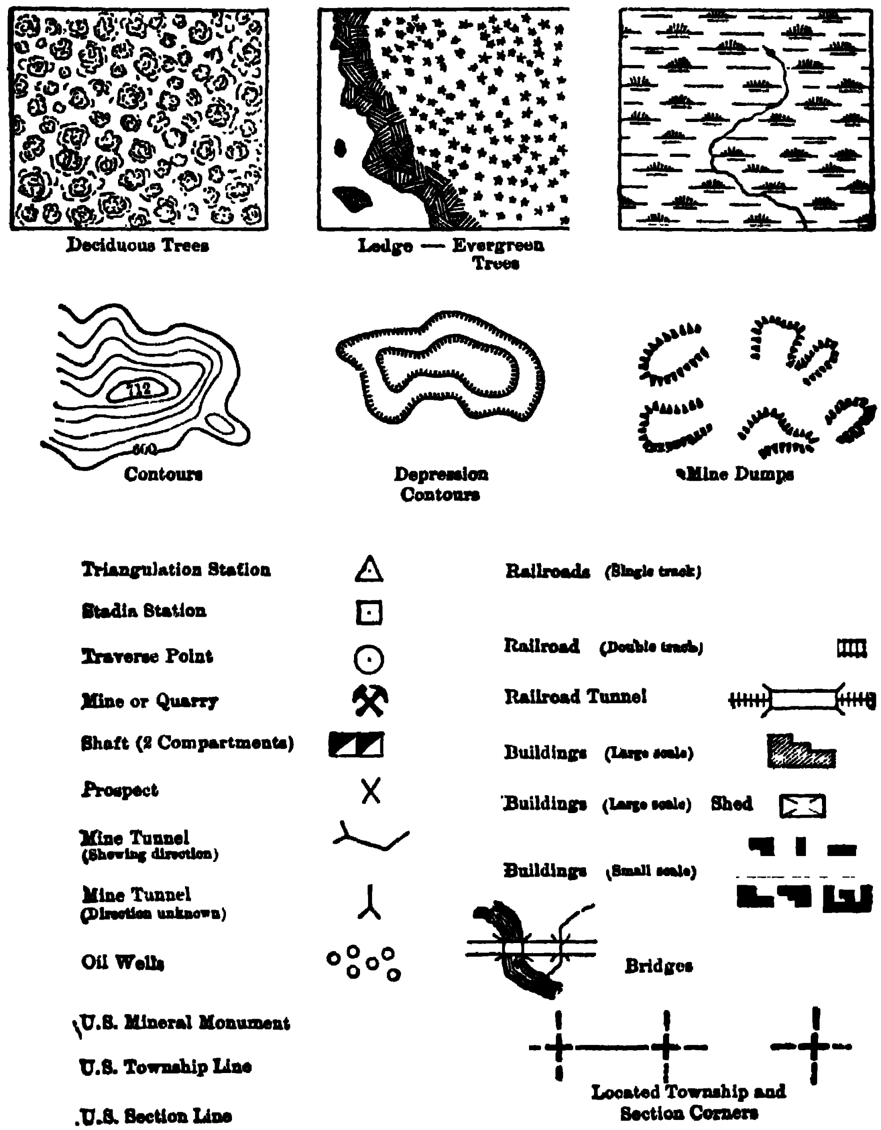

Fig 10. Conventional Topographic Signs

either in black, as is custom with U S Coast and Geodetic Survey, or in color, as on maps of U S Geol
for
part... to bottom of map. ...
full line about half as heavy as shore line, drawn as close to the shore line as possible, and should follow very carefully every irregularity. The next line is parallel to first, but a little lighter and with a little more space, and so on; 5 to 10 lines are sufficient. Water-lining and fresh marsh symbols are frequently drawn in Prussian blue. In executing the symbol for evergreen trees, draw each individual symbol in lines of uniform weight, although the various symbols are made of lines of different weights (Fig 10). To avoid tendency to make them in rows, it is well to draw irregular groups of symbols in different parts of area to be covered, and to fill in between these groups with smaller or lighter symbols. In the symbol for deciduous trees it is intended to represent the plan of a tree in foliage, with a slight shading toward lower right-hand side. On the back of the U S Geol Surv maps are printed the conventional signs used by that office.

Contour lines are almost always drawn in burnt sienna water-color, using either a Gillott No 303 or a contour pen. Every fifth or tenth contour is represented by a line slightly wider and a little darker in color. In numbering contours, give no more figures than are necessary to find the eleva-

tion of any contour without difficulty; they should be small figures in burnt sienna. A common mistake is to make contours so heavy that they subordinate the more important features on map.

Sub-aqueous contours are usually represented on hydrographic maps by dot-and-dash black lines, the shallowest contour having one dot between dashes, the next contour in depth having two dots between dashes, and so on. In some cases, contours representing fathoms of water are shown as single dots for first fathom, two dots and a space for second fathom, dots in groups of three for the third, and so on.

LAND SURVEYING

10. TRAVERSE WITH COMPASS AND TAPE

Surveys with compass and tape are adapted only to surveys of inexpensive land, in localities where there is little danger of local magnetic attraction. Even serious local

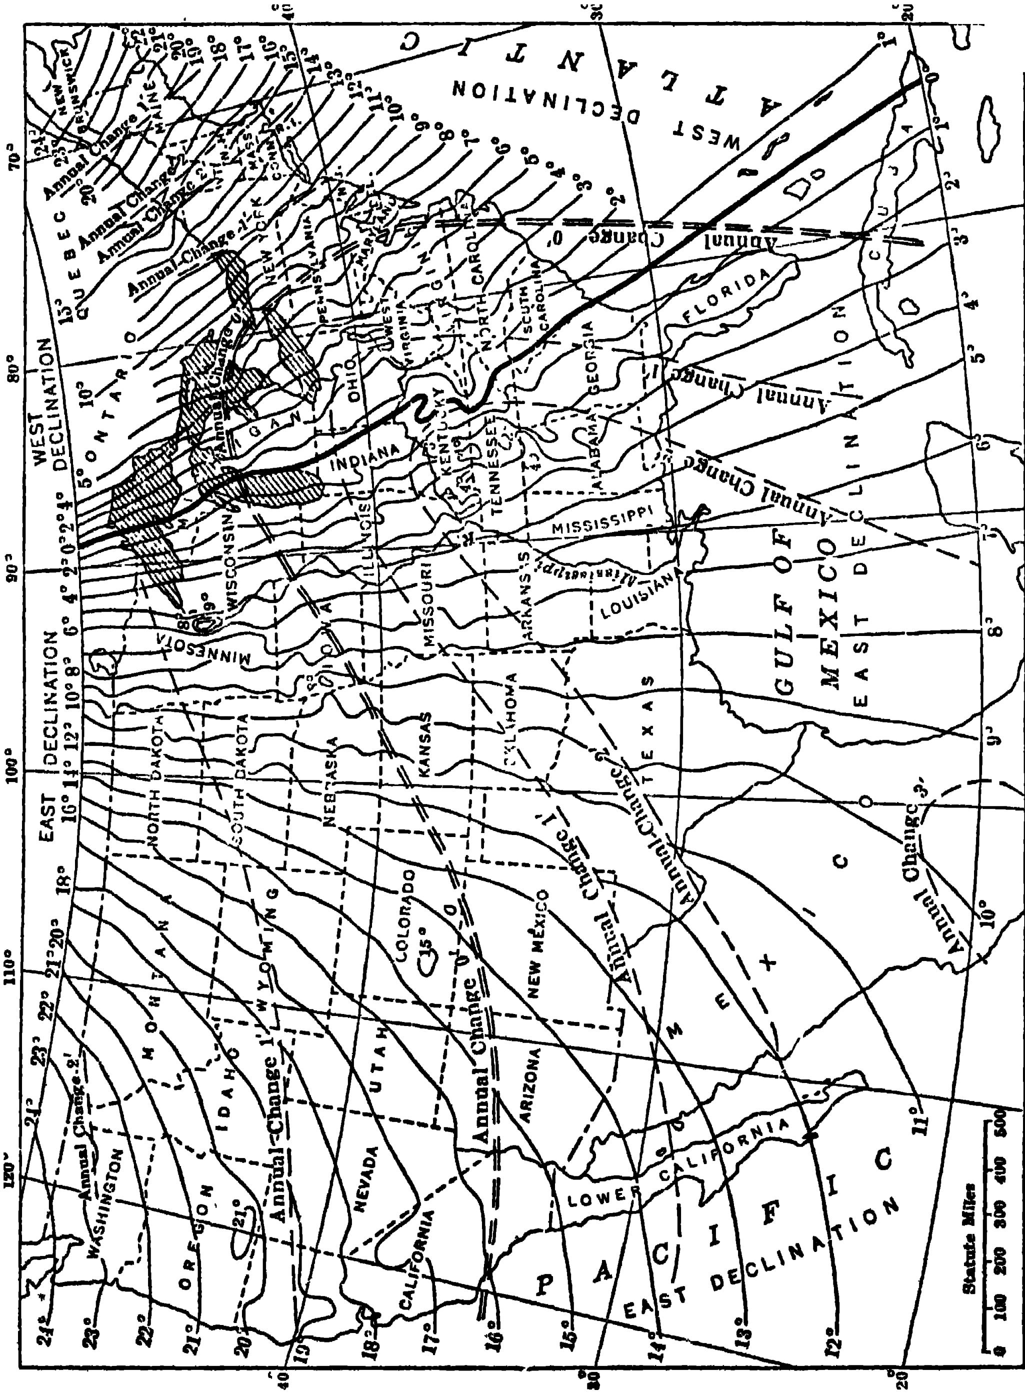

Fig 11. Isogonic Chart of the United States for 1935 (Permission of U S Coast and Geodetic Survey)

attraction may be circumvented if the surveyor has warning of its occurrence, but when rocks containing magnetic iron are distributed generally throughout a district, it is difficult, if not impossible, to obtain consistent compass readings. At every station the reverse as well as forward bearing should be read, to detect local attraction, and, if found, its amount should be determined and the erroneous bearings corrected (Art 3). Bearings are not usually read closer than $^1/_4°$.

If a compass survey were made of a square lot 1 000 ft on a side, an error of $^1/_8°$ (which corresponds to reading bearings to nearest $^1/_4°$) in an angle would correspond to an error of 2.2 ft on a side. In a compass survey, therefore, it is obviously not consistent to measure the sides closer than to nearest half-foot or foot. Under favorable conditions compass surveys can not be relied upon for an accuracy exceeding 1 part in 500. Formerly surveys were often made by compass and chain. In re-running old lines, the compass on transit can be used to aid in finding the physical features which mark the corners, and a reliable transit and tape survey is then substituted for the old approx compass survey (Art 11 and 15).

Magnetic declination is the angle which the needle makes with the true meridian. When necessary to determine this angle accurately, the true meridian is found by observation on the sun or on Polaris (Art 13), and then noting its compass bearing. If north end of needle points east of true meridian, it is called an east declination. Even at a given place the declination changes continually by small amounts; these changes are called VARIATIONS.

To set off the declination so that the compass will give true bearings, turn N point of compass box toward north. Then, if the declination is east, turn graduated circle to the right by the amount of the declination; if the declination is west, move the zero to the left. Needle readings will then be true bearings.

Isogonic lines are curves connecting points at which the magnetic declination is the same. Isogonic charts are prepared by the U S Coast and Geodetic Survey, by plotting on a map the observed declination at numerous magnetic stations, and interpolating declinations at intermediate places (see Fig 11). These charts do not give precise results, but are useful for learning approx declinations. Observed declinations at interpolated places are frequently quite different from those stated on isogonic charts; hence, whenever the magnetic declination is desired with precision, it is necessary to make observations on the true meridian (Art 13).

Changes in declination make it necessary, in re-running old lines, to modify given bearings by an amount equal to the change in declination which has taken place since lines were first run. To determine declination for some past date, records of U S Coast Survey are useful, provided a magnetic station was situated near location of survey; but it is not safe to rely on records of a magnetic station, even only 5 miles distant, except in a general way. It is always safer to determine the present declination, and compare it with the declination at the time lines were first run, which may have been recorded with old survey. If it was not then recorded, the best way to find the correction in bearing is to determine the present magnetic bearing of any well-defined line of the old survey, such as between two identified stone monuments, and apply the difference between present and original bearing to all original bearings (Art 15).

11. TRAVERSE WITH TRANSIT AND TAPE

Precision with which measurements should be made depends upon object of survey. If it is a city survey of valuable property, angles will be measured to the nearest 10 sec, and distances to a hundredth of a foot; while in a farm survey, angles to nearest minute and distances to a tenth or even to within a foot (by stadia method, Art 22) are exact enough. Transits for general surveying read to minutes or half-minutes. It is therefore necessary in precise surveys to measure angles by repetition (see end of this article), to obtain results consistent with accuracy of tape measurements. For better appreciation of relation between distances and angles bear in mind that 0.03 ft, at a distance of 100 ft, subtends 1 min of angle. The degree of precision of transit and tape surveys varies from 1 in 1 500 to 1 in 40 000; to attain an error of less than 1 in 10 000 requires special care, particularly in taping.

Errors in tape measurements are due to: (*a*) erroneous length of tape; (*b*) incorrect amount of pull on tape; (*c*) inaccurate plumbing; (*d*) incorrect alinement of tape; (*e*) sag of tape; (*f*) changes in temperature; (*g*) effect of wind.

(*a*) **Erroneous length** can be corrected by comparing the tape with a standard; most cities maintain a 100-ft standard at some convenient place. To test a tape stretch its full length beside the standard, and leave it until it acquires the same temperature, before comparison is made. Test at intermediate points as well as for total length. Its tempera-

ture and pull should be noted; also whether it is suspended or supported. For a nominal charge the U S Bureau of Standards, Washington, will test a tape and forward results. If tape is too long, measurements made with it are recorded too short, and proper correction should be added. It is good practice to have a new tape standardized by the Bureau of Standards, and then keep it for the sole purpose of standardizing other tapes in daily use. A tape subjected to rough usage will soon have several repaired places, which often cause errors in its length.

(*b*) **Amount of pull** has a very appreciable effect upon the length of a tape; ordinary, light 100-ft tapes will stretch 0.01 to 0.02 ft with an increase of 10 lb above the ordinary pull of 10 lb. The amount of stretch in any given tape can be readily determined by fastening its ring end to a stout nail in the floor, and applying different tensions as determined by a spring balance, the tape lying throughout on floor. Spring-balance handles are manufactured to be attached to tape in the field for measuring amount of pull.

(*c*) **Inaccurate plumbing** is the most fruitful source of errors in taping; if plumbing is unavoidable, more accurate results can be obtained when measuring downhill than uphill. In spite of greatest care, so much error is introduced by plumbing that for accurate results it is better to measure the inclined distance from horiz axis of instrument to a nail in the stake at next station; read, on the vert arc, the inclination of tape, and compute horiz distance from cosine of this angle; *hor dist* = *incl dist* × *cosine vert angle*. If angle is small, the computation may be simplified by using versed sine of angle, thus: *hor dist* = *incl dist* − (*incl dist* × *versin vert angle*). The versed sine (1 − cos), which will be a small number, may be taken from a table of natural functions and the multiplication can be made with sufficient accuracy on a slide rule. This method requires a transit set-up at every other tape-length, but it is more expeditious and gives much more accurate results than plumbing. Another way is to tape directly from stake to stake in one tape-length; set up instrument at every alternate stake and measure vert angles to both adjoining stations, by sighting at a rod target set at same height at which the horiz axis stands above the stake under transit; this gives inclination of tape; then compute horiz distance by either method given above. Still another method is to measure inclined distance from stake to stake, and obtain difference in elevation by leveling; then compute horiz distance by formula in following paragraph. When much inclined work is to be done, it is advisable to use a 200-ft or 300-ft tape.

(*d*) **Alinement errors** are not likely to be large; lining in the tape by eye is exact enough for most measurements. If, in measuring 100-ft tape-lengths, a point is 1 ft out of line, it will introduce an error of only 0.005 ft in that tape-length. Error due to poor alinement may be computed by the formula: $c - a = h^2 \div 2c$, where c is the taped distance, h the offset from the line, and a the correct length. In this formula c is the hypotenuse, a the long leg, and h the short leg of a right triangle. Thus, if one end of a 100-ft tape is on line and the other 0.8 ft off line, the error in that one tape-length is $0.8^2 \div 200 = 0.0032$ ft. Of course there will be a similar error in next tape-length, making a total error of 0.0064 ft in the 200 ft. The shorter the taped distance the greater proportionately is the error due to faulty alinement. This formula is correct to the nearest 0.01 ft, if taped distance is less than 300 ft and offset does not exceed 10% of taped distance.

(*e*) **Sag.** Measurements frequently have to be taken with tape unsupported between its ends. It is customary, in this case, to exert a stronger pull than normally, to counteract effect of sag. With a 12-lb pull, on an ordinary 100-ft ribbon-steel tape supported at its ends, the increased tape reading due to sag is about 0.01 ft. This may be found for any particular tape by the formula: lengthening due to sag = $(L \div 24) \times (wl \div t)^2$, where w = wt of tape in lb per ft of length, t = pull in lb, l = length of tape between supports in ft, and L = total length of tape in ft. The result will be in ft. If the ordinary pull of 10 to 12 lb is given, the correction for sag may be applied by use of this formula, though this is seldom done. The most practical and accurate way of eliminating the error due to sag is to determine by actual test the amount of pull necessary to apply to a suspended tape to bring its ends exactly 100 ft apart. Support plumb lines from points previously set 100 ft apart by a standardized tape when supported horizontally throughout, then note pull required to stretch the suspended tape to be tested so that its end marks will coincide with the plumb lines. U S Bur Standards will do this and report results.

(*f*) **Temperature correction.** A new tape is of standard length at 68° F, with a pull of 10 lb when supported throughout its length. As the average coeff of expansion is desired, the temp of the tape must be noted and temp correction applied. Small tape-thermometers are made for this purpose; the thermometer should be in contact with tape, to obtain as closely as possible the temp of tape itself. Even then, in sunlight, it is difficult to obtain correct temp.

Cumulative and compensating errors. In all measurements it is of utmost importance to distinguish between errors which tend to balance and those which accumulate, the latter

being far more important. For those which tend to balance, the number of errors which will probably remain uncompensated, according to method of least squares, will be the square root of total number of opportunities for error. For example, if a 100-ft tape is 0.02 ft too long a cumulative error of about 1 ft will be made in measuring a one-mile line. If, on other hand, tape-lengths are not marked closer than 0.05 ft, the total error made by this compensating error of 0.05 ft will be only $\sqrt{52} \times 0.05 = 0.36$ ft.

Angle measured may be the deflection angle, the actual angle, or the azimuth angle. The DEFLECTION angle is that between the last course produced and the forward course. The ACTUAL ANGLE measured is usually the smaller of the two angles formed by two diverging lines, although, in case of a closed polygon, many surveyors prefer to read consistently either interior or exterior angles. The AZIMUTH angle is the angle a course makes with the meridian (true or assumed) direction measured clockwise, usually from the south. In measuring a deflection angle the telescope has to be inverted, whence any error in line of collimation will be introduced into deflection angle; such error may be compensated by turning the angle with the telescope, first direct and then inverted, and taking half final reading as correct angle. Deflection angles are recorded R (right) or L (left), according to direction turned.

To measure azimuth, set up the instrument at A with the vernier reading 0°, and lower clamp loose. Point telescope at magnetic south, true south, or other arbitrarily selected meridian, and clamp the lower motion. Unclamp the upper plate, sight B, and read the angle in a clockwise direction. This is azimuth of line AB. Take the instrument to B, being careful not to let the upper plate be moved, invert telescope and backsight on A; clamp the lower motion, reverse telescope to its direct position, loosen upper clamp, and sight C. The reading is the aximuth of BC, referred to same meridian as AB. By this method an error in line of collimation becomes cumulative; the survey should therefore be closed, if possible, by noting final azimuth of starting line AB. The difference between the first and the final determination of azimuth of AB indicates at once the total error in the angular work.

As a check against large errors in azimuth readings, the magnetic bearing of each line should be read, when practicable, and compared with calculated bearing. The calculated bearing of first line is assumed to be its observed bearing; the calculated bearing of any line is obtained from calculated bearing of the line next preceding, combined with the measured angle between the two lines. If a right deflection, add it to NE and SW bearings and subtract from NW and SE bearings; if a left deflection, reverse the process. If resulting angle is between 90° and 180°, take its supplement; if over 180°, subtract 180° from it. Care should be exercised in noting quadrant in which the new line lies.

Since azimuths are read from the S direction, clockwise through 360°, azimuths between 0° and 90° have a SW bearing of the same number of degrees; azimuths between 90° and 180° have a NW bearing equal to supplement of the azimuth; azimuths from 180° to 270° have a NE bearing equal to the azimuth minus 180°; azimuths between 270° and 360° have a SE bearing equal to 360° minus the azimuth. (It is the practice of astronomers to assume the south point as zero azimuth; whence this method has been officially adopted by the U S Coast and Geodetic Survey, and the Public Lands surveyors. North is assumed as zero by the U S Army, in the Infantry, but not in the Artillery.—ED.)

Checking closed traverses. The algebraic sum of the deflection angles should equal 360°, right deflection being considered positive and left deflection negative. If the interior angles are read, or computed, the sum of all interior angles of a closed traverse should be $(n - 2) \times 180°$, where n is number of lines in traverse. If angles are read to nearest min, each angle is probably correct within 30 sec. If a is the number of angles in a traverse, the allowable error in their sum is $30'' \times \sqrt{a}$. Thus, if $a = 9$, allowable error is 1 min 30 sec. This check should be investigated before leaving the field; if angular error is much larger than that allowable, a mistake is indicated, which should be found and corrected. For method of checking distances see Art 12.

Checking unclosed traverses. The only check on distances is re-measurement of the lines, preferably in the direction opposite that first traversed. (A portion of a traverse can sometimes be closed and checked by the method of Art 12.) Angles can be checked by determination of the true bearing (to nearest minute) by solar or stellar observation (Art 13) of the first and any subsequent course of the traverse.

To measure an angle by repetition, set up transit at A, with circle reading 0°, sight B, and clamp lower motion. Loosen upper clamp and sight C; read and record angle. Leaving the two plates clamped together, invert telescope, and sight B, with the lower motion, unclamp upper circle and sight C; read and record the angle. One-half this angle should check closely the first reading, but will be more exact than the first. By repeating an angle six times, and observing final reading to nearest minute, an accuracy within 10 sec can be obtained. The method might be carried even further, starting with the vernier

set at other points on the circle, but ordinary transits are not reliable for results closer than 10 sec. The purpose of making half the repetitions with telescope direct, and half with it inverted is to compensate errors of adjustment in line of collimation and horizontal axis.

To lay off an angle this method can be applied as follows: The angle is first laid off as usual and a point is set; this angle is then measured by repetition. If found to be in error, say 15 sec, the point is moved in proper direction a distance computed by multiplying *tan* 15 sec by distance from the point to the instrument.

For determination of an area three general methods of traversing are: (*a*) Set transit at corners of the property and measure angles directly; also measure distances along property lines. (*b*) If boundary lines are occupied by high fences or other obstacles which prevent setting up instrument at corners, but still permit distances to be measured along property lines, the angles are obtained by measurement between lines staked out parallel to property lines, by equal offsets. (*c*) If boundaries of property are such that it is practicable neither to set up transit at corners, nor to measure distances directly along property lines, an independent traverse is run, regardless of boundaries. To convenient stations of this traverse the property corners are connected by the reading of angles and distances. In this case, a transit station should be set far enough from a property corner to permit telescope to be focused on it (not closer than 6 to 8 ft). The property lines should also be measured, where possible, as a check.

12. COMPUTATION OF AREAS

Adjustment of notes. First correct all slight errors in angles, provided they are not large enough to indicate mistakes, by altering value of those which were taken from short sights, or those in which error is most likely to lie, until the sum of all interior angles is $(n - 2) \times 180°$. Next compute bearing of each course, starting from one of which the bearing is known or assumed. Next correct tape measurements for erroneous length of tape, for sag, or for temp, if necessary. Field data are now in form for computing area.

Double meridian distance method. The data are conveniently tabulated as shown below. The LATITUDE of a course is its length times the cosine of its bearing; its DEPARTURE is its length times the sine of its bearing. Latitudes to the northward and departures to the eastward are called positive, and southward latitudes and westward departures are called negative. After these have been computed for all courses, and entered in their appropriate note-book columns, find total of each column.

(**Note.**—The parallelism between other synonymous terms for latitude and departure, which have been and are used by many surveyors, may be indicated thus: Easting or westing (used in old practice) = departure. Northing or southing = latitude difference = latitude. In this article, the word latitude is used, not in its geodetic sense, but as an abbreviation of latitude difference.—ED.)

If the work were exact, the sums of the positive and of the negative latitudes would be equal; similarly with positive and negative departures. If the discrepancies between positive and negative totals are not large enough to indicate mistakes in tape measurements or computations, errors may be distributed among the latitudes and departures according to following rule, provided angles have been read by TRANSIT: The correction to be applied to the latitude (departure) of any course is to the total error in latitudes (departures) as the latitude (departure) of that course is to the sum of all the latitudes (departures), without regard to algebraic signs. This rule assumes that errors are more likely to occur in tape measurements than in angles. Any knowledge of difficulties met in the field, which would lead surveyor to suspect that the error lay in certain lines, should take precedence over this rule. Furthermore, it is probable that, on account of sag of tape and small obstacles on the line, recorded distances are too long rather than too short; as a general rule, therefore, it is not good practice to apply the above rule when it would lengthen any of the distances. The algebraic sum of balanced latitudes and departures must be zero. In the tabulated example given below latitudes and departures have been balanced so as not to increase length of any lines, and so as to decrease particularly the line HA, which is known to have been measured under difficulties.

In the case of a COMPASS survey, the errors are as likely to be in bearings as in distances; hence, if nothing is suspected as to the probable locus of errors, they should be assumed to be proportional to lengths of courses, and the survey is balanced by the following rule, which alters not only the lengths of courses but also their directions: The correction to be applied to the latitude (departure) of any course is to total error in latitudes (departures) as length of that course is to perimeter of traverse

Having balanced the latitudes and departures, next compute the double meridian distance (D M D) of each course. The D M D of first course equals departure of first

course. The D M D of any other course equals the D M D of preceding course, plus departure of preceding course, plus departure of course itself. The D M D of last course should be numerically equal to departure of last course, but should have the opposite algebraic sign. Algebraic signs must be carefully observed, not only in computing D M D's, but in the whole computation of area. If D M D's are computed beginning at the most westerly point in the traverse, all D M D's will be positive. The last column of positive and negative double areas is found by multiplying each D M D by its corresponding latitude. Half the algebraic sum of the double areas gives area of the traverse.

Computation of Area by Double Meridian Distance Method

Course	Bearing	Dist, feet	Lat	Dep	Balanced Lat	Balanced Dep	D M D	Double area
AB	N 62° 05′1/2 W	361.92	+ 169.40	− 319.83	+169.40	−319.81	− 319.81	− 54 176

Note.—In extensive work it is better to enter positive and negative latitudes and departures in separate columns, for convenience in adding.

Checks on accuracy. Close agreement between the sums of plus and minus latitudes and between plus and minus departures gives a check on the accuracy of multiplication by cosine and sine of the bearings. The D M D's are checked as shown above, but there is no check on the double areas. The final area can be roughly checked by planimeter (Art 6), or by dividing the plotted traverse into rectangles or triangles, scaling their dimensions and computing their areas. A more exact check on the area is to compute from the latitudes the double parallel distances (D P D), just as the D M D's were computed from the departures, and then obtain double areas by multiplying each D P D by its departure.

If l be error in latitudes and d error in departures, the ERROR OF CLOSURE of survey equals $\sqrt{l^2 + d^2}$. Thus, the error of closure of survey shown above is

$$\sqrt{0.09^2 + 0.10^2} = 0.135 \text{ ft},$$

and the relative error of closure is 0.135 ÷ 3 802, or 1 part per 28 300.

Large mistakes in taping distances will be detected in the process of computation. If latitudes and departures do not balance within reasonable limits, the error in departures divided by error in latitudes equals tangent of bearing of that line which would represent error of closure on the plan, and if only one mistake has been made in measuring distances it probably occurred on a line having approximately this bearing.

If error between plus and minus latitudes, or departures, should be seen to be about double the latitude, or departure, of any one course, it is probable that the bearing of that course was read or recorded in wrong quadrant.

Traverse tables shorten the work of computations. One of the best is that by R. L. Gurden, computed to four decimal places, for every minute of angle and up to 100 units of distance.

The same tables can be used for computing horiz and vert distances corresponding to inclined tapings. Nearly every textbook of surveying and civil engineers' pocketbooks contain a traverse table computed to 15 min of angle. In the absence of a traverse table computed to single minutes, a table of log sines and cosines can be used (Sec 45).

When a traverse does not follow property lines (Fig 12), areas may be computed as simple geometric figures, as in following example:

In Fig 12, ABC is property line and XYZ, traverse line.

$$aA = 25.2 \times \sin 76° 24' = 24.5$$
$$aX = 25.2 \times \cos 76° 24' = 5.9$$

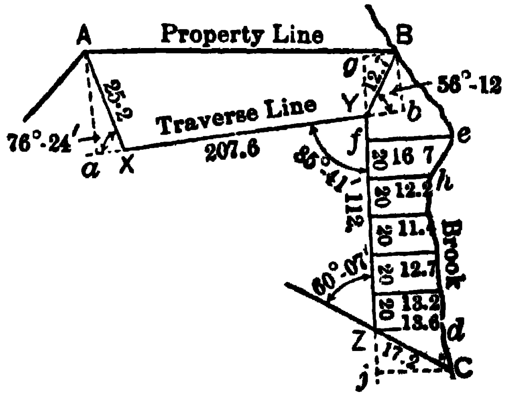

Fig 12. Traverse not on Property Lines

$$ab = 5.9 \quad + 207.6 + 7.1 \quad = 220.6$$
$$bB = \quad 12.7 \times \sin 56° \, 12' \quad = \quad 10.6$$
$$bY = \quad 12.7 \times \cos 56° \, 12' \quad = \quad 7.1$$
$$AB = 220.6 + \frac{(24.5 - 10.6)^2}{2 \times 220.6} = 221.0$$
$$\text{Area } AabB = 220.6 \times \frac{24.5 + 10.6}{2} = 3\,872$$
$$\text{Area } \quad AXa = \frac{24.5 \times 5.9}{2} \qquad = -72$$
$$\text{Area } \quad BYb = \frac{10.6 \times 7.1}{2} \qquad = \underline{-38}$$
$$\text{Area } AXYB \qquad\qquad = 3\,762 \text{ sq ft}$$

Another method, of special application to mine surveys, is to compute area from the COORDINATES of the corners of a tract (see Art 8, this Sec, and Art 9, Sec 18). Coordinates of the corners are computed in ordinary manner by noting bearing and distance of each from nearest, or most accessible, traverse station, of which the coordinates are ascertained by method previously described. Number the corners consecutively around the tract. Multiply each latitude (ordinate) by the difference between following and preceding longitude (abscissa), always subtracting the preceding from the following. One-half the sum of the products is the area.

Meandering boundaries, such as brooks, roads, etc, are usually located by measuring perpendicular offsets from a traverse line which has been run conveniently near the boundary. If curvature of boundary be fairly uniform, offsets are taken at regular intervals, but if it be erratic, offsets must be taken at each point where direction changes. In either case, areas of the several trapezoids are computed, and their sum added to or subtracted from area within traverse lines. If offsets be taken at equal intervals, the computation may be made by one of the following methods.

Trapezoidal rule. Area $= \frac{1}{2} d \, (h_e + 2 \, \Sigma h + h_e')$, where d = common interval between offsets, h_e and h_e' = end offsets of the series of trapezoids, and Σh = sum of intermediate offsets. This rule assumes that the boundary is a straight line between adjacent offsets.

Simpson's one-third rule. Area $= \frac{1}{3} d \, (h_e + 2 \, \Sigma h_{odd} + 4 \, \Sigma h_{even} + h_e')$, where d = common interval between offsets; h_e and h_e' = first and last offset; $2 \, \Sigma h_{odd}$ = twice the sum of the odd offsets (3d, 5th, 7th, etc); $4 \, \Sigma h_{even}$ = four times the sum of the even offsets (2d, 4th, 6th, etc). To apply this rule there must be an odd number of offsets; if the number is even, compute the area of one end trapezoid separately. This rule assumes that between adjacent offsets the boundary is a parabola, through 3 consecutive points.

In Fig 12 the area of *efZd* by the trapezoidal rule $= \frac{1}{2} \times 20 \times [13.6 + 2(13.2 + 12.7 + 11.4 + 12.2) + 16.7] = 1\,293$ sq ft. By Simpson's rule the same area $= \frac{1}{3} \times 20 \, [13.6 + 2 \times 12.7 + 4 \, (13.2 + 11.4) + 12.2] + \frac{1}{2} \times 20 \, (12.2 + 16.7) = 1\,286$ sq ft. Area *BYfe* is computed by finding area of trapezoid *Bgfe* and subtracting triangle *BgY*, giving 235 sq ft. Similarly *dZC* is computed by finding area of trapezoid *dZjC* and subtracting triangle *ZjC*, giving 58 sq ft. The length of side *BC* can be found by computing the several parts *Be*, *eh*, etc, by method of Art 10. For example

$$eh = 20 + \frac{(16.7 - 12.2)^2}{2 \times 20} = 20.5 \text{ ft.}$$

13. DETERMINING THE TRUE MERIDIAN

The three methods best adapted to the needs of an engineer are: (*a*) by observing with ordinary transit the bearing of sun, found from its altitude; (*b*) by use of the solar attachment for transit; (*c*) by observing the bearing of pole-star at its greatest elongation. The observations consist in measuring directly the horizontal angle between sun or star and the survey line of which the bearing is to be determined; preliminary observations on other factors required for solution of problem, such as the altitude of sun or star, the latitude of place, or the time, are usually also necessary.

In solar observations certain times of day are more favorable than others, while at certain times the observations should not be made at all. During summer (in northern hemisphere) observations may be made at almost any time between 7 and 10 a m, and between 2 and 5 p m. Observations before 7 a m or after 5 p m are usually unsatisfactory, because the sun is so near horizon that atmospheric refraction introduces a large error into the measured altitude of the sun; for best results, sun should be at least 10° above horizon. In midwinter it will therefore be necessary to wait until nearly 9 a m before making an observation. Between 10 a m and 2 p m astronomical conditions are not favorable for

an accurate solution of the spherical triangle that must be employed to compute the sun's azimuth. In general, when sun is well to the east or west, conditions are favorable; when it is near meridian they are unfavorable.

Observation of sun's bearing. The only additional equipment necessary for an ordinary engineer's transit is a colored glass over the eye-piece. Even this may be dispensed with in the following manner: Draw out the eye-piece tube a little way and hold a card behind it; if telescope be then pointed at sun, an image of sun and of the cross-hairs can be seen on card. The image may be focused by moving card to or from eye-piece; the cross-hairs can not usually be seen except when projected on to the sun's disk. In computing sun's azimuth it is necessary to know the time within 5 min or less. If possible the watch used should be regulated to standard (railroad) time.

The observation consists in measuring simultaneously the horiz angle from some reference line, and the altitude of sun's center. Set the vernier at 0°, and sight telescope along the reference line. Then unclamp the upper motion, and sight at the sun. The horiz and vert angles, and time of pointing are recorded. For a comparatively rough result, say, when an error of 1 to 2 min is not serious, it will be sufficient to bisect the sun's disk, by estimation, with both vert and horiz cross-hair; for more precise results, it is necessary to observe upper and then lower edge of sun for altitude, and right and left edges for horiz angle. The means of these pairs may be taken as altitude and horiz angle to the center, as though they were both measured directly at same instant of time. To make these double observations on the sun with least effort, the edges to be sighted should be so selected that only one tangent screw will have to be turned at a time. In the morning (in northern hemisphere) the sun is rising and moving to right. If telescope be set so that sun appears in upper left-hand quadrant of field, the sun will approach the vert and recede from the horiz cross-hair. If transit has an inverting eye-piece the motion will appear reversed. By setting the horiz hair a little above lower edge of sun's disk, the sun's motion itself will bring cross-hair into contact with lower edge of the disk; it is therefore necessary only to keep vert cross-hair in contact with right edge, by means of the upper tangent screw, stopping this motion the instant both cross-hairs are simultaneously in contact with the edge of disk. When this position is reached the watch time should be recorded, the vert and horiz circles read, and the index error of vert circle determined. The second half of the observation consists in bringing the disk into the lower right-hand quadrant, setting the vert hair a little to right of left edge, and keeping the horiz hair steadily in contact with upper edge of disk, by the vert tangent screw, until both hairs are again in contact. The watch time is recorded, both circles are read again, and index error of vert arc determined. The mean of the two vert angles is assumed to correspond to the mean of the two horiz angles, and to the aver of the two times. These two pointings should give sun's bearing to nearest min of angle; for greater precision, observations may be repeated, 3 readings being made in each position of cross-hairs. If instrument has a complete vert circle, so that altitudes may be read with telescope inverted, it is advisable to take the second half-set of readings with telescope in inverted position, thus compensating errors of adjustment (Sec 4). It is good practice, after observation is made, to sight back at the reference mark: if vernier reads 0°, it indicates the horiz circle did not move during observation. It is undesirable to let the observations extend over more than 10 or 12 min of time, since the curvature of sun's path will introduce error into result. If observation be made in afternoon, the disk should be placed in upper right-hand and in lower left-hand quadrants.

To calculate the sun's bearing, take the mean of measured altitudes, subtract from it the refraction correction in following table, and call this *h* in formulas below.

Refraction Correction to the Altitude (Minutes to be Subtracted)

Altitude	Refraction	Altitude	Refraction	Altitude	Refraction
5°	9′.9	13°	4′.1	25°	2′.1
6	8.5	14	3.8	30	1.7
5	7.4	15	3.6	35	1.4
8	6.6	16	3.3	40	1.2
9	5.9	17	3.1	45	1.0
10	5.3	18	3.0	50	0.8
11	4.9	19	2.8	55	0.7
12	4.5	20	2.6	60	0.6

Next find sun's " declination " for the instant of observation, from (*a*) American Ephemeris and Nautical Almanac, (*b*) Nautical Almanac, or (*c*) handbook of any instrument maker who publishes a " Solar Ephemeris." (*a*) and (*b*) are published by Navy Dept, Wash, D C. In (*a*) the " apparent declination " is given for each day of month for the instant of " 0 hr Greenwich Civil Time," together with the tabular difference for 24 hr. In (*b*) it is given for every 2 hr, together with the

"hourly difference." In (c) it is given as in (a), together with the "variation per hr." To correct the declination for the number of hours since 0 hr (midnight), multiply, if (a) is used, the tabular difference for 24 hr by the number of hr of Greenwich Civil Time, divide by 24 and add this correction algebraically to the declination for 0 hr. To find number of hr of Greenwich Time, add 12 hr if time is P M; then add 5 hr if given time is Eastern Standard, 6 hr if Central Time, 7 hr if Mountain Time, 8 hr if Pacific Time. If given time is local, add west longitude in hr, min, and sec. If given time is "apparent" (true sun time), first subtract from it algebraically the "equation of time"; which is difference between Civil and Apparent time at any instant. Values of the "Eq Time" are given in the above publications in same manner as the declination. When converting "apparent time" to mean time, it is necessary, since the Eq Time is tabulated for civil time, to first find the civil time with sufficient accuracy to find the correct Eq Time. Corrected declination is called D in the formulas.

Example. Compute sun's declination at 2 P M Eastern Standard Time, Jan 8, 1938.

Sun's decl Jan 8, 1938, at Greenwich Civ Time 0 = $-22° 21' 25.6''$. Tab diff for 24 hr = 476.2″, Greenwich Civ Time, corresponding to 2 P M, E S T = 19^h. Hence, declination = $-22° 21' 25.6'' + \frac{476.2 \times 19}{24} = -22° 15' 07.8''$.

Example. Compute the sun's decl, Jan 8, 1938, when the "apparent time" is 12^h (noon) in longitude 71° 04′ W (= $4^h\ 44^m\ 18^s$ = 4.74 hr W). Sun's decl at G C T 0^h = $-22° 21' 25.6''$; tab diff for 24 hr = 476.2″. Eq Time at G C T, 0^h = $-6^m\ 25^s.60$; tab diff. for 24 hr = $25^s.59$. The Greenwich Apparent Time = $12^h\ 00^m\ 00^s + 4^h\ 44^m\ 18^s = 16^h\ 44^m\ 18^s$ = 16.74 hr. The approx Gr Civil Time = $16^h\ 44^m\ 18^s + (-6^m\ 25^s.6) = 16^h\ 50^m\ 43^s.6$ = 16.85 hr, a value sufficiently accurate for ordinary purposes for computing the Eq Time. Hence, the corrected equation of time = $-6^m\ 25^s.60 + \frac{16^h.85 \times (-25^s.59)}{24} = -6^m\ 43^s.56$; then the Gr C T = $16^h\ 44^m\ 18^s + (-6^m\ 43^s.6) = 16^h\ 51^m\ 01^s.6$ = 16.85 hr. Required declination is $-22° 21' 25.6'' + \frac{16.85 \text{ hr} \times 476.2''}{24} = -22° 15' 51.3''$.

The latitude of the place must be obtained either from a map or by direct observation. If taken from a map it must be obtained within about 1/2 min. If observed directly, it is found as follows: The max altitude of the sun should be found at noon, with the transit, by setting horiz cross-hair on lower edge of sun and following it as long as it continues to rise. When sun drops below cross-hair, the altitude is read from the vert arc. This reading must be corrected for index error, refraction, and semi-diameter. The semi-diameter may be taken from the Nautical Almanac at the same opening as the declination. Call the corrected altitude h. The latitude is then found from the equation, $L = 90° - (h - D)$. South declination must be considered negative.

Example. On Jan 8, 1938, in longitude 71° 04′ W (= $4^h\ 44^m\ 18^s$ W = $4^h.74$ W), observed meridian altitude of the sun's lower limit was 25° 06′; index-error, +01′; refraction correction, −02′; sun's semi-diam, 16′.3; hence true altitude of sun's center = 25° 21′.3. Sun's declination (from Ephemeris) at 0 hr Greenwich Civil Time −22° 21′ 25.6″; tabular difference for 24 hr = 476.2″. Apparent time at place of observation is 12 hr (noon); hence Gr Apparent Time is $16^h\ 44^m\ 18^s$. Equation of time at Gr Civ Time 0^h = $-6^m\ 25^s.6$. Tabular diff for 24 hr = $25^s.59$. The required Equation of Time is $-6^m\ 43^s.56$ (see preceding page); adding this to the Gr App Time = $16^h\ 51^m\ 01^s$ = 16.85 hr is found for the Gr Civ Time. Declination D, at instant of observation, is −22° 15′ 51.3″. The formula then gives the latitude, L = 42° 23.1′ N.

The azimuth of the sun's center at instant of observation is now found by the formula:

$$\cos Z = \frac{\sin D - \sin h \sin L}{\cos h \cos L}$$

in which Z is azimuth from north point (either east or west).

Example. Azimuth observation on sun, April 12, 1925.

Instrument at sta 19
Reading at sta 20 = 0° 00′

Upper and left edges	Horiz angle (to right) = 84° 28′	Vert angle = 41° 30′
Lower and right edges	Horiz angle = 86° 11′	Vert angle = 41° 16′
Watch, Eastern Time, $9^h\ 07^m$ AM	Mean = 85° 19′.5	Mean = 41° 23′
Greenwich Civil Time, $14^h\ 07^m$		Refraction = − 1′.2
		h = 41° 21′.8

Declination at "0^h Greenwich Civil Time" = + 8° 24′ 44″.3
Correction = + 54″.09 × 44^h.12 = + 12 56. 6
D = + 8° 37′ 40″.9

Angles	Nat Sin	Log Sin	Log Cos
D +8° 37′.7	0.15002		
h 41° 21′.8		9.82009	9.87537
L 42° 23′.8		9.82882	9.86834
product	−0.44557	9.64891	9.74371
numerator	−0.29555		9.47063n
		57° 46′.5	9.72692n

Z = 122° 13′.5(N E)
Angle = 85 19 .5
Bearing = N 36° 44′.0° E
As = 216° 44′.0

In case it is not convenient to use the natural functions, Z may be found by

$$\cos^2\frac{Z}{2} = \left(\frac{\cos s \cos (s - p)}{\cos L \cos h}\right)$$

in which $p = 90 - D$, and $s = 1/2\,(L + h' + p)$.

In case there is doubt about error of the watch on standard time, local time may be obtained by formula:

$$\sin^2 1/2P = \frac{\cos s \sin (s - h)}{\cos L \sin p}$$

Angle P (expressed in hr, min, and sec), added to west longitude of place gives Greenwich apparent time. To obtain Greenwich Civil Time subtract "equation of time" given in the Almanac.

Solar attachment is a small appliance, which may be attached to an engineer's transit and used for finding the meridian by an observation on the sun. There are several different forms, but the general principle is that the attachment itself can be rotated about a polar axis (parallel to earth's axis), so as to follow the sun's daily motion, while the whole instrument can be rotated about vertical axis of transit, to swing transit telescope into plane of meridian. By a combination of these two motions the telescope of the attachment (or its equivalent) may be pointed at sun. If proper settings be made for observer's latitude and sun's declination, this pointing at sun can be accomplished only by bringing transit telescope into plane of meridian.

The three steps required in the process are as follows: First lay off declination of sun in such manner that the solar telescope may be pointed at sun, while the polar axis is

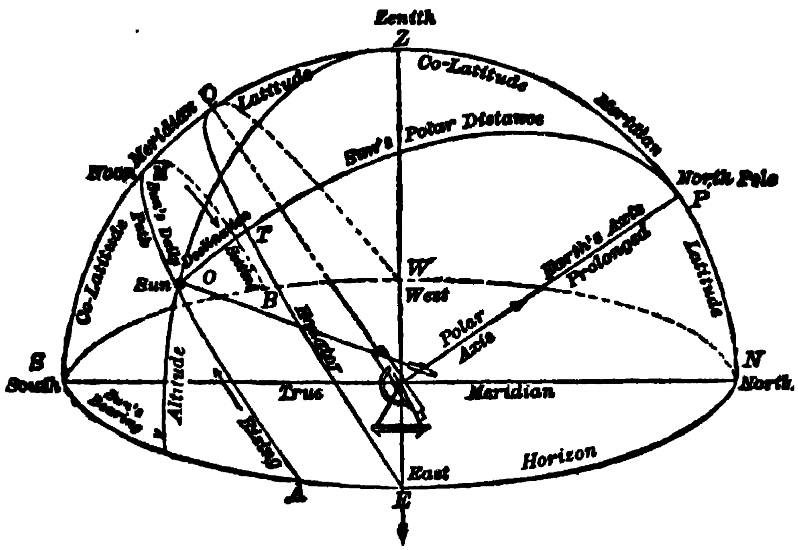

Fig 13. Half Celestial Sphere

parallel to earth's axis. The method of doing this depends upon construction of instrument. In the Burt solar attachment the declination is set off directly on a special arc provided for this purpose. In the Saegmuller pattern it is set off by means of vertical arc of transit and an attached level, the small telescope being in same plane as transit telescope when declination is laid off. In other forms of attachment, such as Shattuck's and Smith's, which contain mirrors, this setting is made by special devices depending upon construction of instrument. After the declination setting is made, the polar axis of the attachment is given an inclination to horizon equal to latitude of place of observation. In the Burt and Saegmuller attachments this is done by making vert arc read the co-latitude of the place. In the Shattuck and Smith attachments the transit telescope is placed in position by setting vert circle to read latitude of the place. When these two settings have been made the solar telescope is sighted at sun, or, in case of those attachments having mirrors, the mirrors are turned so that sun can be seen in telescope. When sun's disk is bisected exactly by the cross-hairs, the plane of transit telescope must be coincident with plane of meridian.

The declination referred to in preceding paragraph may be taken from the Nautical Almanac for given date and for the instant of 0^h Greenwich Civil Time; the tabular difference for 24 hr is given in the next column. To obtain correct declination take number of hours in the Greenwich Civil Time and multiply this by the tab diff for 24 hr ÷ 24. The number of hours in the Greenwich Civil Time is obtained as follows: If the time is P M add 12 hr; then, if it is Eastern Standard Time, add 5 hr, if Central Time add 6 hr, if Mountain Time add 7 hr, and if Pacific Time, add 8 hr.

If local time is given, add the west longitude expressed in hr, min, and sec. The corrected declination has still to be corrected for effect of atmospheric refraction, as found in the handbooks of instrument makers, or determined by Comstock's method, as follows: Set vert hair on one edge of sun and note time; set vernier of plate 10 min ahead and note time when same edge of sun is again on cross-hair. If n be seconds of time between observations and h the altitude, degrees, the refraction in minutes equals $2\,000 \div h \times n$. Add this correction to north declinations, and subtract from south declinations. The latitude used in solar observations may be taken from a reliable map, or directly observed by method already described.

Chief objection to solar attachments is that, for even fair results, the adjustments must be frequently inspected. Direct solar observations with an engineer's transit are more accurate, and take very little more time than with the attachment.

For details of construction and use of different solar attachments, see catalogs of makers. W. & L. E. Gurley, Troy, N Y, make the Burt solar attachment; Ainsworth & Sons, Denver, Colo, the Shattuck; Young & Sons, Phila, Pa, the Smith. Nearly all instrument-makers manufacture attachments similar to the Saegmuller Solar.

Burt solar compass is an instrument for determining direction of the true meridian by observations on the sun. It consists of a horiz plate upon which are mounted two vert sights, like those of the ordinary needle compass and also a polar axis which is fixed in same vert plane as sights; the whole instrument revolves about a vert axis. An arm, carrying a lens and a screw is so attached to the polar axis that it may be set at any inclination to it, and may be revolved about it.

To determine the meridian, set the arm at proper inclination to polar axis by setting off sun's declination on the declination arc. Next give polar axis an inclination equal to latitude of the place, by setting off this latitude on the latitude arc. If the arm is now turned about the polar axis and the whole instrument about the vert axis, so that the lens throws an image of sun on center (square) of screen, the sights are in plane of the meridian.

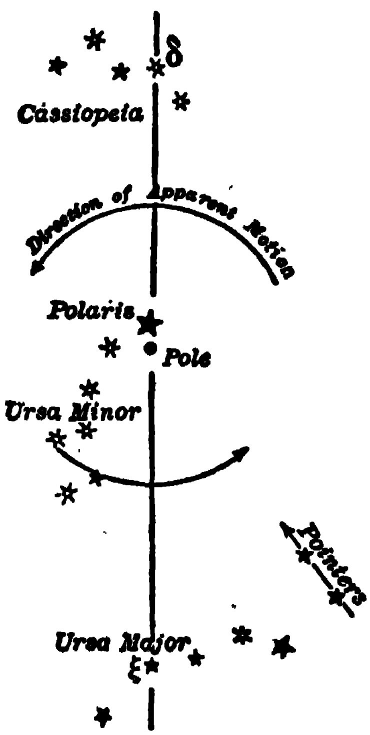

Fig 14. Circumpolar Stars

Observations on the pole-star are less conveniently made than those on the sun, but the calculations are simpler and accuracy is somewhat greater. To identify Polaris, first find Great Dipper, comprising 7 fairly bright stars forming a dipper with bent handle (Fig 14). The 2 stars on side of bowl farthest from handle are called the "Pointers," because a line through them, prolonged about 5 times the distance between them, passes through a point close to Polaris. Its position may also be verified by noting that Cassiopeia (the W) is on opposite side of Polaris from the dipper. Once each sidereal day, Polaris describes a small circle about the invisible pole, with radius (in 1938) of about 1° 01′. Twice each day the star is on the meridian; once when directly above the pole, called "upper culmination," and again when below the pole, at "lower culmination." Its extreme eastern position is the "eastern elongation"; its extreme western position, the "western elongation." Observations are best made at either elongation. Fig 14 shows the constellations as they appear when Polaris is at its upper culmination; by looking at the figure inverted they are seen as they appear at lower culmination; by looking at it from left and right margins of page, the positions are seen for western and eastern elongations of Polaris.

Equipment necessary, besides the transit, comprises a flash light or lantern, and a reflector to throw light into the telescope field and make the cross-hairs visible. It is not necessary to know accurately the instant at which elongation will occur, but it is convenient to know the time within a few min, so as to have ample time to prepare for the observation. Position of the constellations gives a fair idea of the time before Polaris will reach the position of elongation. A closer time estimate can be made from following table for latitude 40° N.

Date	Eastern elongation	Western elongation	Date	Eastern elongation	Western elongation
Jan 1	$13^h\ 04^m$	$0^h\ 59^m$	July 1	$1^h\ 11^m$	$13^h\ 03^m$
Feb 1	11 01	22 52	Aug 1	23 06	11 01
Mar 1	9 10	21 02	Sept 1	21 05	9 00
Apr 1	7 08	19 00	Oct 1	19 07	7 03
May 1	5 10	17 02	Nov 1	17 06	5 01
June 1	3 09	15 00	Dec 1	15 08	3 03

Note. The figures given are local civil time (those greater than 12 hr being P M): local time of east or west elongation does not vary more than a min in different parts of the U S. To change to standard time, take difference in longitude between standard meridian and observer's meridian, and convert this into time; 1 hr corresponds to 15° of longitude. Add this to local time if place is west of standard meridian, and *vice versa*. Standard meridians are those divisible by 15. To find the time for a date other than first day of month, interpolate between values given.

Example. Find Central Standard Time of eastern elongation of Polaris on Aug 3, at longitude 91° W of Greenwich. The time for Aug 1 is $23^h\ 06^m$, or $11^h\ 06^m$ P M; the difference is about 2 hr for the month, or about 4 min per day. Hence, for Aug 3, the time is about $10^h\ 58^m$ P M; the place is 1° or 4 min west of Central (90°) meridian; Central standard time is therefore $11^h\ 02^m$ P M.

About 0.5 hr before time of elongation, transit should be set up and star bisected by vertical cross-hair. As it slowly moves right or left toward its greatest elongation it is followed by using lower tangent screw. At eastern elongation the star will be rising; at western elongation, setting. When extreme position is reached, the line may be transferred to a stake on the ground, or an angle measured to a reference line. For greater accuracy, a second observation is made immediately afterward, with telescope in reversed position, the plate bubble being leveled again before sighting. Mean of the results will be free from errors of adjustment.

It now remains to find the true bearing of the line marked out, or the bearing of the star at elongation, which is computed by:

Sin azimuth = *sin* polar distance × *sec* latitude. To establish the meridian line, this angle is laid off to right for western elongation, to left for eastern elongation. This may be done by transit, or by a perpendicular offset measured with tape.

Latitude used in formula need not be known with great accuracy; it may be taken from a map if it can be found within 1 or 2 min of true value. For a direct observation, use following method: If the altitude of Polaris be observed when above the pole (upper culmination), its max altitude found by trial is the meridian altitude. Latitude is then computed by: $L = h - p$. To obtain true altitude h, the measured altitude must be corrected for refraction and for index error. POLAR DISTANCE p is found by finding declination of Polaris in Nautical Almanac, in Table headed "Circumpolar Stars," and subtracting it from 90°. If the star be observed at lower culmination, the polar distance must be added to altitude.

Example, observation for latitude. Observed altitude of Polaris at upper culmination = 43° 37′ 00″; index correction = + 30″; refraction correction = 1′ 01″; hence, true altitude = 43° 36′ 29″. Declination of Polaris is +88° 58′ 24″; polar distance 1° 01′ 36″ and latitude is therefore 42° 34′ 53″ N.

Example, observation for meridian. Direction of Polaris is observed at its western elongation Mch 11, 1938, in latitude 42° 30′ N. Declination of Polaris is +88° 58′ 27″; polar distance, 1° 01′ 33″. Azimuth is computed as follows:

$$\begin{aligned} \log \sin p &= 8.25293 \\ \log \sec L &= \underline{0.13237} \\ \log \sin Z &= 8.38530; \text{ hence, } Z = 1^\circ\ 23'\ 29''\ \text{W}. \end{aligned}$$

This angle is to be laid off to the right, to fix a point on meridian 310 ft N of transit. The offset is found as follows:

$$\begin{aligned} \log 310.0 &= 2.49136 \\ \log \tan 1^\circ\ 23'\ 29'' &= \underline{8.38541} \\ & \ 10.87677; \text{ hence, offset } = 7.530 \text{ ft}. \end{aligned}$$

Azimuth is obtained with greater accuracy by this method than by observation on the sun, provided the instrument is used in both direct and reversed positions, and plate is releveled before each pointing on star.

14. OBSTACLES AND INACCESSIBLE DISTANCES

Random line is often necessary when obstacles occur on a traverse line. If it be required to run line AB (Fig 15), neither end being visible from the other, and there is no intermediate point from which both ends are visible, a random line AX can be run. Measure perpendicular distance CB and also AC. Compute AB by trigonometry (or by method of Art 10, if BC is short and AC long), and set any desired point D on AB as follows: $AE = AD \times (AC \div AB)$, and $ED = BC \times (AD \div AB)$. By this method points on AB can be set without running out and actually measuring line AB. $Tan\ CAB = CB \div AC$.

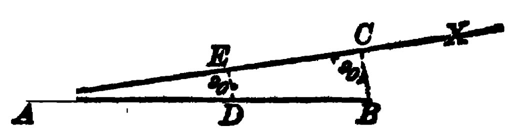

Fig 15. Running Random Line

When a straight line AX can not be run, a traverse from A to B can be run in which line AB would form closing side; its direction and length can then be computed by methods of Art 12 and 17. Any point D can be set on AB by computing its latitude and departure and comparing these with latitude and departure of nearest transit point H on the random traverse, as follows: the difference in their departures divided by difference in their latitudes gives tangent of bearing of line HD, and length is

$$HD = \sqrt{\text{diff lat}^2 + \text{diff dep}^2}.$$

By setting transit at H, pointing in direction of calculated bearing, and laying off distance HD, point D can be accurately set on AB. Since this traverse method involves measurement of angles, it will not lend itself so readily to accurate results as the case first described, where random line is straight. In running any straight line, when necessary to produce the line by reversing telescope, the mean result of a double reversal should always be taken, the telescope being first erect and then inverted, to compensate errors in adjustment.

Running parallel line past obstacle. One of the most exact methods of extending a straight line past an obstacle of limited size is to run a parallel offset line past the obstacle. The instrument is set at B (Fig 16) and BB' is laid off at right angles; BB' is made any convenient distance which will bring the auxiliary line beyond obstacle. Similarly, point A' is set opposite point A; although if AA' be short the transit need not be used for laying off right angle at A. Points A and B must have been accurately set on line. The instrument is then set at B', backsighted on A', the telescope inverted, and points C' and D' set on line. Leaving telescope inverted, another backsight is taken on A', and process repeated to compensate instrumental errors; points C' and D' will be set on mean of these two lines if any errors are evident. Transit is then moved to C', a right angle turned off, and point C set, the distance $C'C$ being made equal to $B'B$. By then setting at C and sighting ahead on $D(DD' = CC')$, the original transit line is then again run forward. Distance $B'C'$ is measured carefully, to give distance BC; this is why it is necessary that lines BB' and $C'C$ shall be laid off at right angles by the transit.

Fig 16. Running Parallel Line Past an Obstacle

The other offsets AA' and DD' are not in any way connected with measurement along the line; they simply define its direction; hence, if convenient, it is often necessary only to show these distances as swing offsets for transitman to sight on. Offsets AA' and DD' should be taken 200 ft or more from obstacle, if practicable.

Should obstacle be in a hollow, so that it is possible to see over it with instrument at A, the point D, or a foresight of some sort, should be set on line beyond obstacle, to be used as foresight when transit returns to original line. The distance may be obtained, as above, by an offset line around obstacle. Sometimes it is possible to place a nail exactly on line on ridgepole of a building (if that is the obstacle), which gives an excellent backsight for extending line on other side.

Equilateral triangle traverse. In Fig 17, set instrument at C, lay off 120°, set stake D a sufficient distance away, measure CD. Then set up at D, lay off 60°, and set point E, making $DE = CD$. Set up at E, lay off 120°, which defines line EB. Evidently $CE = CD = DE$.

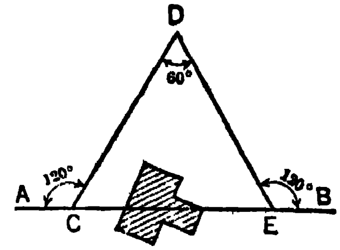

Fig 17. Triangular Traverse Past an Obstacle

To pass obstructed portions of main traverse an auxiliary traverse with small deflection angles may be run which will lie near the former. Since the deflection angles are small the distances measured on auxiliary traverse can be applied as though they were measured on main traverse, from point of departure to point where main traverse is again reached. The simplest case is where an isosceles triangle is formed with main traverse as the base. Suppose at A on main traverse a deflection of 0′ 24′ R is taken to B on auxiliary traverse (AB = 421.7 ft): at B deflection 0° 48′ L (2 × 0° 24′) is turned and BC made 421.7 ft. Then C lies on main traverse and by laying off at C deflection 0° 24′ R, the main traverse line is resumed. This method can be extended to comprise a series of isosceles triangles, the bases of which are either main traverse line or lines parallel to it.

To measure an inaccessible distance, where line is visible, such as across a pond, any of following methods may be employed:

(a) Lay off from transit line AC (Fig 18) a line AB, which clears end of pond and can be taped, and set stake B; then lay off ABC = 90° and set point C by intersecting main transit line. Measure angle CAB and side AB, from which $AC = AB + \cos CAB$; or

better, $AC = AB + AB\ exsec\ CAB$. Angle C and distance CB can be computed, and checked against their field measurements.

(*b*) With instrument at A (Fig 19) and a swing offset of 100 ft from C (some point on

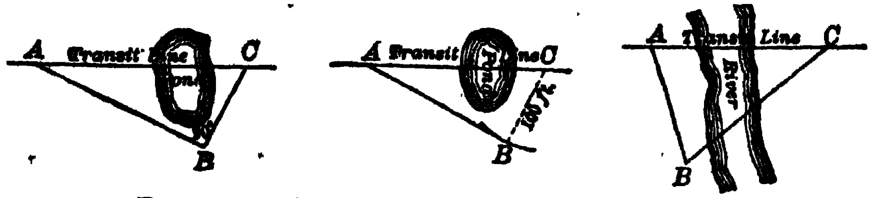

Fig 18, 19, and 20. Measuring Inaccessible Distances

main traverse line on other side of pond) measure angle between CA and a tangent AB to the swing offset. $AC = 100 \div sin\ CAB$.

(*c*) Any line AB (Fig 20) may be laid off along shore of a river, and a point C set on main traverse line across the river. Measure angles A and B, and also C as a check, and from AB as a base compute AC by trigonometry. If AB be made perpendicular to CA and some multiple of 100 ft long, computation is simplified.

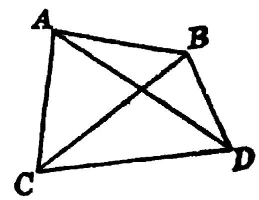

Fig 21

To obtain distance between two inaccessible points A and B (Fig 21), by observations from two accessible points C and D, measure DC and angles ADC, ADB, ACB, and BCD. Compute CB in triangle CBD, AC in triangle ACD, and then in triangle ACB compute AB.

To obtain the inaccessible distance AB (Fig 21) between two accessible points, by observation on two inaccessible points C and D when distance CD is known, measure angles CAD, DAB, CBD, and ABC. Assume $AB = 1$. Then compute CD by process described in above paragraph. This gives a ratio between AB and CD, and since CD is known, the actual length of AB may be computed.

15. RE-RUNNING OLD LINES

In re-running old property lines, surveyor must first determine where original boundaries of property lie, and then survey those boundary lines. He should not attempt to correct original lines, even though sure that errors exist in them. He must first of all look for physical evidence of monuments or other marks, known to have existed on the boundary lines; failing in this, he should base his judgment as to their location on such evidence as occupancy, dimensions stated in deeds, or the testimony of competent witnesses. It must not be assumed that a boundary is missing because not at once visible. Stone bounds are often buried two or three feet deep; the top of a stake soon rots off, but evidences of the stake are often found many years after the top has disappeared, and the supposed location should be carefully dug over to find traces of the old stake.

In interpreting a deed it is assumed that the document was intended to convey property the boundaries of which form a closed traverse. Therefore, if it be found that the omission of a whole chain-length, or the reversing of direction of a bearing, will cause a deed description to close, this change may properly be made. Where record of original survey does not close, deeds of adjoining property are often of assistance. Where artificial features are mentioned as boundaries, these always take precedence over the recorded distances and angles, but such marks must be mentioned in deed to acquire force or authority of monuments. When area does not agree with boundaries, as described in deed, the boundaries control. All distances, unless otherwise specified, are to be taken as straight lines; but distances stated as so many feet along a wall, or highway, are supposed to follow these lines even if not straight. When a deed refers to a plan, the dimensions on this plan become a part of description of property.

Legal boundaries. Where property is bounded on or by a highway, the abutters own the fee to middle line, but where it is an accepted street each abutter yields his portion of street for public use. If, however, the street be abandoned, the land reverts to owner if his deed reads that the property is bounded *on* the street; but if it reads that it is bounded *by* the street he owns no fee in street. If a street has been opened and used for a long series of years, bounded by walls or fences, and there has been no protest regarding them, these lines usually hold as legal boundaries; but if street lines have been defined by proper officials, and evidence of these lines is such that they can be re-run, then the law usually requires a much longer period of occupancy before a private owner can acquire rights from the public in the street. In the case of a line between private owners, acquiescence in location of the boundary will, in general, make it the legal line; but if there be a

mistake in its location, and it has not been brought to attention of the interested parties, nor any question raised as to position, then occupancy for many years does not make it a legal line.

Property bounded by a non-navigable stream extends to the thread of stream, the legal meaning of which is a line midway between shore lines, not necessarily the thread in time of drought. If property be described as running to a river, it is interpreted to mean to low-water mark, unless otherwise stated; if described as running to bank of a river, it means to edge of the uplands; if to shore line, it means to water's edge when stream has its average regimen of flow. Where original ownership ran to shore of a navigable stream, and the water has subsequently receded, the proper subdivision is one which gives to each owner along shore his proportional share of river channel; in general, these lines will therefore run perpendicular to channel of stream from the original intersection of division and shore lines. A more complete statement of the principles mentioned above, particularly with reference to U S Public Land Surveys, will be found in an address on "The Judicial Functions of Surveyors," by Chief-Justice Cooley of Michigan Supreme Court. (*Proc* Mich Assoc of Eng and Surveyors, 1882, pp 112–122.)

Should all evidence of artificial boundaries of a property be missing, surveyor will have to accept deed description as best evidence. If directions of lines be given as magnetic bearings, it is necessary first to determine declination of needle at date of survey. The declination should be stated in deed or on original plan, but frequently it appears in neither. If the date can be established, the declination for that year and place may be obtained from records of local surveyors or from past U S Coast Survey records. If one line can be identified as a boundary, the difference between its present magnetic bearing and its original bearing gives difference in declination directly, and the remaining deed lines can be run out by correcting all bearings by this amount. The chain used in original survey may have been of different length from the one now used; this can be readily determined by measuring length of any well-defined line of the property, and the difference thus found is applied proportionally in measurements locating lost corners.

16. UNITED STATES PUBLIC LANDS

The system. The United States system of surveying public lands, inaugurated in 1784 and since modified by various acts of Congress, requires that public lands "shall be divided by north and south lines run according to the true meridian, and by others crossing them at right angles so as to form townships six miles square," and that corners of townships thus surveyed "must be marked with progressive numbers from the beginning." Also, that townships shall be subdivided into 36 sections, each of which shall contain 640 acres, as nearly as may be, by a system of two sets of parallel lines, one governed by true meridians and the other by parallels of latitude, the latter intersecting the former at right angles, at intervals of a mile. Since meridians converge, it is evident that the requirement that the lines shall conform to true meridians, and also that townships shall be six miles square, is mathematically impossible.

A surveyor whose work lies in a district formerly a part of the U S public lands should procure from General Land Office, at Washington, a copy of "Manual of Surveying Instructions for Survey of the Public Lands of the United States." In this will be found all general and many specific instructions regarding the system, only the general scheme of which is described below.

Subdivision work is carried on as follows: *First*, the establishment of an INITIAL POINT, a PRINCIPAL MERIDIAN, by astronomical observations, which is a true meridian through initial point; and a BASE-LINE, which is a true parallel of latitude through initial point (Fig 22).

These operations are performed in different localities as a basis for surveys in those regions. The principal meridian is a straight line and the base-line a curve, being at every point at right angles to the meridian through that point. The base-line is laid out by first running a straight line and measuring offsets from it to locate points on the parallel of latitude. Two methods are used for this, called the secant method and the tangent method, complete explanations of which, with tables, will be found in the manual issued by the General Land Office.

Second, the division of the area into tracts approx 24 miles square, by establishment of STANDARD PARALLELS, sometimes called CORRECTION LINES, which are true parallels of latitude extending east and west through 24-mile points on the principal meridian; and also establishment of GUIDE MERIDIANS, which are true meridians through 24-mile points on base-line and on standard parallels, and extending north to intersection of next standard parallel or base-line.

Since these guide meridians converge, the tracts will be 24 miles on their southern and less on their northern boundaries (Fig 22). The southerly end of these guide meridians, where they leave the standard parallel or base-line, are called STANDARD CORNERS, and points where they meet the next standard parallel to the north are called CLOSING CORNERS.

Third, the division of each 24-mile tract into TOWNSHIPS (Fig 22), each approximately 6 miles square, by establishment of MERIDIONAL LINES, or RANGE LINES, which are true

meridians through standard township corners, established at intervals of 6 miles on the base-line and on the standard parallels, and extending north to an intersection with the next standard parallel or base-line; also establishment of LATITUDINAL LINES, or TOWNSHIP LINES, joining township corners previously established at intervals of 6 miles on principal meridian, guide meridians, and range lines.

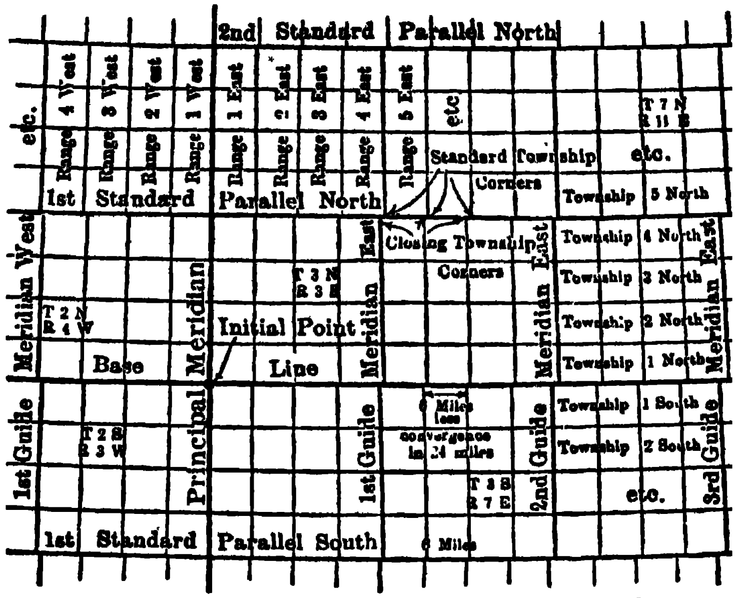

Fig 22. Subdivision of 24-mile Tract into Townships

Neglecting discrepancies in fieldwork, the E and W boundaries of all townships will be 6 miles in length, but the north and south will vary in length, being a max of 6 miles at standard parallel or base-line forming southern limit of a 24-mile tract, and a minimum at that forming its northern limit. Townships are designated by numbering them in order north and south from base-line and east and west from principal meridian. Any series of contiguous townships or sections situated north and south of each other constitute a RANGE, while such a series in an east and west direction constitutes a TIER. Thus "Township 2 North, range 4 west of the sixth principal meridian" locates its position; usually abbreviated to "T 2 N, R 4 W, 6th P M" (Fig 22). The half-mile intervals on range lines are made full 40 chains for the entire 24 miles, except the most northerly half-mile, into which all excess or deficiency due to irregularities of measurement is thrown. Similarly, corners on E and W lines are so placed that excess or deficiency of measurements is thrown into the most westerly half-mile of each latitudinal township boundary.

Fourth, the division of each township into SECTIONS (Fig 23), each approx 1 mile square (640 acres), by establishing SECTION LINES, both meridional and latitudinal, parallel to and at intervals of 1 mile from eastern and southern boundaries of township. Sections in all townships are numbered.

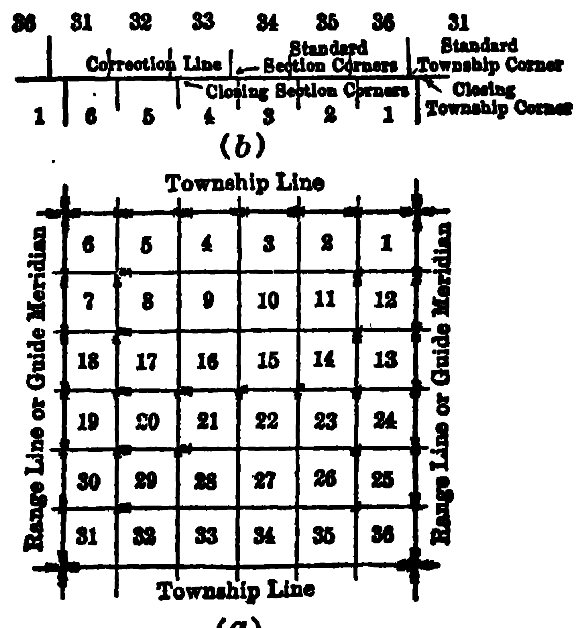

Fig 23. Subdivision of Township into Sections and Method of Marking Corners

In staking out section corners, surveyor sets up instrument at southeast corner of township, observes the meridian, and retraces range line northward 1 mile, and township line westward the same distance. This is for a comparison of his retracement of those lines with the record field notes, to ascertain possible discrepancies to be dealt with. The retracements are extended where necessary. Then from southwest corner of section 36 he runs north on a line parallel with east boundary of township, setting a quarter-section corner at 40 chains and a section corner at 80 chains. Then from section corner just set he runs east on a random line, parallel to S boundary of section, setting a

temporary quarter-section corner at 40 chains. On intersecting the range line he notes the falling of his random line and also distance it overruns or falls short of length of S boundary of section. If the falling is not more than 50 links (33 ft, representing angular deviation of 21 min), and if distance overruns or falls short of length of southern boundary of section 36 by not more than same amount, a return course which will join the two section corners is calculated; this new line is then run toward the W, the permanent quarter-section corner being set at its middle point.

From the section corner just regained, the survey is now continued north between sections 25 and 26, parallel with E boundary of township, the direction being changed slightly to E or W according to whether latitudinal section line just completed exceeded or fell short of desired length. At 40 and 80 chains on this line quarter-section and section corners, respectively, are set: from the section corner a random line is run across to the range line, a return course being calculated and run as before. This process is continued until 5 of the 6 sections in the series are enclosed. Then, if N boundary of township is not a correction line, from the section corner last established a random is run N to township boundary, and from data thus secured a true line is calculated and run from section corner on township line back to initial corner. If N boundary of township is a correction line, however, the point at which the random intersects this boundary is established as a CLOSING CORNER, and its distance from nearest STANDARD CORNER is measured and recorded. In either case the permanent quarter-section corner is established at 40 chains north of the initial corner, the excess or deficiency being thrown into the most northerly half-mile.

In a similar manner the succeeding ranges of sections are enclosed, randoms being run eastward to section corners previously established, and true lines corrected back. But, from the fifth series of section corners thus established, random lines are projected to westward also, and are closed on corresponding section corners in range line forming western boundary of township. In correcting these lines back, however, the permanent quarter-section corners are established at points 40 chains from initial corners of the randoms, thereby throwing all fractional measurements into the most westerly half-miles. This method of subdivision is shown in Fig 23.

Subdivision of sections. When public lands were parceled out to settlers, the quarter-section was usually the unit area granted as a "homestead"; this required establishment of the quarter-section corner at center of a section. Also, the subsequent division of original "quarters" into "eighties," "forties," or other minor subdivisions, has necessitated location of numerous corners in addition to those originally established by government.

The interior quarter-section corner of a section is always located at the intersection of straight lines joining quarter corners on opposite sides of section. This holds wherever the section may be located within township; that is, it applies to those in N and W sides as well as to other sections of township. A modification of this method is required in W and N sides of a township; in case of sections lying in W range the meridional line from the quarter corner on N or S boundary of section is run parallel to E line of section; similarly, in case of sections lying in N tier, the latitudinal interior line initiated at the quarter corner on E or W boundary is run parallel to S line of section. The reasons for this procedure in these special cases are apparent from consideration of methods previously described for establishment of original quarter-section corners in such sections. For subdivisions smaller than quarter-sections the same general methods are employed. Normally, no modification of this method is required, except that in a fractional section, where no opposite corresponding quarter-section corner has been or can be established, the center line must be run from the proper quarter-section corner as nearly in a cardinal direction as due parallelism with the section boundaries will permit.

In current practice, beginning in 1908, all regular corners are marked with an iron post having a bronze cap, and filled with concrete; older corners are marked by various kinds of monument, depending upon character and importance of the corner to be perpetuated, the soil, and materials available. Stone or wooden posts are common. Where these materials are not available, a mound of earth may be raised over the corner, a small marked stone, a charred stake, or a quart of charcoal, being deposited beneath it. Occasionally, in timber lands, the corner falls on a spot occupied by a tree, which may stand as the monument.

Stones or posts are marked with horiz notches, to indicate their respective positions in the township. Section corners on range lines, including under this term principal and guide meridians, are marked with notches on their north and south faces, the number of notches being equal to number of miles to next adjacent township corner north or south. Similarly, section corners on township lines, including base-lines and standard parallels, are notched on their east and west faces. Township corners, being located on both range and township lines, are marked with six notches on each of the four sides. Besides being notched, corners on correction lines are marked SC on their northern or CC on their southern faces, depending upon whether they are standard or closing corners. Section corners in interior of a township are given notches on their east and south faces, corresponding to number of miles to east and south boundaries of township. Thus, the corner common to sections 20, 21, 28, and 29 would have two notches on south and four on east face, as indicated in Fig 21. Quarter-section corners are marked with the fraction "1/4," those on meridional lines on their west and those on latitudinal lines on their north faces. Wherever possible, a monument set at a corner is witnessed by several nearby objects which may easily be found, are not readily moved or obliterated, and are comparatively permanent. In timbered country the stone or post is usually witnessed by "bearing trees," situated near the corner.

Field notes. Duplicate copies of all field notes and plats of public land surveys are on file in the General Land Office. The notes contain complete descriptions of all corner monuments, and give in narrative form complete data of alinement and topographic features crossed or near the lines. Original notes and plats of these surveys in the following states have been transferred to the state authorities, from whom may be obtained copies on request.

Alabama, Secretary of State, Montgomery; Arkansas, Commissioner of State Lands, Little

Rock; Florida, Commissioner of Agriculture, Tallahassee; Illinois, Auditor of State, Springfield; Indiana, Auditor of State, Indianapolis; Iowa, Secretary of State, Des Moines; Kansas, Auditor of State and Register of State Lands, Topeka; Louisiana, Register of State Lands, Baton Rouge; Michigan, Director, Dept of Conservation, Lansing; Minnesota, Secretary of State, St. Paul; Mississippi, Commissioner of State Lands, Jackson; Missouri, Secretary of State, Jefferson City; Nebraska, Commissioner of Public Lands and Buildings, Lincoln; North Dakota, State Engineer, Bismarck; Ohio, Auditor of State, Columbus; Oklahoma, Commissioner of General Land Office, Wash, D C; South Dakota, Commissioner of School and Public Lands, Pierre; Wisconsin, Commissioners of Public Lands, Madison.

In many of the states, copies of the field notes and plats have been secured for the various counties, and are kept for reference and inspection in office of County Register of Deeds, County Surveyor, or other official.

Photo-lithographic copies of township plats and field notes of surveys of area covered by public land surveys in above states may also be obtained from General Land Office, Washington, at nominal prices. In other public-land states, copies of records can be procured on application to Surveyor General at State Capitol, except in California and Oregon, whose Surveyors General are at San Francisco and Portland respectively.

Surveys are continuing in the other public-land states, where the records may be examined in the U S public survey offices, as follows: Arizona, Phoenix; California, Glendale; Colorado, Supervisor of Surveys, Denver; Idaho, Boise; Montana, Helena; Nevada, Reno; New Mexico, Santa Fé; Oregon, Portland; Utah, Salt Lake City; Washington, Olympia; Wyoming, Cheyenne; Territory of Alaska, Juneau.

Relocating lost corners. An act of Congress specifically provides that corners actually located in the field shall be established as proper corners of sections or quarter-sections which they were intended to designate, irrespective of whether or not they were properly located in the first place. A further provision is that " the boundary lines actually run and marked " (in the field) " shall be established as the proper boundary lines of the sections, or subdivisions for which they were intended, and the length of such lines as returned by . . . the surveyors aforesaid shall be held and considered as the true length thereof." The principles upon which present practice in relocating corners of original surveys are based are given in " Circular on the Restoration of Lost or Obliterated Corners and Subdivisions of Sections," published by General Land Office, Washington.

17. SPECIAL PROBLEMS

To straighten a crooked boundary. The new division line AB (Fig 24) is to be a straight line, so laid out as to make no change in areas of lots P and Q. First run trial line AC. Measure necessary offsets to the crooked line and compute areas X, Y, and Z lying between AC and the crooked boundary (Art 12). The condition desired is that $X + Z = Y$. As difference between $X + Z$ and Y is the amount which the trial line has taken from one parcel and given to the other, the whole difference must be returned to proper lot.

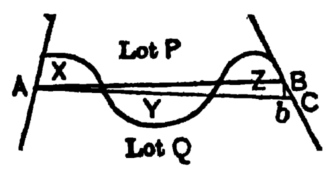

Fig 24. To Straighten a Crooked Boundary

For example, suppose Lot P originally contained 20 000 and Q, 30 000, and it is found that area $X = 500$, $Y = 800$, and $Z = 600$. The trial line has, therefore, made lot $P = 20\,000 + 500 - 800 + 600 = 20\,300$, and lot $Q = 30\,000 - 500 + 800 - 600 = 29\,700$. Lot P has been made 300 too large and lot Q 300 too small, which is equal to $X + Y - Z$. This 300 must be taken from lot P and returned to lot Q by running line AB in such manner that the area of triangle $ACB = 300$. Multiply area of triangle ACB by 2 and divide product by AC. This gives perpendicular bB, from which, together with angle at C, compute BC and set point B. Compute AB and its bearing.

Supplying closing side of a traverse. If the latitudes and departures of the several courses of a traverse which does not close be computed, the algebraic sum of latitudes gives latitude of closing side, and the algebraic sum of departures gives departure of closing side (Art 12). The tangent of its bearing is its departure divided by its latitude; length of closing side is the latitude divided by *cos* of bearing, or departure divided by *sin* of bearing.

To cut off a given area by a straight line MX from a given point M on one of the sides of a field. Plot the field and known point; draw a trial line ML from this point to a corner on other side of field, so as to lay off approximately the required area. The purpose of the plot is simply to determine to which corner to draw this trial line. As lengths and bearings of all lines except ML are known, its length and bearing can be computed as above, and the area of portion cut off by ML computed. The difference between this area and required area is a triangle MLX, of which trial line ML is the base; the altitude Xa can be computed by dividing twice the area by ML. The distance along side LX can then be computed, since it is the hypotenuse of right triangle LaX. The length and bearing of required closing side MX, which is hypotenuse of right triangle MaX, can now be computed, and the total intercepted area calculated, as a check.

To find area cut off by a line in given direction from given point. Let the cut-off line be AM. This problem may be solved by drawing a line from A in the traverse to corner E, which lies nearest other extremity M of cut-off line. The area of portion of traverse cut off by AE is then computed (Art 12) and to this area is added, or from it is subtracted, the area of triangle AEM.

Setting batter-boards for a foundation. For a brick or stone foundation the lines to be defined are the outside lines of building, and the elevation desired is usually the top of first floor. For a wooden building, the line usually given is outside line of brick or stone underpinning, and the elevation given is top of this underpinning, on which sill of structure is to rest. Sometimes the outside line of sill is desired, instead of outside line of underpinning; there should be a definite understanding in regard to these points before work of staking out is begun.

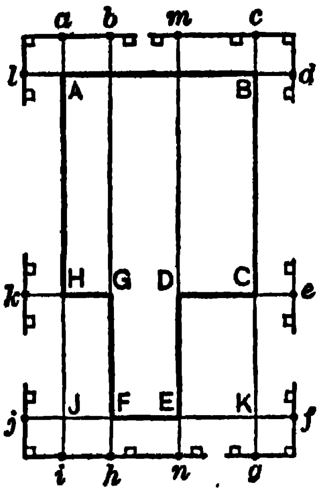

Fig 25. Setting Batter-boards for a Foundation

First stake out accurately the location of building by temporary stakes at all corners, as in Fig 25, at A, B, C, D, E, F, G, and H. Set stakes at J and K also, so that entire work can be checked by measuring diagonals AK and BJ, AC and BH. These checks should always be applied where possible. The posts for batter-boards are next driven into the ground 3 or 4 ft outside line of cellar, so that they will not be disturbed when cellar walls are being constructed. On the posts, which are usually 2 by 4 in, 1-in boards are nailed. The boards are so set by surveyor that their upper edges are level with top of underpinning, or with whatever other part of building of which the grades are required. After batter-boards are all in place, they should be checked roughly by sighting across them; all should appear at same level. Sometimes, however, on account of slope of ground, some of them have to be set a definite number of feet above or below grade.

The lines are then marked by nails driven in upper edges of batter-boards. The transit is set up on one of corner stakes of house, at B for example, and a sight is taken on K. This line is then marked on the farther batter-board (at g) and on the one near transit (at c). A sight is next taken along BA, this line is produced both ways, and nails are set on batter-boards at l and d. All lines are similarly marked on the batters.

Staking out lines and grades for streets, sewers, and drains. Street lines are usually marked by monuments, but best practice requires that accurate offsets to the underpinning of buildings along the line shall be measured and recorded, so that if monuments be disturbed, by building operations or road building, they can be exactly replaced. These monuments are usually stone bounds 3 or 4 ft long and 4 to 8 in square on top. The stone should be long enough to reach below frost. A drill-hole near center of top marks the point; this drill-hole may be filled with lead and a small copper tack driven into it, or a copper plug may be inserted and exact point marked with a center-punch.

To set a stone bound to take place of a stake marking a corner, first drive four temporary stakes in such manner that cords stretched between tacks in opposite stakes will intersect over the tack in corner stake. Then remove corner stake and dig the hole for the monument, going no deeper than is necessary to set it on firm earth. Then set monument plumb in hole, and fill around it with care, so that mark in top coincides with intersection of strings. Where a very substantial bound is required, or where ground is too soft to furnish a secure foundation, a concrete footing may be put in and concrete filled around monument to within 1 ft of surface.

Grade stakes for sewers or drains are usually set parallel to line stakes and 3 to 6 ft to one side of them, their tops being a full number of feet above flow line of pipe. Some engineers prefer to drive a grade stake to a good bearing and then mark on side of it a line which shall be a full number of feet above flow line. When ground is hard, it is good practice to drive heavy spikes flush with ground and to take the elevation of their tops. Record is made of amount by which the several spikes are above or below grade.

A target rod is especially useful, although a self-reading rod is satisfactory, for "shooting in a grade," which is done as follows: If grade from sta 0 to 5 be straight and if stakes have been set at 0 and 5, the instrument is set up just to one side of sta 0, the rod is held on that grade stake, and target clamped at height of telescope; the rod is then held on stake at sta 5, the telescope is inclined to sight target and clamped. The line of sight is now parallel to grade line, and any intermediate stake may be set by driving it until target is bisected by horizontal hair of telescope when rod is held on stake.

After grade stakes are set, batter-boards are placed to span the trench, the upper edge of every board being a full number of feet above flow line of pipe; they are so set by

leveling from grade stakes by a carpenter's level. The center line is marked on batter-boards by measuring over from line stakes, which have been set on, say, a 4-ft offset line. In absence of engineer, all this work can be done by foreman. It is well, therefore, to set grade stakes and offset-line stakes even though engineer be nearby, for the foreman will then be able to check lines and grades at any time.

To lay off any angle with a tape only, first lay off a perpendicular, say 100 ft from vertex A of angle, by the 3–4–5 method, using any of following combinations of dimensions for the two legs and hypotenuse of right triangle CAB: (3–4–5), (6–8–10), (9–12–15), (12–16–20), (15–20–25), (18–24–30), (21–28–35), etc. On the perpendicular, measure distance BC equal to 100 times natural tangent of angle; angle CAB is the required angle.

LEVELING AND CONTOURS

18. PROFILE LEVELING

Profile leveling consists in determining elev of ground at enough points on a line so that its profile can be plotted and computations made from it. The line is first marked off in 100-ft stations, or at shorter intervals if desired. The level is set up and a reading, called a backsight (B S or + S), is taken on a leveling rod held on a BENCH-MARK (B M), which is a point of which the elev above mean sea level or any other assumed datum plane has been accurately determined. The B S is added to elev of B M, giving height of instrument (H I), or elev of line of sight above datum plane. Rod-readings, called foresights (F S or − S), are then read on as many station points on line as can conveniently be seen from instrument, and elevations of these points are found by subtracting F S readings from H I. Rod-readings are taken at all distinct changes in slope which occur on the line, whether at full-station points or not; such intermediate points are located by tape (sometimes by pacing) and recorded as plus stations, as shown below.

When necessary to move level to a new position along line, a TURNING POINT (T P) is selected and its elevation determined, to be used at the next set-up of level for computing its new H I. When new H I is found, by a backsight, F S readings are taken at points ahead on the line, after which the elevation of a new T P is established, and so on. The turning point may be a regular station, or any other solid point.

Usually B M's are established before profile levels are run, in which case readings should be taken on those B M's which are passed during profile leveling, and all such B M's should if possible be used as T P's. If B M's have been previously established, the closing check is made on the B M nearest end of line of profile levels, as indicated in above notes. Sometimes the line of levels is made to form a closed circuit by returning to original

B M. By comparing its final elevation with that used at beginning of the work, the error of closure is ascertained as a check on the T P readings, although a mistake may still occur in an individual reading at a station point.

Bench-marks should be chosen with regard to permanence, and should be points readily described and found. The rod readings on B M's and T P's should usually be taken to one more decimal place than those read for profile. To eliminate errors of adjustment, the distances between level and rod, when held on a T P or B M, should be about equal for backsight and foresight. The proper length of sight will depend upon distance at which rod can be read distinctly, and upon the precision required. Generally, sights should not exceed 300 ft where elevations are required to nearest 0.01 ft, and even at a much shorter distance "boiling" of the air may prevent such precision.

Calculation of level notes may be checked by computing the sum of the backsights and of foresights on the first and last bench-mark and on intermediate turning points; the difference of these sums should check the difference in elevation between first and final bench-marks. It is well to apply this check at bottom of every page of level notes. If station points have been marked in advance of the level party, two experienced men can run a line of profile levels over country smooth enough to permit a set-up every 600 ft, at rate of about 1 mile per hr, or say 10 set-ups per hr.

Double rodded lines are frequently adopted when it is impracticable to complete a circuit, or for a profile through new country, where no B M's have been established. Instead of foresighting on a single T P, readings are taken on two different T P's, near together and varying in elevation by at least 1 ft. From next set-up, a backsight is taken on each T P and two H I's are computed, which should agree within whatever limit of error is allowable for class of work in hand. This is an excellent method; it requires little more time than to run a line of levels by the ordinary method described above, and gives a valuable check at every new set-up, by detecting mistakes as soon as made.

Precise levels for establishing B M's are sometimes run by a precise level (Art 5), or by taking the following special precautions with ordinary level. The observations are made in such manner as to eliminate the recognized common errors in leveling, which are: (*a*) settling of level on soft ground; (*b*) unequal expansion and contraction of parts of instrument, due to changes of temperature; (*c*) variable refraction of air near ground; (*d*) unequal length of backsight and foresight; (*e*) selecting unstable turning points; (*f*) rod not held plumb; (*g*) bubble not in center of tube at instant of reading.

Errors due to settling of tripod are eliminated by making two readings on backsight and two on foresight at each set-up, in following manner; first, B S is read, then F S; F S is then read again, and lastly B S once more; two rodmen are employed. Correct elevation of T P is obtained from average B S and F S readings. Errors due to changes of temp may be partly prevented by shortening time between reading of B S and F S; in all cases, the instrument should be shielded from sun's rays, and from wind, by an umbrella or special shield. Rapidity is of great advantage in eliminating errors due to settling of tripod. Errors due to refraction of air may be partly avoided by using long-legged tripods, setting the level high above ground, and by making observations in the middle of the day, rather than in early morning or late afternoon. Backsights and foresights are kept nearly equal in length by reading these distances with the stadia hairs; notes should be so kept that they will show at a glance whether the sums of F S and B S distances are equal or not. A foot-plate or wooden pin may be driven into the ground to use for a T P, when a satisfactory point can not be found at proper distance from instrument. To aid in holding rod plumb various types of spirit-level are used.

In work of precise character, allowance must be made for curvature of the earth and refraction of atmosphere. These corrections are usually combined, and amount to the following: for sights of 300 ft, combined correction is 0.002 ft; for 500 ft, 0.005 ft; for 1 000 ft, 0.020 ft. The correction is applied by subtracting it from any single rod-reading, but if rod be held equally distant from instrument on F S and B S, the effect of curvature and refraction is compensated.

Allowable errors in precise leveling of various surveys are as follows: U S Coast Survey, $4^{mm} \times \sqrt{\text{kilometers}}$; U S Lake Survey, $10^{mm} \times \sqrt{\text{kilometers}}$; Mississippi River Survey, $5^{mm} \times \sqrt{\text{kilometers}}$; U S Geological Survey, $0.017^{ft} \times \sqrt{\text{miles}}$. Results actually reached fall well within these limits. A high grade of leveling has been done on the Barge Canal Survey of New York with an ordinary Y-level of good construction; allowable error of closure was only $0.02^{ft} \times \sqrt{\text{miles}}$. An accuracy almost equal to that attained by a precise leveling instrument can be reached with ordinary Y-level or the dumpy level, but not so economically.

19. CROSS-SECTION LEVELING

Leveling for cross-sections is required for determining volume of material, whether excavated from a cutting or a borrow-pit, or removed by hydraulic mining, or occurring in a mine dump. The entire upper surface of volume is divided by transit and tape into 10- to 100-ft squares (or rectangles); elevations to nearest tenth are taken at all corners of squares, and at as many intermediate points as necessary, in case of irregular ground. Lines running in one direction are usually lettered, numbers being used for the other system of lines. Thus, point F, 8 lies at intersection of line F and line 8; and an intermediate point (not at a corner) is designated thus $(H + 6,\ 7 + 2)$, which means that it lies 6 ft from line H toward line I and 2 ft from line 7 toward line 8. By laying out and leveling over the same system of cross-section lines, before and after excavation, the differences between original and final elevations at corners give lengths of vertical edges of a series of vertical truncated rectangular prisms. Toward edges of a borrow-pit, for example, will probably occur several triangular and trapezoidal truncated prisms. If A = area of horiz section of truncated prism, h_1, h_2, h_3, h_4 = lengths of vert edges of prism, and V = vol, then:

For truncated triangular prism, $V = A \times (h_1 + h_2 + h_3) \div 3$.

For truncated rectangular prism, $V = A \times (h_1 + h_2 + h_3 + h_4) \div 4$.

When additional elevations are taken at intermediate points, a rectangular prism should be divided into triangular prisms; the additional measured height forms the vertical edge at one corner of each triangular prism. Where several rectangular prisms occur, having same area of cross-section, A, the computation of volume may be simplified thus: Volume of assembly of truncated rectangular prisms $= A(p_1 + 2\,p_2 + 3\,p_3 + 4\,p_4) \div 4$, in which p_1 = sum of heights common to one prism, p_2 = sum of heights common to two prisms, p_3 = sum of those common to three, p_4 = sum of those common to four.

If several intermediate elevations have been ascertained, it is well to compute volume from original surface down to some plane below final surface. Then make similar computations for volume between final surface and the same plane. The difference between these two volumes will give required volume.

Road cross-sections, as a basis for estimating quantity of earthwork in railroad or highway construction, are taken by a method entirely different from the above. From plan of proposed road its alinement is staked out, a profile is taken along center line (Art 18), and is subsequently plotted. On this profile the grade line is drawn, which corresponds either to sub-grade or to finished grade of road. Roads are usually first finished to sub-grade, which is below the completed surface by an amount equal to thickness of road covering, as pavement of a highway, or ballast of a railroad. The width of base of road and inclination of side slopes are known. For ordinary earth the slope is usually 1.5 ft horiz to 1 ft vert, called "a slope of 1.5 to 1."

For construction work the engineer sets grade stakes at every full station, or oftener, on center line, and slope stakes at both sides, where finished slope will intersect surface of ground. All three stakes are marked, stating amount of "cut" or "fill" to be made at center point, or, in case of slope stakes, stating the vertical distance from base of the road to surface of ground at these points. Cross-sections are taken not only at every full station, but at every distinct change in slope along center line, and also where surface on either side of center line demands an intermediate section properly to represent the volume included between cross-sections. Cross-sections are taken perpendicular to center line of road, and radially on curves.

To find the cut or fill at the center, set up the level and find the H I to nearest 0.01 ft, by sighting on nearest station or bench-mark of which the elev is known. From the profile obtain grade elev at given station. The H I minus grade elev gives ROD-READING FOR GRADE, which is computed to nearest 0.1 ft. Take a rod-reading on ground at center stake; the difference between rod-reading for grade and surface rod-reading gives cut or fill at that point. It is customary to record cuts as + and fills −. The surface elev is obtained by adding the cut to grade elev, or by subtracting, in case of fill. A grade stake on center line is marked with cut or fill, thus: "C 3.2" or "F 6.7."

Slope stakes are set at the points where side slopes meet surface. These stakes are also marked with the distance the ground lies above or below base of section; it is called the cut or fill at the side slope, but, strictly speaking, there is no cut or fill at slope stakes. The position of a slope stake is found by trial as follows: In the case of a cut, estimate from the center cut just determined, and from slope of surface, what the probable side cut will be. The distance from center stake to a point on side slope having this cut equals ($1/2$ base + cut × slope). Make this computation roughly, measure out this distance from center stake, and take a rod-reading at that point. The rod-reading for grade (distance from H I to base of section) minus this surface rod-reading gives cut at trial point. Compute the exact distance out from center stake to a point on side slope having this cut. If this computed distance equals measured distance from center to rod, the trial point was correct·

if not, a second trial must be made by holding rod on another point and repeating operation; the difference between measured and calculated distance aids in judging where to hold the rod for second trial. When correct point is found, at which the measured distance equals calculated distance, the stake is marked " C," followed by the vert distance this point lies above the base. The depth of cut, and distance from center to slope stakes, are entered in notes. The same process is repeated for slope stake on other side of center. Rod-readings are taken at intermediate points on the cross-section, if needed to define shape of surface; their positions are located by measuring distances from center stake, while the cuts at these points are the differences between rod-reading for grade and surface rod-readings. The field notes of a section of embankment having 30-ft base and slopes 1.5 to 1, which required 4 readings to represent its slope properly, would be entered thus: $\frac{21.3}{-4.2}$ $\frac{14.7}{-6.1}$ -3.2 $\frac{17.1}{-1.4}$.

The area of each cross-section may be computed by dividing it into triangles, or cross-sections may be plotted and their areas determined by planimeter (Art 6). By the end area method the volume between sections A_1 and $A_2 = \frac{1}{2}(A_1 + A_2) \times$ distance between sections.

Cross-sections for dams, canals, and other engineering structures are begun by making short profiles at right angles to line of structure, at intervals of 10 to 100 ft, depending upon conditions, and extending far enough on either side to include the possible location of structure. These cross-section lines, representing the surface, are plotted for each station, and on them are also plotted the cross-sections of proposed completed structure at the respective stations. This gives a complete record of conditions before work is started, and as it progresses a continuous graphic record of work may be kept from month to month by use of different colored lines on the various cross-sections.

Masonry volumes are computed either by methods of solid geometry or by the Prismoidal Formula: Vol $= L \div 6\,(A_1 + 4\,M + A_2)$, in which L is the length of the solid, A_1 is cross sec area at one end normal to length, A_2 is cross sec area of other end, and M is cross sec area midway between the two ends, which is seldom the aver of the end areas.

20. BAROMETRIC LEVELING

The barometer is based upon the principle that atmos pressure is a function of elev above sea level, a change of 1 in in mercury column corresponding to a change of about 900 ft in elev. Atmos pressure varies also with changes in temp and humidity, whence it is necessary, while measuring differences of altitude with a barometer, to determine these variations and make proper allowance for them. Both mercurial and aneroid barometers are used in surveying, but the latter, due to its compactness, is generally employed.

Barometric leveling is used for reconnoissance, or for determining contours for a small-scale map. With an aneroid, results as close as 10 ft may be obtained, but not without repeating observations and using instrument with great care. The error in elevations determined by barometer is approx constant, whence the percentage error is smaller for large differences in elevation than for small differences. The barometer does not give actual elevations, but the difference between two readings will be a function of difference in elev of the two points, provided atmospheric conditions have not so changed as to affect readings.

The aneroid barometer has two scales, the inner one corresponding to inches of mercury and the outer one to feet of altitude, the zero of the altitude scale being, in most instruments, at 31 in on mercury scale. The outer scale *should not be movable* with respect to inner scale, for the number of feet of altitude corresponding to 1 in of mercury varies in different parts of scale. Aneroids marked "compensated" are supposed to be so adjusted that changes in temp of the instrument will not affect readings. The instrument should be handled carefully, to avoid disturbing its delicate mechanism. When it is to be read, tap the case lightly to make sure that the instrument has adjusted itself to the changed pressure; it should then stand a few minutes to allow it to come to the true reading. It should not be heated by the sun nor by the body. It may be held in either vertical or horizontal position when being read, but as the readings in these two positions are different it should be held in same position at all stations. As accurate results may be obtained from small as from large aneroids.

The best method of determining elevations by barometer is to use two instruments, one being kept at a fixed station of known elev and read at regular intervals to indicate changes in atmos pressure, while the other is carried to the various points of which elevations are to be determined. The differences in elevation shown by the traveling barometer, corrected for differences indicated by fixed barometer, will be the true differences in elev. The time should be noted whenever the field barometer is read, in order to apply proper correction as indicated by the fixed barometer. Air temp should always be noted whenever barometer is read. If only one barometer be available, it should be read at initial station

and again at same station after completing the other observations, atmos changes during the interval being interpolated from difference between first and last readings.

For Determining Difference in Elevation by Barometer

Barom Inches	Feet	Barom Inches	Feet	Barom Inches	Feet	Barom Inches	Feet	Barom Inches	Feet

Calculating the altitude. The Laplace formula for calculating difference in elevation (neglecting small corrections) is:

$$D = 60\,158.6\,(\log h - \log H)\,\{1 + (t_a' + t_a - 64°) \div 900\},$$

where D = difference in elev in feet; h = height of mercury at lower station in inches; H = height of mercury at upper station in inches; t_a' and t_a, the observed air temp, Fah. The temp correction is the only one necessary to apply to the aneroid; it is often large. In case a mercurial barometer

is used, H is height of mercury at upper station reduced to temp of mercury at lower station by the equation:

$$H = h' \{1 + 0.00008967 (t_m - t_m')\},$$

where t_m = temp of mercury at lower station and t_m' = temp of mercury at upper station. Table on preceding page, condensed from that of Guyot, is based on the Laplace formula; it gives the values of log height × 60 158.6.

Example, using one aneroid to find difference in elev between Neponset River and Blue Hill:

Station	Time	Inches, barom	Air temp
Neponset River	1.00 p m	30.395	53° F
Blue Hill	1.45 "	29.730	47
Neponset River	2.25 "	30.390	42

Time going up = 45 min; total time = 85 min. Difference in readings at lower station = 0.005. Probable reading at Neponset River at 1.45 p m = 30.395 − (45 ÷ 85 × 0.005) = 30.392 in.

From barometric table 30.395 in = 29 042 ft
29.730 " = 28 466
Difference = 576 ft
Temp corr = 576 [{1/2 (53 + 42) + 47} − 64] ÷ 900 = + 20
Difference in elev = 596 ft

Boiling-point thermometer. Great differences in elev may be determined roughly by means of the boiling-point thermometer. Such measurements depend upon the fact that the boiling point of water diminishes as atmos pressure diminishes and therefore the temp of boiling point is a function of the height of the instrument. The observation consists in noting temp of boiling water by a thermometer placed in a boiler made especially for the purpose. The approx height above sea level may then be found by referring to the following table.

Boiling point (Fah)	Alt in feet above sea level	Boiling point (Fah)	Alt in feet above sea level
190	11 720	208	2 050
195	8 950	209	1 545
200	6 250	210	1 020
202	5 185	211	510
204	4 130	212	0
206	3 085	213	−505

This table is taken from Wilson's *Topographic Surveying.*

21. CONTOURS

A contour line is the intersection of a level surface with surface of the ground. The shore line of a lake is a contour, and if lake level were raised 1 ft the new shore line would be of different shape and would form a contour line of 1 ft greater elevation. Contours, therefore, connecting points of same elevation, can be used to represent the slope of ground, and provide a means for reading directly from a map the approximate elevation of any point. Contours are usually located a full number of feet above the datum and at regular intervals, say, every 5, 10, or 50 ft; the number marked on contour is its elevation above datum.

Characteristics of contours are: (*a*) All points on any contour have same elevation. (*b*) Every contour closes on itself, either within or beyond limits of map. (*c*) A contour which closes within limits of map encloses either a summit or a depression. In depressions will usually be found a pond or a lake; but where there is no water the contours are usually marked in some way to indicate a depression. (*d*) Contours can never cross one another, except where there is an overhanging cliff, in which case there must be two intersections. (*e*) On a uniform slope contours are spaced equally. (*f*) On a plane surface they are straight and parallel. (*g*) In crossing a valley, contours run up the valley on one side and, turning at the stream, run back on other side. Since contours are always at right angles to the lines of steepest slope they will generally be at right angles to the thread of stream at point of crossing. (*h*) Contours cross ridge lines (divides) at right angles.

If a line be drawn across a contour map, the profile of that line may be constructed, since the elevations of points at which contours are cut by the line are known, and horizontal distances between these points can be scaled or projected from the map. Conversely, if profiles of a sufficient number of lines are given, it is possible to plot these lines on a map, mark the elevations, and sketch the contours.

In locating contours it should be borne in mind that they can be interpolated on uniform slopes and that the data necessary to obtain in the field are therefore elevations of characteristic points on profiles, such as tops of knolls, low places in valleys, profiles of ridges and of streams. Contours are usually farther apart at top and bottom of a natural eroded slope (where no wave action is present) than in middle. Where contour interval is small, and much detail is desired, the ground may be cross-sectioned (Art 19) and from elevations thus determined contours may be sketched; or contours may be actually traced out and located in the field by stadia; in this case the rodman moves up or down slope until a level rod-reading shows that the foot of his rod is on a contour. The position of rod is then located by distance and azimuth (Art 23).

A hand level (Art 5) is often used to determine elevation of additional points, taking elevations of points on transit line as B M's, as follows: First measure distance from ground to levelman's eye, which may be, say, 5.2 ft. Then, from a reading of the rod held on a point of known elevation the height of levelman's eye is determined. The leveler then directs rodman uphill or down until rod-reading is such as will correspond to that computed for a contour; the point thus found is located by tape or by pacing. If contours are being located on a side-hill, the levelman then moves uphill past the located point, on which rodman stands, until he reads the contour interval plus 5.2 on the rod; he is now standing on a contour, which is then located by taping. The levelman remains on this point, while rodman travels uphill until levelman reads on rod 5.2 minus the contour interval; rod is now resting on the next higher contour. In going downhill, the rod is held on a contour while levelman backs down the hill until he reads 5.2 minus the contour interval, when he will be standing on contour next below rodman; the rodman then passes levelman and backs down the hill until the rod-reading is 5.2 plus the interval, which determines next lower contour. Hand-leveling is not accurate enough to be used for more than about 400 ft away from a B M. If several profiles be run along characteristic lines, to be plotted on map, and then a few necessary side shots be located by hand level, contours can be sketched. The best method of locating contours is by stadia or plane-table methods (Art 22 to 25).

TOPOGRAPHIC, AERIAL, MINERAL AND RAILROAD SURVEYING

22. STADIA METHOD

The stadia method measures distances by observing, through telescope of a surveying instrument, the space on a graduated rod intercepted between two horizontal hairs, called STADIA HAIRS, which are spaced equal distances above and below the middle horizontal cross-hair. When rod is held at different distances from instrument, proportional spaces on the rod will be included between the stadia hairs. This is a rapid method of measuring distances while filling in details of topographic and hydrographic surveys. It has the great advantages that the intervening country does not have to be traveled, that inaccessible distances, as across water surfaces, can be measured, that errors of measurement are compensating rather than cumulative, while its accuracy is sufficient for many kinds of work, even for determination of area in some cases since an accuracy of one part in 500 may be attained with the stadia. STADIA RODS are described in Art 1.

Fundamental principle of the stadia is the geometric theorem that in similar triangles homologous sides are proportional. The common vertex of the triangles, in this case, is not the center of the transit, but a point in front of telescope objective, at a distance equal to F, the focal length of objective. Hence the distance from center of instrument to rod, when the sight is horiz and the rod vert $= (F \div i)s + (F + c)$, where i is distance between upper and lower stadia hairs, s is the intercepted space on the rod, and c the distance from center of instrument to objective. Evidently $(F + c)$ is practically a constant for any given instrument (varied only by focussing the telescope); for ordinary purposes it is taken as 1 ft for transits and 2 ft for plane-table alidades. The other function $(F \div i)\ s$ is a variable, but as it is customary to space stadia hairs so that $F \div i = 100$, the equation for transit instruments reduces to: *distance* $= 100\ s + 1$. Every 0.01 ft on rod therefore corresponds to a distance of 1 ft.

Inclined sights. It is necessary always to hold rod vertically when readings are being taken. When line of sight is inclined, the distance intercepted on a vert rod represents a distance greater even than the inclined distance to rod, while inclined distance is greater also than horiz distance. All inclined readings must therefore be reduced to the

horiz, and if difference in elev between instrument station and rod station is desired the vert distance also must be computed from the inclined sight.

By trigonometry, making one slight assumption, it may be shown that in Fig 25a:

$$\textit{Vertical Distance} = (F + i)\, s \times {}^1/_2 \sin 2\alpha + (F + c) \sin \alpha.$$

$$\textit{Horizontal Distance} = (F + i)\, s \times \cos^2 \alpha + (F + c) \cos \alpha.$$

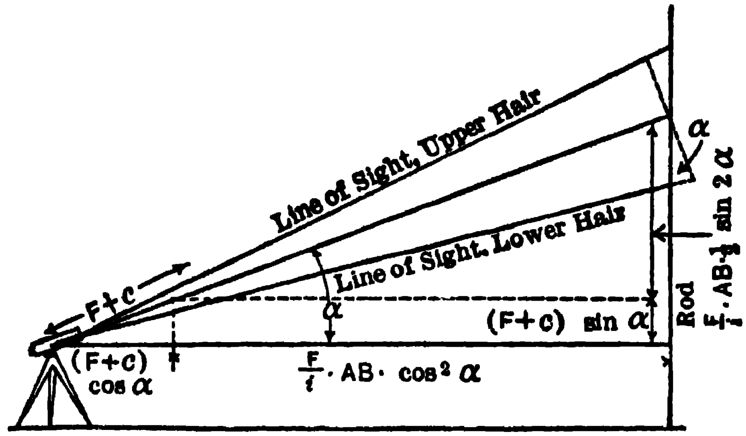

Fig 25a. Diagram of Stadia Reading

For the ordinary conditions (when $F \div i = 100$, and $F + c = 1$), and making the approximations that $\sin \alpha = {}^1/_2 \sin 2\alpha$, and that $\cos \alpha = \cos^2 \alpha$, in last terms of above formulas, which assumptions are nearly true for small angles,

$$\textit{Vertical Distance} = (100 \times \textit{rod interval} + 1)\ {}^1/_2 \sin 2\alpha.$$

$$\textit{Horizontal Distance} = (100 \times \textit{rod interval} + 1) \cos^2 \alpha.$$

These are the formulas used for ordinary stadia work. The reduction of field-notes can be best accomplished, however, by use of tables, diagrams, or stadia slide-rules, all of which are based upon these formulas.

23. STADIA FIELDWORK

Points are located by (*a*) azimuth, (*b*) distance, and (*c*) angle of elev or depression. If elevations are not required, the vert angle is read only to nearest 10 min, since that is close enough for determining horiz distance; but if elevations are required, vert angles should be read to nearest minute, sometimes to half-minute, and vernier index correction noted for each important vert angle. Distance and azimuth angle are read with whatever refinement is necessary for work in hand; as a rule, distances are recorded to nearest foot, and azimuths to nearest minute, although for side-shots, which are to be plotted by protractor, the azimuth to nearest 5 min is close enough. Traverse lines which control the survey are measured by tape, or by stadia, as accuracy of survey may demand. Some surveyors prefer to run traverse lines by transit and tape; then to take a level over traverse to determine elev of certain transit stations, boulders, or other bench-marks, thus establishing an accurate skeleton for a stadia survey, which follows over same ground for filling in details. For large-scale maps it may be advisable to tape the courses of control survey, but for small-scale maps the stadia method is sufficiently accurate. In latter case, distances should be read on both foresight and backsight.

Azimuths. In starting a survey, if the true azimuth of any course be known, all azimuths of survey may refer to the true meridian; but if no meridian has been established, as is frequently the case, the azimuths may be referred to magnetic meridian, or to any other arbitrary direction. Azimuth angles are most commonly read from the south clockwise for 360°. The horiz vernier is set on 0°, the telescope turned to point toward magnetic S, and lower clamp tightened. The upper clamp is next loosened and telescope sighted on next station; the horiz arc is then read clockwise to determine azimuth of first course, referred to the magnetic meridian through first station. The azimuth to any other point is obtained by sighting telescope on it and reading the vernier, the lower motion remaining clamped. On moving to the next instrument station, the telescope is oriented by inverting and backsighting, as explained in Art 11. Magnetic bearings of courses may be noted as a rough check on azimuths.

Distances are read by setting one of stadia hairs on a whole foot-mark, by vertical tangent screw, and noting the intercept between the stadia hairs to nearest 0.01 ft. Care

must be taken not to mistake middle horizontal cross-hair for a stadia hair; this can be avoided by always making a mental estimate of the distance, or by adding oblique hairs to the instrument. Occasionally a half-interval may be read when an object obstructs view of the whole interval; it should be recorded as twice the interval read (or, better, the sum of the two "halves" taken separately).

Vertical angles are read by sighting middle cross-hair on the point on rod corresponding to distance from horiz axis of telescope to station beneath transit. This distance is HEIGHT OF INSTRUMENT (H I); it is not the same as H I in leveling, which is the elevation of telescope above datum. The line of sight is thus made parallel to a line from station to station, and vert angle read is the inclination of this line, whence difference in elev of the two stations can be directly computed. Same vert angle is used in computing horiz distance. If it be impossible to sight on H I point of rod, owing to obstacles in line of sight, the angle is noted when sighting at any convenient foot-mark on rod, this reading of middle hair being recorded in notes, with the vert angle.

Fieldwork is carried on as follows: When transit has been set up and properly oriented for reading azimuth angles, the transitman loosens the upper motion and sights on a rod held on point to be located. He first reads the stadia intercept from that part of rod nearest the H I point, and records it; then sets middle cross-hair on H I point of rod, and the vert hair bisecting rod. He then signals rodman to go to next point, and meanwhile reads the azimuth, vert angle, and index error, if necessary. If elevations are not required, he does not set on the H I, nor read vertical arc unless angle is greater than 3°; if it exceeds 3°, it is recorded only to the nearest 10 min, since it is used only for horiz corrections.

Stadia notes are kept on left-hand page in columns headed, from left to right, as follows: Station, Distance, Vertical Angle, Difference in Elevation, Elevation. The last two columns, as a rule, are computed in the office (Art 24). On the right-hand page should be drawn such sketches and details as are required to convey sufficient information to enable a draftsman unfamiliar with locality to plot the notes. Transit stations are usually designated by letters, and side shots by numbers. These numbers should be recorded on sketch within small circles, or in some other manner, so that they will not be mistaken for measured distances, which will also appear in sketch. Where purpose of survey is to produce a contour map, the accuracy of map depends in large measure upon the completeness of description given in notes regarding slope of the ground between located points. The elev of points on ridges, valleys, knolls, and depressions will be determined in the field; but, without a full description of intervening slopes, a correct interpolation of contours is often almost impossible. Notes like the following convey the required information: "Straight slopes from pt 16 to 17, 17 to 12, 13 to 17." Supplementary sketches illustrating shape of the ground are often necessary. The interpretation of field-notes, and their expression on map, are the weakest features of topographical surveys made by stadia; whence the importance of complete descriptive notes can not be overestimated. In open rolling country, where a 5-ft contour interval is required, a party of three men should cover about 5 acres per day.

24. STADIA COMPUTATIONS

Reduction of stadia notes includes computation of DIFFERENCE IN ELEVATION (vert heights) and HORIZ DISTANCES (or horiz corrections). Computations are almost always made by tables, diagrams, or stadia slide-rule, the latter being the most convenient means for reductions both in field and in office. Horiz distances can be quickly computed also by use of HORIZ CORRECTIONS, which are the distances to be subtracted from inclined readings to obtain horiz distances; to the latter must be added the instrument constant $(F + c)$, provided character of work in hand requires taking account of this 1 or 2 ft. Since the rod intercepts are usually read to nearest 0.01 ft, distances are recorded only to nearest foot; hence, in most topographic work the constant $(F + c)$ may be neglected, and there is no need of applying horiz correction for vert angles under 3°.

The stadia diagram, Fig 26 (by J. K. Finch, C. E., of Columbia University), gives 100 × rod interval, on vert lines; vert angles, on inclined lines, differences in elev, on horiz lines; and horiz corrections, on curved lines. The diagram is used as follows: Rod interval × 100, as recorded in field-notes under Distance, was 427; vert angle 3° 51′; instrument constant $(F + c) = 1$ ft. Follow up vert line 428 to inclined line 3° 51′; horiz line reads 28.7, which is entered in the field-notes in the column headed Diff in Elev. It is then applied to the elev of transit station to give elev of the point desired; if vert angle is upward (+) it is added to the elev of transit point and if downward it is subtracted. The horiz correction is read from the curved line which lies nearest the intersection of vert line 428 and inclined line 3° 51′; in this case it is a correction of 2 ft, to be subtracted after the value of $(F + c)$ has been added, as follows: $427 + 1 - 2 = 426$ ft.

This diagram will be found of great assistance in applying rough checks on computations, especially in the use of plane table, if it be remembered that on a vertical angle of 34′, the vert height is 1% of inclined distance; on a vert angle of 2° 52′, it is 5%; and on an angle of 5° 46′, it is 10% of inclined distance.

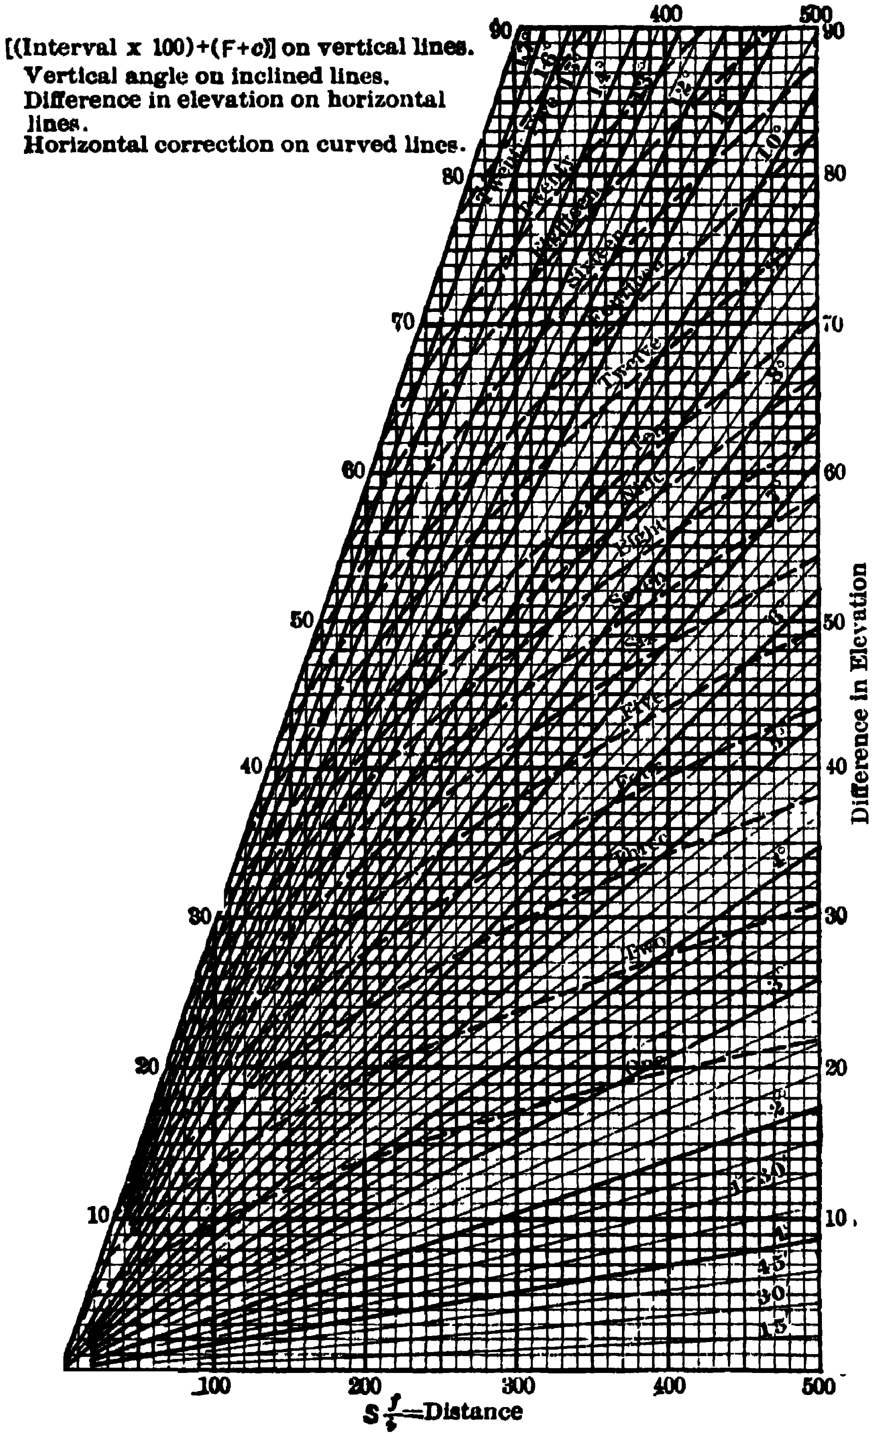

Fig 26. Stadia Diagram for Obtaining

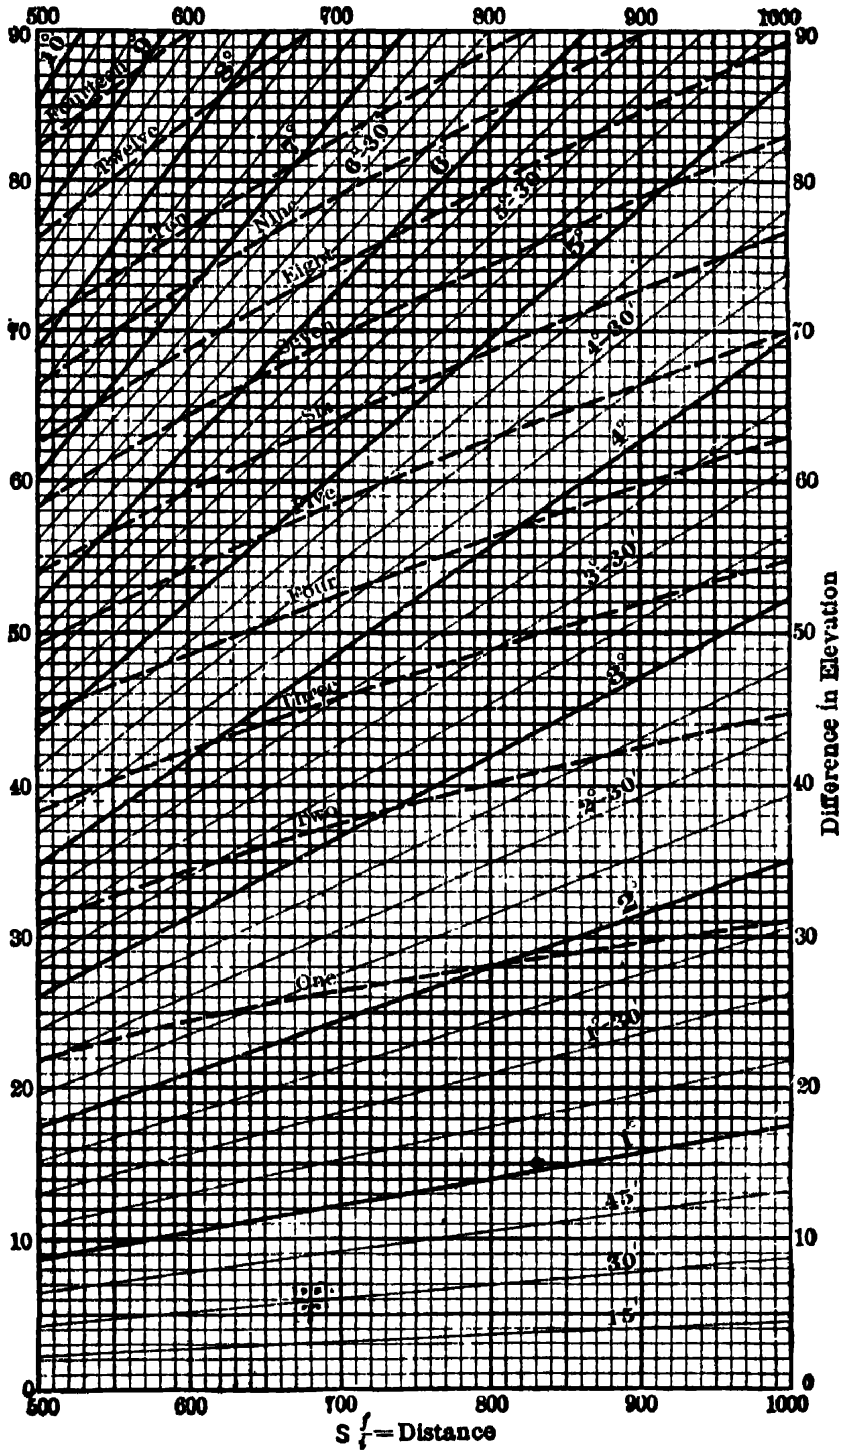
Even without this diagram, differences in elev may be computed if the short table of horiz corrections is available. After horiz distance has been found, multiply it by tangent of vert angle, to get vert distance; this can be conveniently performed on the tangent scale of an ordinary slide-rule.

When vertical angle is not read to the H I mark on rod, this fact must be taken into account in computing differences in elevation, as follows: Suppose the distance read was 135; vert angle,

−8° 50′ on 2.5; H I, 4.5. From diagram, diff elev = − 20.6, to which add +2.0, giving −18.6 The 2 ft is positive because the vert angle was measured to a point on rod 2 ft lower then H I point, which made observed vert angle greater than it would have been if sight had been taken at H I point on rod.



Vertical and Horizontal Distances (J. K. Finch)

Beaman's stadia arc is an attachment to the vertical arc, giving readings which obviate the use of stadia tables, diagrams or slide-rule. It requires more manipulation of the instrument than the usual method, but is of advantage particularly when elevations must be computed in the field as work progresses.

25. THE PLANE TABLE

The plane table is used for constructing a map directly in the field. The paper is fastened to a board, like a drafting board, supported on a tripod, with a device for leveling and clamping so that it can be oriented in any desired azimuth. The usual size of table top is 24 by 30 in, and the tripod most commonly used is the Johnson, which has an ingenious ball-and-socket leveling device and clamp. On the map an ALIDADE is used to define directions and measure distances. It has a telescope equipped with stadia hairs and is mounted on a horizontal axis resting in Y supports; these are connected to a metal column which rises from center of a flat piece of metal about 18 in long, of which both edges are straight and parallel to plane of telescope. On this base are two spirit-levels for leveling the table. The telescope has only a vert motion and a vert arc. The entire alidade is moved about on top of map after table has been leveled.

The use of the plane table has generally been limited to topographical maps drawn on a small scale, but its legitimate field is much broader than that. A system of triangulation (Art 26) or a transit and tape traverse may first be carefully surveyed and plotted on map; levels also may be run to determine elevation of triangulation or traverse points, which will then be used as a control for plane-table survey. In this case the plane table is used only to fill in details, and accurate maps on a scale as small as 40 ft to the inch can be rapidly made. The most important advantage of the plane-table over other topographic methods is that all the sketching is done in the field, where topographer can see form of ground that he is mapping. He can sketch details at once in their proper position, without burdening his memory and without making elaborate notes. For this reason details may be accurately sketched from a much smaller number of located points than would be required, for instance, by transit and stadia method.

If not practicable to run out a system of triangulation, or a transit and tape traverse, the plane table can be used for making such a survey graphically, as explained below. In all cases, however, the accuracy of those points located by plane table is limited by precision of the plotting rather than of the measurements. In the field the map must be protected from distortion by moisture, so as to preserve accuracy of plot. Celluloid sheets are obtainable, which can be used even in rainy weather.

The plane-table method usually, though not always, requires more time for fieldwork than transit and stadia methods; it is also more dependent upon favorable weather. But taking into account both the field and the office work, the plane table has proved more economical than the transit and stadia for work in open country, and the results, as a whole, are more reliable. In open rolling country, a contour interval of 5 ft being required, a party of 3 men should survey about 8 acres per day.

Locating points by intersection. To begin a plane-table survey it will generally be necessary to have on the map two plotted points corresponding to two points on the ground, distance between which is known, and of which one, at least, can be occupied with the table. A simple method of locating points, without measuring any distance, is as follows: The base-line ab is plotted on plane-table sheet, representing the measured base AB to the adopted scale. The table is first leveled and so set that a on the map is vertically above A on the ground (a special plumbing appliance is used for this adjustment). One edge of alidade is placed along base-line ab drawn on map, the table is turned in azimuth until telescope sights signal B, and horiz motion is clamped. Line ab is now parallel to AB and the table is said to be oriented The alidade is now placed with its straight-edge passing through a, the telescope is sighted to some signal C, and an indefinite line is drawn toward C; the point c on map is somewhere on this line. Now moving table to B (setting b vertically over B) and repeating the process of orienting the table and sighting toward C, point c is located at intersection of lines ac and bc. In similar manner any number of points may be located.

Locating points by direction and distance. The commonest way to locate points by plane table is to obtain direction with alidade and measure distance by stadia, which is then laid off to scale along the straight-edge. If a control traverse has been run, the table can be set up over any of the plotted points and oriented as explained above.

Locating points by resection. It is sometimes desired to locate a plane-table station from a base of which only one end can be occupied by the table. A and B are the points on ground at ends of base-line; C is the point to be located; and ab is base-line plotted on plane-table sheet. Set up at A, the accessible end of the base, and orient table by sighting B with alidade pointing along ab. Then, centering alidade on a, draw an indefinite line toward C, for full length of the alidade. The table is then taken to C and oriented by the indefinite line just drawn. Since position of c on the indefinite line is not known, its position on map must be estimated for setting table over point C. The alidade is now sighted toward B, with the edge of its base on b and a resection line is drawn, which cuts the first indefinite line, thus locating point c desired. If point c thus found is not over point C on ground, reset over C and repeat process. The position of c found by this method should be checked, if possible, by resection lines from other points of which the positions are known to be correct.

26. TRIANGULATION AND TRIGONOMETRIC LEVELING

Triangulation consists in locating certain points by observation of angles, starting from a base-line which has been accurately measured; the method is often used as a control for a topographic or hydrographic survey. A triangulation system comprises a series of triangles, the corners of which are the observing stations or points which it is desired to locate. In this system of triangles, the length of one side of some triangle must be measured; then if all the angles in each triangle be observed, lengths of all other lines in the system may be calculated by trigonometry. Three types of triangulation system may be recognized: First, a series of approximately equilateral triangles; second, a series of central polygons, for example, a row of hexagons each having an interior station; third, a series of quadrilaterals with both diagonals drawn. The first system is the cheapest when it is desired to extend survey along a narrow belt, as in surveying a river. It has the disadvantage of having but few "checks," that is, few geometric conditions which must be satisfied by the measurements. The second system is adapted to surveying an area of greater width than the first. The third is the most accurate, because it has the greatest number of checks. No attempt will here be made to describe the precise work carried on by the U S Coast Survey in mapping large areas, the following notes relating only to such work as the mapping of a few square miles.

Fieldwork consists in first making a reconnaissance of the country, selecting suitable triangulation points with due regard to shape of the triangles, which should be as nearly equilateral as possible, choosing a favorable position for the base-line to be measured by tape, and ascertaining that the chosen points are visible each from the others.

Base-line should be located on fairly even ground, for convenience in measurement, and its position should be such as to admit of accurate connection with the triangulation system. After clearing line of obstructions, stakes are lined in by transit one tape length apart. Grade of each tape length is determined by direct leveling. In measuring each length the intermediate supports are lined in vert and horiz, proper tension is applied with a spring balance, and temperature is read on two or more thermometers attached to the tape. Marks indicating ends of tape length are scratched on metal strips tacked to tops of posts. At least 2 measurements of entire base should be made. INVAR tape (Art 1) is used by U S Geodetic Survey for base-line measurements. For description of methods of base measurement, see U S Coast and Geod Surv, Pubs 120 and 145.

Angle measurements. The transit is set up at each end of base-line and angles are carefully measured by repetition (Art 11), to the signals erected at those triangulation points which are intended to be connected directly with the base. The transit is then taken to the various points of triangulation system, and the necessary angles are measured so that length of each line in the system can be computed, and as many as desired can be checked by computation through different triangles.

Signals over triangulation points are frequently made of a 4 by 4-in pole supported by a tripod; on the pole are tacked black and white cloth bands of definite width, or flags. The foot of pole is supported 7 or 8 ft above the ground, so that theodolite may be set up beneath signal when measuring angles. Tripod signals may also be made of young saplings, and in the smaller ones the pole usually rests on the station point; this necessitates removal of the entire signal when angles are measured at that station. Where necessary to build a high signal, on account of forests, a tall mast may be made of 2 or 3 poles spliced together, and braced by wire guys. In all cases it is advisable to tack a black and white band to that part of the pole which is *vertically over the station*, so that observations may always be made on that particular point.

Trigonometric leveling consists in computing difference in elevation of two points on the basis of horiz distance and vertical angle between them; it is usually combined with triangulation work, the vert angles being measured at same time as horiz angles. A vert angle is measured to some definite point on signal, the height of which above station was determined when signal was erected; the height of instrument above its own station should also be measured and recorded. In very precise work, angles are measured with a special vertical-circle instrument. In less precise work, an ordinary theodolite, the vert arc of which reads to 30 sec or to 20 sec, may be used, but with such instruments only single readings can be made; in which case the best results are obtained by averaging several independent readings, half of which are taken with telescope direct and the other half with telescope inverted. In every case the index correction, or reading of vert arc when telescope is level, must be recorded.

The chief difficulty in obtaining accurate results by trigonometric leveling is the uncertainty in the coefficient of refraction of the air. This varies with locality, temperature, and atmospheric pressure, and the only way its effect can be eliminated is by taking simultaneous observations between two stations.

Observations at one station. Multiply horiz distance by tangent of vert angle, and apply a single correction for curvature and refraction by the formula: $h = K^2 \div 1.7426$, where K is distance between stations in miles, and h is correction in feet. If K be in units of 1 000 ft, then $h = 0.02\,K^2$ (nearly). This correction is applied to increase difference in elevation if vert angle is positive, or to decrease it if angle is negative.

When two simultaneous observations can be made, $h_1 - h_2 = K\,tan\,{}^1/_2\,(\alpha_2 - \alpha_1)\,\{1 + (h_1 + h_2) \div 2\,R + K^2 \div 12\,R^2\}$, where $h_1 - h_2$ = difference in elevation of stations in feet; K = arc of the earth subtended between plumb lines through the two stations (approx equal to horiz distance between the two stations) in feet; α_1 and α_2 are simultaneously observed vert angles; R = radius of earth at latitude of stations; for most work it is close enough to take $\log R$ (in feet) = 7.32068.

27. TERRESTRIAL PHOTOGRAPHIC SURVEYING

A rapid method of locating topographic details for construction of small-scale maps (say 2 or 3 miles to 1 in) is afforded by photographic surveying. Best results are obtained where country has characteristic shapes, and is not too thickly wooded to afford good positions for taking the views. To locate a point, it is photographed from two stations, the positions of which are known. It is necessary to know the direction in which camera was pointed when each photograph was taken and the focal length f of lens. For further details, see "Higher Surveying," by Breed and Hosmer, 5th Edn, 1938, Chap VII, VIII.

Instrument used for this work sometimes consists of a transit, so constructed that standards and telescope can be removed and a camera mounted in their place, so that azimuth angles can be measured, or laid off, by the horizontal circle. The instrument is leveled and horiz angles between certain well-defined points are measured while telescope is on transit; when the camera is substituted, the same angles are laid off on the circle and the exposures are made. Such instruments cost about $500.

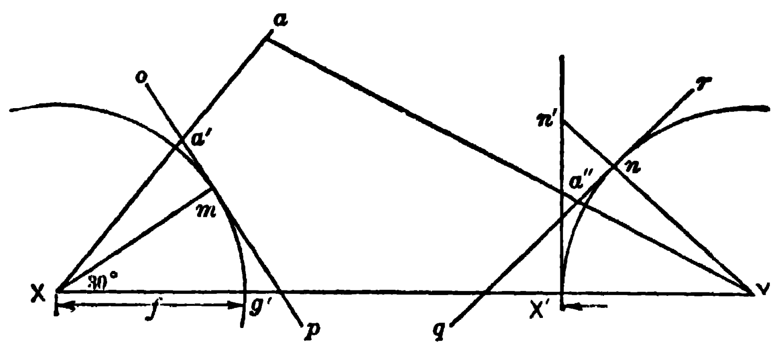


Fig 27. Plotting Camera Stations

Notches on the 4 sides of the camera opening yield corresponding points on edges of every picture; lines are then drawn across photograph connecting these 4 points. The vertical line is known as the PRINCIPAL and the other as the HORIZON line; their intersection is called the PRINCIPAL POINT.

If photograph be held at distance f in front of the eye, and normal to line of sight, points a, b, and c on the picture will appear to cover corresponding points A, B, and C in the landscape. The photograph, when held in this position, thus gives a measure of the angles between various points in the view; a fact utilized in plotting.

To plot map, first plot the base line XY to the desired scale (Fig 27). With each base station as a center draw a circle of radius f (true focal distance), intersecting the base at x' and y'. Next plot the traces of the photographs. If the angle between the base and direction the camera was pointed has been measured, say 30°, lay off radial line Xm. A line op at m, perpendicular to Xm is the trace of photograph taken at X. If the angle is not known and the image of X appears in photograph taken at Y, as x', erect a perpendicular to base at x'. Lay off distance $x'n'$ = to distance measured on print from PRINCIPAL POINT along horizon line to foot of perpendicular dropped from image of the base to horizon line. The intersection n, of $n'Y$ and the circle, is the location of the principal point. Line rq, perpendicular to $n'Y$ at n, is the trace of the photograph. To plot point a, first measure on photograph op, the distance from a to the principal line, and plot that distance on line po as ma'. Similarly, the distance na'' is measured on the other photograph and plotted along trace rq. The plotted position of A thus lies at intersection of Xa' and Ya'', or at a. In same manner are plotted as many points as desired.

Differences in elevation are computed as follows: Scale the distance of point a above horiz line on photograph. This distance divided by distance from camera station to point a' (scaled from map) gives the natural tangent of angle of elevation or depression. The actual horiz distance Xa is then scaled from map, after the point has been plotted, and is multiplied by tangent of vert angle, to give difference in elevation between camera station and point a; or it can be found graphically. Details of map are sketched in from a study of the photograph, after characteristic points have been plotted.

28. AERIAL SURVEYING

For further details, see "Higher Surveying" by Breed and Hosmer, 1938 edn, Chap VIII and IX.

Aerial photographic surveying is used for making maps for highway, railway, waterway, pipe-line and transmission line location; for irrigation, water supply, flood control, river and harbor improvements, soil conservation, geological research, timber estimates, topographic and exploration surveys.

Aerial photographs are classed as vertical, oblique or composite. In taking vert photographs, the optical axis of camera is held as nearly vert as possible at instant of exposure. In oblique photographs, the camera axis is purposely inclined to the vert and may or may not include the horizon. In composite photographs, taken with a multi-lens camera, one photograph is usually vert and the others oblique. Some multi-lens cameras have no vert chamber. The oblique views of composite photographs are rectified (transformed into vert prints) before being used for plotting. Then all prints will appear as verticals, although the oblique prints will no longer be rectangular in shape.

Aerial cameras are precision instruments, comparable to the engineer's transit, and are of single or multi-lens type. The latter consists of two or more cameras mounted *en bloc*, all exposures being made simultaneously. For taking vert or composite photographs, the camera is mounted in gimbals attached to a frame rigidly fastened to the airplane. Exposures are made through a hole in the floor of the plane. By inspection of a level attached to the camera, the operator holds the optical axis as nearly vert as possible at instant of exposure. In taking single oblique photographs the camera is sometimes held in a standard attached to edge of the cockpit, and may be moved in any direction. Present practice in Canada is to mount 3 cameras on a cross beam in the plane; they are inclined at angle of 21° with the horiz when the plane is on even keel.

The cameras are of the fixed focus type. At instant of exposure, the film is held flat in focal plane by a vacuum back or a glass pressure plate. To locate the principal point, notches or collimating marks in the focal plane are photographed on the negative at instant of exposure.

View finders are commonly used. For taking oblique photographs the view finder has a sighting arm, which may be set at any desired angle. The camera is held at the required depression angle by directing the sight at the horizon. For vertical photographs, a vert view finder is mounted, between camera and photographer, over a hole in the floor of the plane. This instrument is essentially a camera with a ground glass plate in its focal plane, by which the terrain is viewed. It is leveled by an attached bubble and the instrument may be rotated about its optical axis. The vert view finder is to determine: (1) when points are vertically under the camera; (2) the "angle of crab," so that the camera may be adjusted along the true line of flight; (3) the interval of time between exposures. The ground glass plate is ruled with lines 0.5 in apart in the direction of flight, and normal to these lines are 2 others. To determine the "angle of crab" (angle between longitudinal axis of the plane and direction of flight) the view finder is turned about its optical axis until objects on the ground appear to move parallel to the lines ruled on the ground glass along the direction of flight. In order that successive pictures shall be directly in front of one another, the camera is turned about its optical axis to an amount equal to "angle of crab." The interval between exposures is determined by the time it apparently takes a ground point to travel between the transverse lines ruled on the ground glass plate.

Taking the pictures. When taking photographs of the area to be mapped, the airplane is flown back and forth over parallel straight lines (" flight lines "), and usually at a predetermined altitude. The proper distances between the flight lines are computed and before the flight the lines are plotted on a map to aid the pilot in keeping his course. Altitude is given by an "altimeter." Where vert photographs are to be used for compiling maps, it is best to show the principal points of preceding and following prints in each print. Hence, exposures are timed so that the overlap between successive pictures in direction of flight will be about 60%. To avoid hiatus between adjacent strips, the

flight lines are so spaced that the photographs will also overlap. This " side lap " is usually 30%–50%.

Relation between scale of print and altitude of camera. Strictly, where the ground varies in elevation, there is no such thing as the scale of a photograph. It is only when the ground is level, and the photograph has been taken truly vert, that the print has a definite, uniform scale. However, any elevation may be selected as a datum, and, if the elev of the camera is known at instant of exposure, the scale of the print may be computed for the given datum.

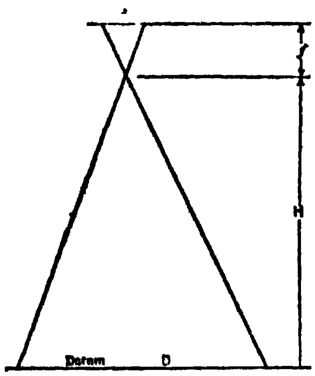

Fig 28

There are two ways of expressing the scale of an aerial photograph: (1) by the representative fraction (R F); (2) by the scale factor. The R F is the usual scale, expressed by a fraction in which the numerator is unity; it is the ratio of a distance on the map to the corresponding distance on the ground, denoted as s. The scale factor, expressed as S, denotes the number of feet on the ground corresponding to 1 in on the map. In Fig 28, if distance D on the ground (datum) is represented by d on the print, then the R F scale $s = d \div D$. Also, $d \div D = f \div H$, where f is focal length of lens and H the altitude of the plane above the datum, f and H being measured in the same units. If the scale factor is desired, $S = H \div f$, where H is in ft and f in inches. Both formulas show the relation between scale of the print and altitude of the plane above the datum.

Example. Compute s and S, when $f = 10$ in and $H = 10\,000$ ft:

$$s = \frac{f}{H} = \frac{10}{10\,000 \times 12} = \frac{1}{12\,000} \text{ and } S = \frac{H}{f} = \frac{10\,000 \text{ ft}}{10 \text{ in}} = \frac{1\,000}{1}, \text{ that is, 1 in} = 1\,000 \text{ ft.}$$

Another form of the scale equation is $s = f \div (H - h)$, where H is the altitude of camera above datum and h the elevation of the datum. From these formulas the altitude at which the plane must fly to give the print a desired scale above a definite datum may be computed.

Time interval between exposures may be determined by the "view finder" (see *ante*). But, if speed of plane, focal length of lens, altitude of exposure station, size of print and end lap are known, then the interval between exposures can be computed.

Example. Speed of plane = 120 mile per hr; $f = 10$ in; altitude of exposure station, 10 000 ft; size of print, 7 by 9 in (the 7-in dimension being in direction of flight); end lap 60%, then

$$s = \frac{10}{10\,000 \times 12} = \frac{1}{12\,000}$$

Total distance covered by the 7 in on print = 7 × 12 000 ÷ 12 = 7 000 ft. Net distance covered by one print = 7 000 × 40% = 2 800 ft. Speed of plane, ft per sec = (120 × 5 280) ÷ (60 × 60) = 176 ft. Interval between exposures = 2 800 ÷ 176 = 15.9 sec.

Number of negatives to cover a given area. When the dimensions of the area, scale and size of print, and the end and side overlaps are known, then the number of prints required may be computed.

Example. Size of area, 15.5 by 20 miles; prints, 7 by 9 in; scale 1 to 1 000; end lap 60%; side lap 30%. Total area covered by 1 print = (7 × 12 000)/12 × 5 280) × (9 × 12 000) ÷ (12 × 5 280) = 2.26 sq miles. Net area covered by one print = 2.26 (1.00 − .60) (1.00 − .30) = 0 633 sq mile. Required number of prints to cover area = (15.5 × 20) ÷ 0.633 = 490 prints. To this value add a sufficient number of prints to cover the margins. It is customary to make 1 or 2 additional exposures at beginning and end of each flight line, to insure proper coverage. In the example, if 1 additional print was taken at both beginning and end of each flight line, 26 prints should be added to the 494; total, 520.

Scale errors. For mapping, the plane is often flown at a precomputed altitude. As altimeters are not precise instruments, and because of varying meteorological conditions, the altitude will vary, thus causing a change in scale of photographs. If $f = 10$ in and $H = 5\,000$ ft, the scale S is 1 in = 500 ft. If, due to above mentioned changes, H is 4 800, scale S would be 1 in = 480 ft. Under good flying conditions the altitude should not vary more than 100 ft.

Definitions. Nadir or ground plumb point is a point on the ground vertically beneath the lens at instant of exposure. Its image on the print is the plate nadir or plate plumb point. " Principal point " is the point where the optical axis of the camera intersects the film. If it is not shown on the print, it is taken at the intersection of the lines between the reference marks on margins of the prints. When the optical axis is truly vert, the

nadir and principal point coincide. When the plate has some tilt (usually the case), these points do not coincide. A point approx midway between nadir and principal point in a tilted photograph is the "isocenter," or center of distortion. Positions of the plumb point and isocenter could be located on the print, provided the amount and direction of tilt are known, which may be determined if the position and elevation of 3 or more ground control points on the print are known.

Displacement caused by relief. As all photographs are perspectives, all objects in the photograph, except the plumb point and those in the datum, are displaced. In Fig 29 the top of chimney A will be shown on the datum at A'. Displacement on the datum is $A''A'$ and on the print $a''a$. Displacement of point B is $B''B'$. Plumb point P' has no displacement. The displacement of points below the datum is inward, and, as it is in a vert plane, the error on the print is radial from the plate plumb point, which in a truly vert photograph coincides with the principal point. Displacement on the print is calculated as follows. The hill A (Fig 30) whose height above datum is h, appears on the

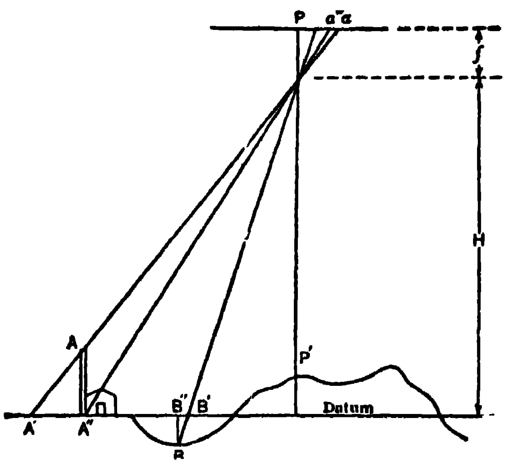

Fig 29

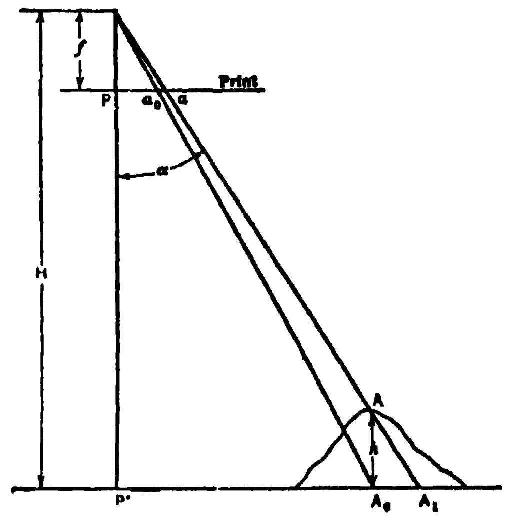

Fig 30

print at a; ground displacement is A_1A_0 and displacement on the print is aa_0. By measuring distance Pa on the print and dividing it by f the angle α = angle A_0AA_1 may be found. Now $a_0a : A_0A_1 = f : H$; whence $a_0a = (f \div H) \times A_0A_1 = s \cdot h \tan \alpha$. Another formula for computing the displacement is derived as follows. In the last equation, $s = f \div H$ and $\tan \alpha = Pa \div f$. Substituting, $a_0a = f \div h \cdot h \cdot Pa \div f = Pa \cdot h \div H$.

Example. H = 10 000 ft, f = 10 in, h = 500 ft, Pa measured on the print = 3.075 in. By the first formula, displacement is a_0a = 10 ÷ (10 000 × 12)·500·12·tan 3.075 ÷ 10 = 0.154 in; by the second formula, a_0a = 3.075 × 500 ÷ 10 000 = 0.154 in. Thus, by computing the displacement of a point, its correct position on the print may be plotted.

Tilt. In taking vert photographs, the ideal position for the optical axis at the instant of exposure is truly vert; that is, the principal point and plumb point coincide. This condition seldom exists. The angle of inclination of the optical axis and the vert is called the "tilt," which experience shows may be kept within 1° and seldom exceeds 3°. When tilt exists the film, which is at right angles to the optical axis, is not truly horiz, and the images of objects on the film are displaced. If the tilt angle is known, the displacement may be computed. But, there is no simple way of determining the tilt angle. To do so, the image points of at least 3 ground-control points, whose positions have been found by ground surveying, must appear on the photograph. Then the tilt may be determined analytically, graphically, or by rectifying instruments.

Effect of displacement on plotting caused by relief and tilt. Although displacement caused by relief is radial from the plumb point, and that caused by tilt is radial from the isocenter, the positions of these points are indeterminate unless the tilt is known. In plotting, however, relief and tilt are assumed to be radial from the principal point. When both relief and tilt are small, the error in plotting is negligible.

Ground control is the term applied to points identifiable in the photographs, whose horiz positions and elevations referred to a selected datum are known. Their locations and elevations are determined by ordinary ground surveying. The amount of ground control may comprise many or few points, according to accuracy required and the mapping method employed. In deciding the location of control points, it should be observed that

at least 3 points must be known, to fix independently the position of a vert photograph, from which a planimetric map is to be compiled. Where stereoscopic processes are used, at least 2 points known in position and elev, and a third point known in elev, must be available in the area of common overlap. In either instance, the control should be so positioned as to form as strong a geometrical figure as can be drawn with either the single photo or the overlap. Thus, in deciding how control should be located, consideration should be given to the proposed use of the photographs. Note that triangulation stations are usually elevated points, subject to large relief displacements in the pictures. Traverses, on the other hand, may be run along highways, in valleys, near the level of the selected datum, and are therefore nearly free from this objection. In taking levels, the points selected should be easily identified in the pictures, and so placed as to give the best determination of tilt. If the photographs are taken before the ground control has been established, points with little or no displacement and which can be identified on the photographs (as intersections of roads with other roads, railways and streams) are chosen for control and then located in the field. Where there are no easily identifiable objects on the photographs, it may be best to lay on the ground white cheesecloth about a yard wide in form of crosses or circles, so located in open spaces that they will show clearly on the photographs. These cheesecloth stations can be joined to the ground control either before or after photographs are taken. This should be done fairly promptly, unless the cloths are weighted down to prevent displacement.

Photographic maps. This term is a misnomer, because, in general, a photograph can not be both a true photograph and a true map, or projection. As the photograph is a perspective, all points in it above or below the datum are displaced. When pictures are pieced together to form a continuous representation of the ground, the result is a MOSAIC. Maps made on a true horiz projection from data derived from photographs are true maps. In spite of geometric defects of mosaics, they are very useful for certain studies, and are more readily understood by the non-technical man than engineers' plans. In estimating timber, and in other applications, the mosaic is often preferable to the map itself. For

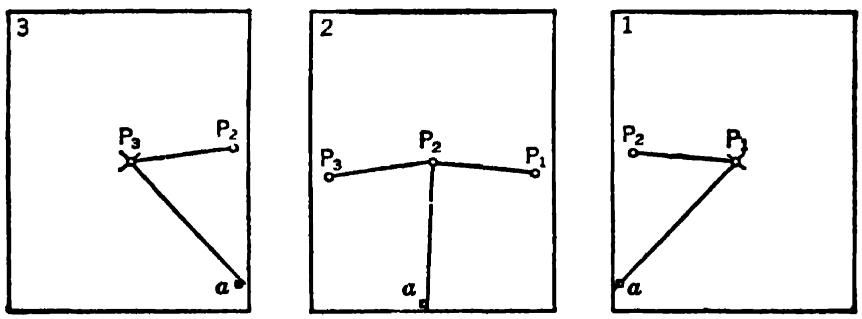

Fig 31

preliminary engineering investigations, engineers often like to have, besides the mosaic, a complete set of photos for stereoscopic inspection.

Photographic maps comprise: UNCONTROLLED MOSAIC, a representation of the ground made by matching aerial photographs without reference to ground control points; CONTROLLED MOSAIC, a representation of the ground made from aerial photos by bringing them to a uniform scale and fitting them to ground control stations; PLANIMETRIC MAP, showing the natural and cultural features in plan only, often called "line map"; TOPOGRAPHIC MAP, made from aerial photographic data, including contour lines derived by ground surveying; STEREOMETRIC MAP, a relief map made by applying the stereoscopic principle to aerial or terrestrial photos.

Orienting prints and compiling maps graphically. All photographs are true perspectives, and for practical purposes maps may be considered as orthographic projections. The perspective or photograph is a view in which the light rays from the object points converge to the lens of the camera, and diverge from lens to the negative. Excepting in the optical axis of the lens, the light rays are not perpendicular to the negative; but, in the map all objects are represented as they would appear if the eye were on a line everywhere perpendicular to the plane of the map. The map compiler must take the perspectives (photographs) and make an orthographic projection from them. A common method is RADIAL TRIANGULATION, RADIAL INTERSECTION, or RADIAL LINE CONTROL, based on the assumption that the photo gives the true horiz angles at the principal point.

In plotting, it is assumed that relief and tilt displacements are radial from the principal point. Suppose that on 3 consecutive overlapping pictures the principal points are P_1, P_2, P_3 (Fig 31), and that from each a radial line is drawn on the corresponding print

to the corner of a building a. By superimposing the pictures (Fig 32) all 3 lines intersect at a common point, but this point of intersection does not coincide exactly with any of the positions of the building on the pictures, as would be supposed. The angles P_2P_1a, P_1P_2a, etc, are true angles because their sides are radial from the principal or the plumb point. No appreciable error is caused in plotting by using the principal point for the plumb point. The true position of the corner of the house is at the intersection of the 3 radial lines b. The error in position on the print may be due to the camera being higher in one case than in another, or to the elevation of the ground on which the building stands. If the 3 lines so drawn have no common intersection, an error should be looked for; if not discovered, one of the pictures is probably distorted by tilt and should be rejected when identified. If the point appears on 4 or 5 prints, it is easier to identify the one causing the error.

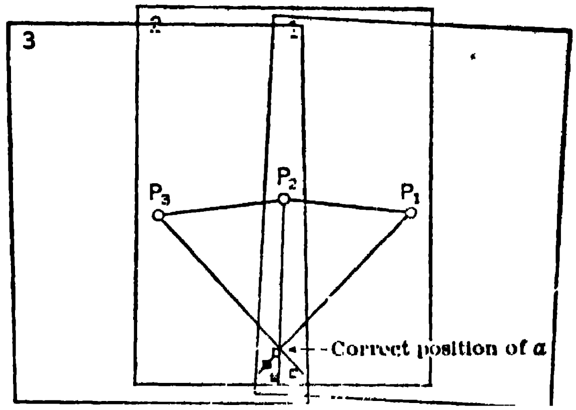

Fig 32

In applying radial intersection to a strip of aerial photos, the approx scale of the prints is first determined, by comparing known distances on the ground with corresponding distances on the prints. When this is done, a map projection of the area is made to this scale. All ground control points from ground surveys are located on the projection. The photos are next examined, the ground control points identified and marked on all prints on which they occur. In Fig 33 these points are shown on photos 1 and 2 at T_1, T_2 and T_3. The principal point of each photo is next identified and marked on all preceding and succeeding photographs in which it appears. These points are shown at P_1, P_2 and P_3. While the principal point is easily located on some one print, it may not be accurately identifiable on adjacent prints. In this case, an identifiable point near the principal point is chosen, and used as if it were the principal point. When such points are near each other, the error caused in plotting by the substitution is negligible. In Fig 33, print III, PS_3 is chosen in place of P_3 (it is also shown on print II). The picture control points are next identified and marked on all prints where they occur: they should be well defined, and at least nine chosen on each print. However, the number of points depends on whether the terrain is flat, medium or heavily accidented. To insure correct plotting, the greater the accidentation the greater the number of picture control points; 3 should be chosen across and near bottom of print, 3 across the center, and 3 across the top. Print II (Fig 33) shows how these points should be distributed normal to direction of flight. A stereoscope greatly aids in properly locating the points.

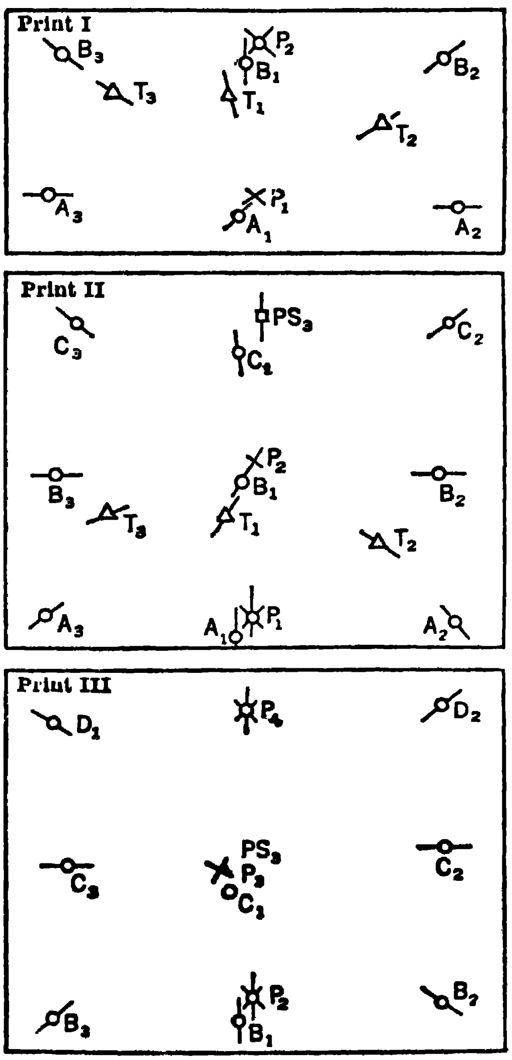

Fig 33

After locating the ground control points, principal points or their substitutes, and picture control points, radial lines are drawn on each print (Fig 33) from the principal point or its

substitute to all control points. The orientation of the successive pictures is based on the principle of resection. Intersection of the radials indicate their orthographic projection, for which the tracing-cloth solution of the 3-point problem is used. The first photo is oriented under the tracing cloth, so that the radial lines from center to ground control points fall through the plotted positions of these points on the tracing. The center of the print is then oriented, and so marked on the tracing. Without moving the photo, radial lines are drawn on the tracing to the selected picture control points, and to the photograph centers. The first print is now removed, the second placed under the tracing and similarly oriented. Radials are drawn from the center to the control points and to the centers, as in the first print. Some of the radials on the tracing from the first print will be intersected by some of those traced from the second print. These intersections may now be used for orienting the third print. Fig 34 is the plot of radial control of the 3 prints in Fig 33, which is used for orienting the prints for making the finished map. The process is continued until a new set of ground control points have been reached, when a check is obtained. If the points on the tracing do not check with the ground control points, they are adjusted to correct the errors. In locating on each print the radial line to its center, radials through the previously established ground control or picture control points are used. If these do not all fit, and no gross error is evident, each radial is shifted slightly, points on opposite edges of the print being on opposite sides of the radial line. Because of errors due to the assumptions that displacements caused by relief and small tilt-angles are radial from the principal point, perfect checks can not be expected, but the tracing may be adjusted so that these errors are equally divided and a compromise position adopted.

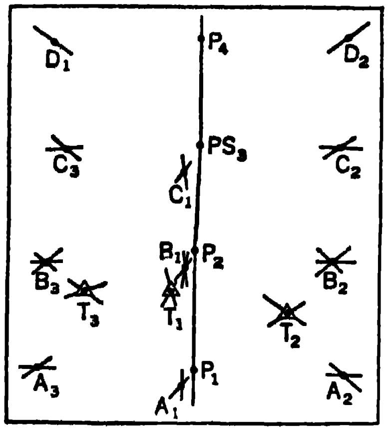

Fig 34

Controlled mosaics. From control established by ground survey methods, or as a result of a radial plot, it is possible to rectify the individual photographs and bring them to a common scale between control points. A mosaic may now be laid with these scale-rectified prints, which will contain very small displacement errors.

Transferring details to the tracing. After the skeleton of the map has been prepared, details are filled in from the original photos. In each case the photo is placed under the tracing cloth and oriented with respect to the points whose positions are now fixed. Detail is taken off along the line joining any two points. The print is oriented so that one point on the photo lies under its map position, and the second point lies on the line joining the two points on the map. Differences in scale between print and plot are then corrected by estimation in the compilation process, due regard being taken for any known relief differences along this line. In the case of controlled mosaics, there will be no apparent difference in scale between positions of control points on the print and on the plot. Detail can be taken from the mosaic, or from rectified prints, and a planimetric map drawn. The operator must use his best judgment based on knowledge of the terrain in selecting the position of detail where mismatches occur as a result of relief.

There is now used a projection camera, like an enlarging camera, into which a photograph may be inserted and its image cast on a drawing board. The drawing board may be tilted by 3 leveling screws. The map projection is placed on the board, and small sections of photographs made to fit the control points by varying the enlargement of the photo and tilting the board. Details may thus be transferred to the map.

Contours. There are two modes of obtaining the contours on a map made from aerial photos: (1) by the ordinary ground survey methods, after completing the horiz locations; (2) by the stereoscopic principle applied to overlapping photos. In the first method there must be enough lines of direct levels to furnish all bench marks necessary, as well as points located horizontally for the plane-table work. Planimetric locations can be checked, and any residual errors removed. For details of stereoscopic work, see Bib references to books listed under *Photographic Surveying.*

29. HYDROGRAPHIC SURVEYING

Hydrographic surveying is usually applied to the determination of shape of bottom of a body of water, sometimes including a determination of character of material composing the bottom. It is customary first to establish points on shore, by triangulation or traverse,

to which the hydrographic survey may be referred, then to measure (usually from a boat) the depth of water at various points, and determine position of these points. Besides ordinary transit and tape outfit, a sounding-pole (or lead-line in deep water) and a boat with necessary equipment will be required. In tidal waters, and in lakes where water level changes rapidly, a tide gage should be installed. Sounding-poles are similar to self-reading rods, graduated to 0.1 ft; a shoe is sometimes attached to lower end, provided with a cup-shaped cavity which, when smeared with tallow or soap, brings up samples of the bottom. The lead-line is a chain, or hemp line, to which is attached a lead weight. A brass sash-chain is satisfactory, having cloth tags of various colors for footmarks. Where there is little current, a 6- to 10-lb weight suffices for depths to 40 ft.

Locating soundings. There are 6 general methods: (*a*) The boat is rowed on a range line, at uniform speed, and soundings are located by time intervals. (*b*) Boat is rowed on a range line, while positions of soundings are "cut in" by a transit reading from shore, or by an angle taken with sextant from boat. (*c*) Boat may be rowed on a range line, or not, while its position is located by angles taken simultaneously by two transits on shore, or by angles taken simultaneously to shore stations from boat by two sextants. (*d*) Soundings are located by stadia method. (*e*) Soundings are defined by the intersection of fixed ranges. (*f*) In case of a stream, a wire or cord is stretched from shore to shore, and soundings are taken at measured points along this line.

Locating by range and angle. In still water, where the boat is easily held on any desired course, soundings are conveniently located by proceeding along a range line of known position, marked by two objects on shore, such as range poles, and then "cutting in" the position of sounding pole by a transit angle observed from a previously determined shore point at instant the sounding is made. The ranges may be fan-shaped if pivot-point of system be a steeple or some other object of known position situated far enough back from shore so that the lines will not diverge too rapidly. The recorder writes in his notebook the depths as called off by leadsman, and also the times of sounding. He also notifies leadsman by calling out "Sound" about 5 sec before each sounding is desired. The leadsman takes soundings as quickly as possible, usually within 2 or 3 sec of the desired time. In hydrographic work of Corps of Engineers, U S Army, in which nearly all soundings are located by two angles taken with transits on shore, soundings are usually taken at 15, 20, or 30-sec intervals, and an observation is made each minute by the instrument men at the instant signal is given from boat. The chief of party usually acts as signalman, directing work in the boat, and seeing that boat is kept on the ranges (if any are used). The signal is given by holding up a flag for about 10 sec and dropping it suddenly at instant the sounding is taken, at which moment the transitmen on shore read angles to the leadsman, or to the pole, if visible. In work of U S Engineers, white, red, and sometimes black flags are used for signaling. Both the recorder's and the instrument men's notes should report color of signal, as well as the time for each located sounding, thus giving two means of identifying angles with their corresponding soundings. This double check is of particular value in taking long lines of soundings. In waters with changing level, the time record is required also, to reduce soundings to Mean Low Water, or other datum. The tide-gage readings are recorded at regular intervals throughout the day.

When purpose of survey is to locate every slight change in shape of bottom, it is desirable to take soundings as frequently as leadsman can handle the pole, instead of at timed intervals. In this case, the boat is usually rowed on a range and the instrument men on shore "cut in" only those soundings that are designated by signalman in boat, the time being recorded to nearest second. As a rule every sixth or eighth sounding is located. In plotting such notes, the soundings being quite close together, the points that were "cut in" are plotted on map and intermediate readings are interpolated, the soundings of which are assumed to be equally spaced between the located ones, unless time record shows a different condition.

30. SURVEYS OF MINERAL LANDS

By Prof G. L. Hosmer, Mass Inst of Tech. Field notes furnished by Prof James Underhill, Colo Sch of Mines, author of "Mineral Land Surveying"

Requirements of the U S Mining Laws respecting location of a claim comprise: discovery of a mineral deposit, marking claim boundaries, posting location notice and filing certificate (Sec 24).

Legal dimensions of claim: Length, not more than 1 500 ft on course (strike) of vein; width, not more than 300 ft on each side of middle of vein; normal claim is thus 600 by 1 500 ft. State legislation may make the width less than the maximum, as in N and S Dak, Wyo, and in 4 counties of Colo (Sec 24). Two surveys are necessary: (*a*) location survey; (*b*) survey for patent.

Location survey, which is comparatively simple, may legally be made by the claimant himself, even without use of instruments; but it is advisable to employ a competent surveyor, to avoid possible loss due to inaccuracies. In making this survey, the strike of the vein is determined as accurately as possible, and used as the center line of claim. This line must pass through the point of discovery, its direction being referred to either

magnetic or true meridian; but, as the subsequent patent survey uses the true meridian, this is advisable also for the location survey (Art 13).

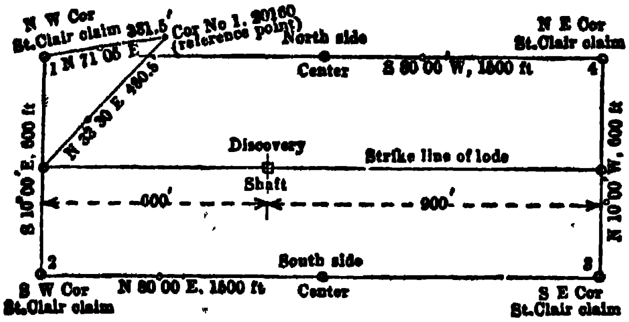

Fig 35. Typical Claim. NOTE —Corner angles may be greater or less than right angles (see Fig 36)

Distances may be measured on slope when necessary, and then reduced to horiz. Corner stakes are set, and marked with corner numbers and name of lode. A marked stake is also set at middle point of each side line. End lines must be parallel, but are not necessarily at right angles to center line. Claims may be of various forms (Fig 35–37), but always within legal dimensions. At least one point on the survey (usually a corner) must be tied to a corner of a neighboring patented claim, to a government survey corner or U S locating monument, or, in absence of these, to any permanent object. If other reference points are not obtainable, bearings of mountain peaks may be taken.

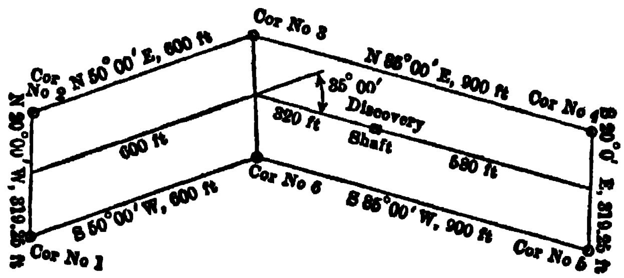

Fig 36. Claim with Broken Side Lines

Location certificate may be written by the claimant, but is usually drawn up for him by the surveyor. It must state: name of lode, name of locator, date of location, number of feet claimed on each side of point of discovery, description of boundaries by bearings and distances, and tie lines to established points. Following is a form that may be purchased in blank:

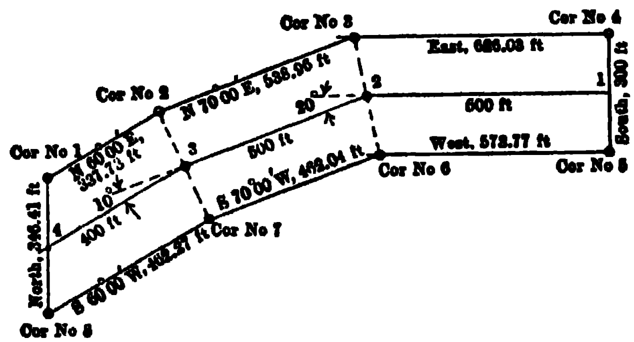

Fig 37. Claim with Broken Side Lines; End Lines Parallel

State of ______________ } ss.
County of ______________ }

Know All Men by These Presents: That ______________, the undersigned, has this ____ day of ______________, ______, located and claimed and by these presents does locate and claim by right of discovery and location, in compliance with the Mining Act of Congress, approved May 10, 1872, and all subsequent acts, and with local customs, laws and regulations, ____________linear feet and horizontal measurement on the ____________ lode, vein, ledge or deposit, along the vein thereof, with all its dips, angles and variations as allowed by law, together with 300 feet on ____________ side of the middle of said vein at the surface, so far as can be determined from present developments; and all veins, lodes, ledges, or deposits and surface ground within the lines of said claim, ________ feet running ____________ from center of discovery ____________ and ____________ feet running ____________ from center of discovery ____________, said discovery ____________ being situate upon said lode, vein, ledge or deposit, and within the lines of said claim in ______________ Mining District, County of ______________, and State of ______________, described by metes and bounds as follows, to-wit:

Beginning at Corner No 1 (here follows detailed description).

Said lode was discovered on the ____________ day of ____________, A. D. ________

Date of location, ____________ A. D. ________.

Date of certificate, ____________ A. D. ________.

______________________ (Seal)

Placer claims (see Sec 24 and Art 13). If situated on lands already surveyed by gov't, and the claim boundaries conform to gov't sub-divisions, no further survey may be necessary; elsewhere the boundaries must be acceptable to the Com'r of the General Land Office. In general, as the boundaries are meridians and east-west lines, an area much larger than the claim itself may sometimes have to be surveyed, to obtain a location that will be approved.

Mill sites are located and surveyed like mining claims, but may be on non-mineral lands only. Their area is limited to 5 acres, and boundaries must be straight lines (Sec 24).

Tunnel site gives a right of way for a tunnel, not more than 3 000 ft long. Rights covering veins cut by the tunnel, and not previously located, extend 1 500 ft on each side of center line. A dump area not over 250 ft square may also be taken. Center line of tunnel is staked out so that each stake can be sighted from the preceding one. The boundaries are also staked, the bearings being obtained by true meridian. Claims on veins cut by the tunnel may be patented, but tunnel itself can not be patented.

Survey for patent. Title to a mining claim is by deed or patent from the U S. A survey must be made by a commissioned U S Deputy Mineral Surveyor, permanent monuments set at the claim corners, and a preliminary plat prepared. Notes, plat. copy of location certificate, and affidavits of surveyor and assistants are sent to Surveyor General's Office, where they are examined and checked; if found correct, they are approved and copies returned to the Deputy, who delivers them to the claimant or his attorney.

Before the surveyor is officially in charge of a survey, the claimant must obtain an order from the Surveyor General; application for which states name and address of claimant, name of claim, name and address of Deputy Mineral Surveyor, and is signed by the claimant or his attorney. This must be accompanied by a certified copy of location certificate, and a certificate showing that the required fees have been paid. The surveyor can not act as attorney for the claimant. When the order is issued, the designated surveyor is directed by the Surveyor General to make the final survey. Although the surveyor is not authorized to do the work before receiving the order, a preliminary verification of the location survey is advisable, to discover possible errors or inconsistencies. If modifications are required, an amended location certificate or a relocation certificate may be filed, saving time and trouble later on. The order for survey contains the survey number to be used, and is accompanied by a certified copy of location certificate, which shows name of claimant, name of location, date of location, date and place of record and certificate of County Clerk.

In a patent survey the final claim must coincide with or lie wholly within the limits of the location survey. All bearings must refer to the true meridian (Art 13). Errors in closure not exceeding one part in 2 000 are permitted.

If the claim overlaps or conflicts with claims already patented or located, the surveyor makes all ties and measurements necessary for a closed traverse around the portion in conflict and for showing its exact relation to surrounding claims. The area of conflict is deducted from that of the claim being surveyed. Survey notes must give a complete statement of all such areas, and the net area claimed.

Field notes are written on printed forms furnished by Surveyor General, and must follow the form given in the "Manual of Instructions for Survey of Mineral Lands of the United States" (Circular No 430, General Land Office). They include a description of the claim boundaries by true bearings and distances, distances to intersections, computed areas, ties to patent corners, and distance and bearing along the lode line on each side of point of discovery. They must also certify that at least $500 worth of work or improvements has been done on the claim. In making this estimate the surveyor sees that it conforms to decisions of General Land Office (Sec 24).

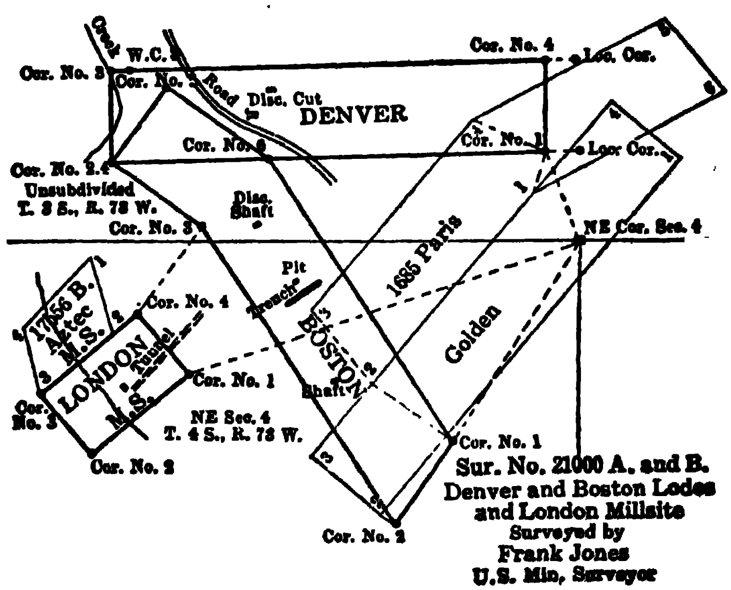

Fig 38. U S Mineral Surveyor's Plat of Patent Survey, showing Conflicts (from James Underhill's "Mineral Land Surveying," by permission)

Surveyor's plat (usually on scale of 1 in = 200 ft) shows the claim boundaries, with bearings, distances, all adjoining or conflicting claims, and all ties to corners or monuments. It must show lengths and bearings of all lines used in the notes. Fig 38 is the plat of the claims described in the following field notes (by Prof James Underhill). They contain additional data not on the map.

Survey notes, preliminary plat, affidavits of surveyor and assistants, copy of location certificate and the order from Surveyor General are sent to Surveyor General's office. When returned with approval, the Deputy surveyor delivers them to the claimant or his attorney. For his own protection and convenience, the surveyor preserves copies of all these documents, as he may have to make further surveys, or act as witness in court proceedings.

Example. Mineral Survey No 21000 A and B, Denver Land District.

FIELD NOTES of the Survey of the Mining Claim of TIMOTHY BROWN, known as the Denver and Boston Lodes and the London Millside, Coral Mining District, Clear Creek Co, Colo.

Unsubdivided Township 3 S. and Section 4, Township 4 S., Range 73 W. 6th P. M. Surveyed under instructions dated Sep 1, 1919.

by Frank Jones
U. S. Mineral Surveyor.

Claim located.........................., 19...; survey begun Sep 5, 1919; completed Oct 31, 1919. Address of claimant, Box 567, Denver, Colorado.

Denver Lode, Survey No. 21000A.

Beginning at Cor. No. 1. A spruce post 5 ft. long, 5 ins square, set 2 ft. in the ground with mound of stone, scribed cross (x) at corner point and D. 1–21000A, whence

The N.E. Cor. Sec. 4 T. 4 S. R. 73 W. 6th P. M. bears S 19° 30′ E, 309 ft.

Cor. No. 1, Sur. No. 1685, Paris lode, claimant unknown, bears S 19° W, 142 ft.

Position of Cor. No. 4, Sur. No. 1685 Paris lode, bears N 66° 36′ W 259.93 ft.

A corner of the location bears N. 88° 25′ E. 100 ft.

A cross (x) and B. R. D. 1–21000A chiseled 4 ft. above the ground on a granite cliff 20 ft. high bears N. 45° E. 25.3 ft. Thence S. 88° 25′ W.

Feet	
333.02	Intersect line 3–4, Sur. No. 1685 Paris lode, at S. 40° W. 146.77 ft. from Cor. No. 4.
770	Road, 10 ft. wide, course Southeast and Northwest.
896.67	Cor. No. 6 Boston lode of this survey.
1400	To Cor. No. 2; identical with a corner of the location. A rock in place 6 × 4 × 2 ft. above the general surface, chiseled cross (x) at corner point and D. 2–21000A. Thence N. 1° 35′ W.
85	Creek, 4 ft. wide, flows Southwest.
300	To Cor. No. 3, identical with position for a corner of the location. Not set, as it falls in the center of the creek, 4 ft. wide, flowing Southeasterly, where corner could not be established. Thence N. 88° 25′ E.
65	Witness Corner to Cor. No. 3. A granite stone, 27 × 12 × 8 ins., set 14 ins. in the ground, with mound of stone, chiseled cross (x) at corner point and W. C. D. 3–21000A, whence, a pine tree, 8 ins. diam. blazed and scribed B. T. W. C. × D. 3–21000A, bears N. 28° E, 15 ft.
250	Road, 10 ft. wide, course Southeast and Northwest.
1400	To Cor. No. 4. A cross (x) at corner point and D. 4–21000A chiseled on a ledge of rock, whence a corner of the location bears N. 88° 25′ E. 100 ft. Thence S. 1° 35′ E.
73.17	Intersect line 4–5, Sur. No. 1685 Paris lode, at N. 62° E. 263.08 ft. from Cor. No. 4.
300	To Cor. No. 1, the place of beginning.

Boston Lode.

Lode Lines. As near as can be determined from present developments, the vein of the Denver location extends 935 ft. N. 88° 25′ E. and 465 ft. S. 88° 25′ W. from face of discovery cut. The vein of the Boston location extends 1000 ft. S. 33° E. and 125 ft. N. 33° W, thence 375 ft. N. 55° W. from the discovery shaft.

Survey No. 21000B. London Millsite.

Beginning at Cor. No. 1. A granite stone 24 × 14 × 7 ins. set 13 ins. in the ground with mound of stone chiseled cross (x) at corner point and L. M. S. 1–21000B, whence, the N. E. Cor. Sec. 4 T. 4S. R. 73 W. 6th P. M. bears N. 71° 32′ E. 1331.22 ft. Thence S. 50° W.

Feet	
250	Creek, 4 ft. wide flows Southeast.
400	To Cor. No. 2. A pine post 4 ft. long, 4 ins. square, set 2 ft. in the ground with mound of stone, scribed cross (x) at corner point and L.M.S. 2–21000B. Thence N. 40° W.
250	To Cor. No. 3. Identical with Cor. No. 3, Sur. No. 17556B, Aztec mill site, claimant unknown. A rock in place showing 4 × 5 × 7 ft. above the general surface, chiseled 3–17556B, cross (x) at corner point, and L.M.S. 3–21000B. Thence N. 50° E.
160	Creek, 4 ft. wide, flows Southeast.
290	Cor. No. 2, Sur. No 17556B, Aztec millsite.
400	To Cor. No. 4. A granite stone 24 × 15 × 6 ins. set 14 ins. in the ground, with mound of stone, chiseled cross (x) at corner point and L.M.S. 4–21000B: whence Cor. No. 3, Sur. No. 21000A Boston lode, bears N 35° 40′ E. 350 ft. Thence S. 40° E.
250	To Cor. No. 1, the place of beginning. Variation at all corners 14° 30′ E. No bearing objects available at the several corners of this survey.

Area	*Acres*	
Total area, Denver lode		9.642
Area in conflict with Sur. No. 1685 Paris lode	1.032	
Total area, Boston lode		10.330
Area in conflict with Sur. No. 1685 Paris lode	0.919	
Golden lode, unsurveyed	2.160	
Denver lode of this survey	1.392	
Total area, London millsite		2.296

Surveys of Boston lode and London millsite are identical with their respective locations as staked upon the ground.

Location. This claim is located in the unsubdivided T. 3 S., R. 73 W., and the N.E. 1/4 of Sec. 4, T. 4 S., R. 73 W., 6th P M.

Expenditure of five hundred dollars. I certify that the value of the labor and improvements made upon, or for the benefit of, each of the lode locations embraced in said mining claim by the claimant or his grantors, is not less than five hundred dollars, and that said improvements consist of: The discovery cut of the Denver lode, the face of which, being the discovery point, is on the center line 465 ft. from the center of line 2–3, 5 ft. wide, 10 ft. face, running S. 88° 25′ W. 20 ft. to mouth. Value, $200.

No. 1. The discovery shaft of the Boston lode which is on the center line, 1 000 ft. from the center of line 1–2, 4 × 6 ft., 25 ft. deep. Value, $250.

No. 2. A pit on the center line 775 ft. from the center of line 1–2, 4 × 4 ft., 10 ft. deep. Value, $50.

No. 3. A trench, the east end of which bears from Cor. No. 6, S. 22° 20′ E. 425 ft., 4 ft. wide, 8 ft. deep, running S. 57° W. 130 ft. Value, $600.

A common improvement, being a crosscut tunnel 5 × 6 ft., the mouth of which, situated on London millsite, bears N. 77° 08′ W. 950 ft. from Cor. No. 2 Boston lode. Tunnel runs thence N. 43° E. 350 ft. to breast. Value, $3 500.

This improvement is in course of construction for development of Denver and Boston lodes, being all the contiguous lode locations owned in common within the range of benefit, and as described has been wholly constructed subsequent to the time since contiguity and common ownership have prevailed as between said lodes. The surface embraced in this claim ascends rapidly from mouth of tunnel towards Cor. No. 4, Denver lode. Therefore, the tunnel, continued with laterals run therefrom, will cut the veins of said locations at great depth, and thus afford an advantageous and economical means of development. An undivided one-half interest in the value of the improvement is therefore hereby credited as patent expenditure to each lode. No portion thereof or interest therein has heretofore been credited as patent expenditure.

Other improvements. A shaft on Boston lode, 4 × 6 ft., 30 ft. deep, which bears from Cor. No. 2, N. 23° 45′ W. 510 ft. Claimant unknown.

A cabin on Denver lode, the N. W. Cor. of which bears from Witness Corner to Cor. No. 3, S. 83° 25′ E. 445 ft., 25 × 15 ft., course of long sides East. Claimant unknown.

A compressor house on London millsite, the S.E. Cor. of which bears from Cor. No. 1, S. 72° 25′ W. 205 ft., 20 × 15 ft., course of long sides S. 75° E. Claimant herein.

Instrument. These surveys were made with a Buff and Berger transit, No. 2 345. The courses were deflected from the true meridian as determined by direct solar observation. The distances were measured with steel tapes.

Report. The boundary lines and connections of these surveys, as well as the lode lines of the two lode locations, were run directly upon the ground. The N.E. Cor. Sec 4, T. 4 S., R. 73 W. 6th P. M. is a stone properly marked. The N. 1/4 Cor. of said section is missing. The N.W. Cor. Sec 4, T. 4 S., R. 73 W. 6th P. M. is a stone properly marked. The N.W. Cor. Sec 4, T. 4 S., R. 73 W. 6th P. M. bears West 5 280 ft. from the N.E. Cor. said section.

Sur. No. 1685 Paris lode: Cors. Nos. 1 and 2 are stones properly set and marked. Cor. No. 6 is a post, standing, properly set and scribed. Cors. Nos. 3, 4 and 5 are missing. Lines 1–2 and 6–1 were found correct as approved. Lines 2–3, 3–4 and 4–5 are shown as approved. From Cor. No. 1, the N.E. Cor. Sec. 4, T. 4 S. R. 73 W. 6th P. M. bears S. 43° 34′ E. 216.71 ft., instead of S. 42° E. 220.5 ft. as approved.

Sur. No. 17556B. Aztec millsite: Cor. No. 3, identical with Cor. No. 3, London millsite of this claim, and Cor. No. 2 are rocks in place properly marked. Line 2–3 was found to be S. 50° W. 290 ft. instead of S. 47° W. 300 ft. as approved.

Location certificates. (NOTE by Editor of this Handbook: Certificates of above LODE CLAIMS are drawn up in the form shown near beginning of this Art.) Certificate for the London millsite:

STATE OF COLORADO }
County of Clear Creek } ss.

TO ALL WHOM THESE PRESENTS MAY CONCERN:

Know ye that I, JAMES FRANKLIN, of Denver, Colorado, do hereby declare and publish as a legal notice to all the world that I have a valid right to the occupation, possession and enjoyment of all and singular that tract or parcel of land not exceeding five acres, situate, lying and being in Coral Mining District, in the County of Clear Creek, in the State of Colorado, bounded and described as follows, to wit: The London millsite, beginning at Cor. No. 1; thence S. 50° W. 400 ft. to Cor. No. 2; thence N. 40° W. 250 ft. to Cor. No. 3; thence N. 50° E. 400 ft. to Cor. No. 4; thence S. 40° E. 250 ft. to Cor. No. 1, the place of beginning. Cor. No. 3 is identical with Cor. No. 3, Sur.

No. 17556B Aztec Millsite, together with all and singular the hereditaments and appurtenances thereunto belonging or in anywise appertaining.

Witness my hand and seal this 6th day of January, in the year of our Lord one thousand nine hundred and ten. James Franklin, SEAL.

Appended hereto are FINAL OATHS of the U S Min Surveyor and his assistants, that they legally made the above surveys, and that the improvements and expenditure on each claim are as stated.

31. MINE SURVEYING (See Section 18, on "Underground Surveying")

32. RAILROAD LOCATION

Preliminary steps. RECONNAISSANCE is an examination of the country through which proposed railroad is to run, for purpose of choosing the general route (or routes) deemed worthy of further investigation. PRELIMINARY SURVEY is a detailed mapping of route chosen as a result of reconnaissance. LOCATION SURVEY follows, consisting in staking out the railroad as straight lines and curves. A mining engineer is often called upon to lay out highways, or branch railroad lines and sidetracks. The treatment here given will, therefore, refer to branch-line work, although the same principles apply to main lines. If reconnaissance be carelessly made, subsequent surveys will not rectify such defect.

The first step is to obtain best available map of the country. For this purpose the U S Geol Surv maps are particularly valuable, because they give elevations as well as flat topography. They can be obtained for 10¢ each from office of U S Geological Survey, Washington, D C. On these maps, a paper reconnaissance can be made in the office, probable grades and alinement can be studied, and a very good general idea obtained without going into the field. Such paper reconnaissance ought always to be followed by an examination of the ground, to determine character of excavation, bridge crossings, and other important details. Large portions of the country have not yet been surveyed by the U S Geol Surv, and it is not uncommon for an engineer to find himself without a map to assist him. In this case he should travel over the most favorable routes, obtaining distances by pacing or stadia, and elevations by aneroid barometer and hand-level; these data are incorporated into a rough reconnaissance map. He should take into consideration not only first cost of road, but also that of maintaining and operating it, noting, therefore, grades, curvature, length of line, earthwork, character of soil, bridging, tunneling, and drainage. MOSAIC MAPS, based upon aerial surveys, are of great value. They may be in form of strip maps of different locations under consideration, and used in addition to or in substitution for existing maps. They are rapidly made, give dependable results both in plan and elev, and may even eliminate necessity for a preliminary survey (Art 28).

A ridge location usually has advantage of affording good drainage. A valley location usually permits better grades, but almost always requires more bridges and culverts, and is more subject to washouts. A sidehill location, where slope is not too irregular, usually has advantage that proposed line can be placed at any desired grade. Often, in mountainous regions, operative grades can not be obtained, even in bottoms of flattest valleys; the road must then be purposely lengthened by entering lateral valleys or by looping upon itself. In routes which cross drainage systems, it is important to determine the lowest passes and use these points as governing the location; in some cases it is advisable either to tunnel at the pass or to operate for a short distance over a steep grade, with a helper engine or by breaking the train in halves. In such locations grade is almost always of much greater importance than length of line or amount of curvature, although due regard must be given to sharpness of curvature, for reasons given below.

Preliminary survey is a topographic survey of the belt in which probable location of the railroad will lie; it will first be run as a transit and tape traverse to be used as a backbone for topographic details. An accurate preliminary survey aids greatly in the location survey which is to follow. Distances are measured usually to 0.1 ft, and deflection angles to nearest minute; in some cases distances are read by stadia. This map is usually plotted on a scale of 100 to 400 ft to 1 in. A preliminary party in open country will cover from 5 to 8 miles per day. The level party following the transit party establishes bench-marks and determines the profile along preliminary line.

Topographic details are sketched to scale on cross-section paper in the field, using elevations given by level party as bench-marks; a stadia survey or a plane table is well adapted to this work in open country; in wooded country a hand-level is satisfactory. A 5-ft contour interval is customary. The preliminary map and topographic details should be plotted at close of each day, from which the locating engineer will judge from day to day whether to push ahead on the line adopted, or to retract and run line over different ground. Not infrequently preliminary surveys of more than one line are made. The kinds of material encountered along the route are noted and the characteristics of bridge crossings. Upon the preliminary plan the locating engineer can draw the location line, composed of straight lines and circular curves, and from the contours a profile of proposed

location line can be plotted. From a study of the different lines and profiles the engineer will determine a final line, which will be drafted upon the preliminary map, and run out by the party as center line of the location.

Location line, as laid out on the preliminary map, will be so chosen as to pass through or lie near controlling points, such as bridge sites and passes, and to minimize total amount of earthwork. Due regard is given to grades and characteristics of the alinement. On curves, the rate of grade should be flattened about 0.04% per degree of curvature, to neutralize additional train resistance; called CURVE COMPENSATION.

It is good practice to lay out grade line for a branch connection as nearly level as practicable for about a train length from its junction with main line. Similarly a flat grade should be given for short distance in vicinity of a mine; this permits locomotive to start its train before climbing up-grade, or, if grade is down, it prevents loaded cars from running away. These flat grades are advisable, from an operating standpoint, even if, to obtain them, it is necessary to steepen other grades. Wherever the line involves a cut more than 500 ft long, it is advisable to let this occur on grades as steep as 0.2%, to provide drainage. In passing through low flat land, the line should be built a few feet above meadows or swamps, with ample culverts for brooks, and the grade should be high enough to permit easy construction of such culverts. It is bad judgment to economize on the size of culvert openings. The width of cuts, at the base, is usually made about 6 ft wider than fills, to provide for side ditches.

When the location line has been finally drawn on map, it will probably cross and recross the preliminary traverse several times. Scaled distances along the traverse line will fix points on location line, to be used by the field party in laying out the tangents of location line. Sometimes when the possible location is constricted, as in a cañon, the final location is worked out by the field party and the preliminary survey omitted. While location line is actually being run out, minor changes are often made on encountering physical conditions not recorded on preliminary map.

In staking out the center line of location, each tangent is first defined and run to an intersection with adjacent tangents; this locates vertices of the curves. The curves are then staked out by DEFLECTION ANGLES. Measurements are taken to nearest 0.1 ft, and angles to nearest minute; a stake is driven at every full station point and at the beginning and end of every curve. The beginning of the curve is called the "T C" (tangent to curve) and the end the "C T" (curve to tangent). A level party, immediately following the transit party, obtains data for a profile, reading surface elevations to 0.1 ft, and T P's and B M's to 0.01 ft. When final alinement has been staked out, the level party, using grade line of location profile as a basis, takes cross-sections and sets grade and slope stakes for construction at every station (Art 19).

Circular curves are used to connect tangents of a branch track, the refinement of transition curves not being necessary. The point at which two tangents meet is called the P I (point of intersection). The deflection angle at intersection of tangents is called the intersection angle, and is equal to the angle subtended between radii drawn to the T C and C T. The length of curve is distance from T C to C T, measured by 100-ft chords (a sub-chord may occur at one or both ends of a curve). Many engineers use the letters P C (Point of Curvature) and P T (Point of Tangency) instead of T C and C T. The degree of curvature D is the angle at center subtended by a chord of 100 ft. A chord less than 100 ft is called a sub-chord and its central angle is a sub-angle. The relation between R and D is expressed by formula $\sin {}^1/_2\, R = 50 \div R$.

In the metric system, the degree of curvature has been defined in two ways: (*a*) As the angle at center subtended by a chord of 20 m. (*b*) As the deflection angle of a chord of 20 m.

Fig 39 represents a simple circular curve. Following terms apply to its elements:

ob = Radius = R	cd = Middle ordinate = M
ab = Chord = C	cPI = External distance = E
aPI = Tangent distance = T	hg = Offset from tangent = t

The following relations between these elements are true when I is less than 180°:

$$\sin {}^1/_2\, D = 50 \div R$$

$$D_{X^\circ} = 5\,730 \div R_{X^\circ}\ \text{(approx)} = T_{1^\circ} \div T_{X^\circ}\ \text{(approx)} = E_{1^\circ} \div E_{X^\circ}\ \text{(approx)}$$

$$R = 5\,730 \div D\ \text{(approx)} = {}^1/_2\, C \div \sin {}^1/_2\, I = T \cot {}^1/_2\, I$$

$$C = 2\,R \sin {}^1/_2\, I = 2\,T \cos {}^1/_2\, I = 2\,M \cot {}^1/_4\, I$$

$$L = 100\, I \div D\ \text{(length of curve in R R and some rural highway practice)}$$

$$T = R \tan {}^1/_2\, I = {}^1/_2\, C \div \cos {}^1/_2\, I = E \cot {}^1/_4\, I$$

$$E = R \operatorname{exsec} {}^1/_2\, I = T \tan {}^1/_4\, I = M \div \cos {}^1/_2\, I$$

$$M = R \operatorname{vers} {}^1/_2\, I = R - \sqrt{(R + {}^1/_2\, C)\,(R - {}^1/_2\, C)} = C^2 + 8\,R\ \text{(approx)}$$

$$t = \text{chord}\ bg^2 \div 2\,R$$

In highway location the length of a curve is usually considered as its actual arc, in which case the degree of curvature D_1 is defined as the central angle for an arc of 100 ft. The central angles of any part of the curve are then proportional to the arcs they subtend. In computing such cases, the above formulas for C, T, E, M, and t apply.

Arc $bca = \pi RI \div 180° = R \times$ (length of arc for radius 1) $= C + (C^3 \div 24\,R^2)$ approx

$C =$ arc $bca - (\text{arc}\ \overline{bca}^3 \div 24\,R^2)$ approx

$R = 18\,000 \div \pi D_1$; L (arc) $= 100\,I \div D_1$.

Deflection angle is the most common method for locating simple curves. To lay out a curve by this method, set transit at the T C, the vernier reading 0°, and sight on A

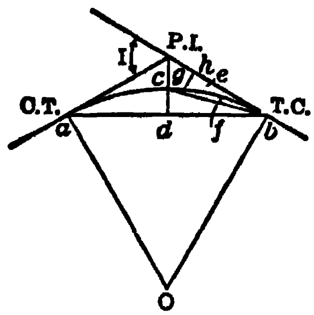

Fig 39. Elements of Circular Curve

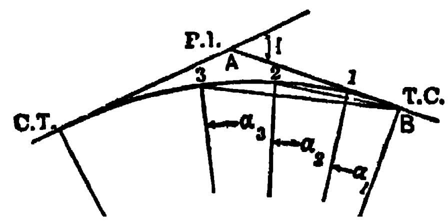

Fig 40. Laying Out Curve by Deflection Angles

(Fig 40). Lay off deflection angles AB 1 and measure chord B 1, thus locating point 1. Angle $AB\ 1 = {}^1/_2\,\alpha_1$, and $\alpha_1 = D \times B\ 1 \div 100$. Leaving lower plate of transit clamped, loosen upper motion, lay off $AB\ 2 = {}^1/_2\,\alpha_2$ and measure chord 1–2, and so on, setting each stake and checking at end of curve on the C T stake. The total deflection angle to any point on curve is evidently half the central angle between T C and that point; where stations are 100 ft apart, the deflections increase by $^1/_2\,D$ for each successive station.

Deflection angle for any sub-chord $= cD \div 200$ (in degrees) $= c \times 0.3 \times D$ (in minutes, when D is in degrees).

Example. Find deflection angles of a 6° curve connecting T C 8 + 41.7 and C T 12 + 73.4, the curve being to right.

$58.3 \times 0.3 \times 6 = 105' =$	$1°\,45'$	to Sta 9
$1°\,45' + 3° =$	$4°\,45'$	" " 10
$4°\,45' + 3° =$	$7°\,45'$	" " 11
$7°\,45' + 3° =$	$10°\,45'$	" " 12
$73.4 \times 0.3 \times 6 = 132' =$	$2°\,12'$	
	$12°\,57'$	to Sta 12 + 73.4

C T 12 + 73.4 − T C 8 + 41.7 = 431.7 = length of curve.
$4.317 \times 6° = 25°.902 = 25°\,54' = I$; and $12°\,57' = {}^1/_2\,I$.

This checks deflection angle from T C to C T. As a rule deflection angles should be computed to nearest half-minute.

Main-line locomotives, as a rule, are limited to curves of 16°–20°, depending upon their length of wheel base and number of wheels having flanges. Some passenger coaches will not go around a 20° curve unless the truck swivel-chains are disconnected. A 4-wheel switching engine will, as a rule, go safely around a curve of 75-ft radius, and a 6-wheel switching engine around one of 90- to 150-ft radius, depending upon its design. A single box car can be pulled around a curve of 50-ft radius, and two box cars around curves of 80- to 100-ft radius if a special long-link coupler be used between cars, and between tender and locomotive. On a curve of about 140-ft radius the corners of freight cars are liable to collide if the equipment has the ordinary M C B coupler. On all especially sharp curves the gage should be properly widened, the rails braced, guard rails set, and curvature maintained uniform. STANDARD GAGE is 4 ft 8.5 in. The widening of gage may be as much as $^3/_4$ in on sharpest curves. It is advisable to lay guard rails on all curves sharper than 14°. It is of importance to lay out a branch line so that a main-line locomotive can run over it; this can be done if the curves are of not less than 300-ft radius.

Cost of branch R R lines varies with amount of earthwork and bridging required. Under ordinary conditions, where cuts and fills average about 5 ft, total cost per mile of single-track branch line is about \$20 000. Ballast and tracks in place will cost from \$2.00 to \$3.00 per linear ft of track. Following estimate assumes ties at 80¢ each, that gravel ballast is obtainable within a few miles, that ballast is 12 in deep under ties, and that relayer rails are used, costing say \$28 per ton (that is, rails previously used on main-line tracks elsewhere, but still serviceable for branch track):

	Cost per ft of track
Gravel ballast @ $1.10 per cu yd in place........	$0.55
Ties, 24 in c-c, @ 80¢ each.....................	0.40
Relayer 85-lb rails, @ $28 per ton..............	0.75
Rail splices, bolts and spikes..................	0.20
Laying and surfacing track, without tie plates....	0.50
Total..................................	$2.40

Cost of turnouts, including rails of both tracks, turnout ties, frogs, switches and guard rails complete, is from $500 to $750 each, for lengths of 70 to 100 ft from point of switch to point of frog.

Wagon roads can be constructed, where excavation and filling is earth, where road follows substantially the ground surface, and few cuts are greater than 3 ft, for $1 000–$4 000 per mile. These costs assume that little material must be hauled and placed upon subgrade, to make a suitable surface for heavy teaming: it also assumes a road with travel way 10 ft wide and occasionally wide enough for teams to pass. To surface a mile of road 10 ft wide with 12 in of gravel, obtained within one mile, will cost from $2 000 to $4 000.

SECTION 18

UNDERGROUND SURVEYING

BY

EDWARD K. JUDD

FORMERLY ASSISTANT PROFESSOR OF MINING, COLUMBIA SCHOOL OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

UNDERGROUND SURVEYING

Introductory. An underground survey is based on precisely the same principles as one on the surface. The methods of reading angles and measuring distances, of computing azimuths, bearings, latitudes and departures, coordinates, and elevations, and of plotting the results, are alike in all essentials; for these principles, reference should be made to the preceding section. In their practical details, however, a number of differences are introduced by certain peculiar conditions under which a mine survey has to be conducted. These conditions are: 1. Working in the dark requires that both the point to be sighted and the cross-hairs of a telescope must be illuminated. 2. Working in constricted places, and in passages through which traffic must not be interrupted, often requires the use of special devices for mounting the instrument. 3. Stations must be placed in the roof, when possible, to assure their permanence and visibility. 4. Steeply inclined sights are more prevalent, requiring that a transit shall be always in perfect adjustment; with very steep sights, an auxiliary telescope is required, involving a correction in the reading of angles. 5. A higher degree of accuracy is usually required than in ordinary land surveying; in this respect, mine surveying is comparable with the locating of bridge piers or the boundaries of city real estate. This is because, in most of the important problems in mine engineering, aside from mere m.pping, an error means loss of time and money in the subsequent mining operations. Furthermore, it frequently happens that a complete circuit can not be made, whereby the error of closure can be determined and distributed, or a mistake located and corrected; hence careful work by refined methods is the only assurance of accuracy. 6. Shaft-plumbing is a special problem, peculiar to underground surveying.

1. STATIONS

Judicious selection of the points to be occupied as stations will facilitate subsequent operations, and extra time devoted to this end is well spent. In modern coal mines, where the workings are regular and long sights possible, it is customary for the head chain man to select and put in the stations as the party proceeds; but in most metal mines, especially if an entire new survey is to be made, it is advisable to select the points throughout the whole workings before beginning the instrumental work. Three men can do this to best advantage. At intersections of workings the point should allow sights to be taken in all directions; intermediate points should allow the sights to be as long as possible. Ordinarily, little advantage is gained by attempting to set a series of points in line, with the idea of reducing office calculations; an exception may occur in the case of a series of chutes along a straight drift, up each of which it is proposed to run short, independent surveys. Sub-stations for this purpose can be set in line with sufficient accuracy by a transit in the drift. When dodging corners in a crooked passage, a longer sight can sometimes be obtained by making an abnormally low or high set-up, at the cost of a little temporary discomfort to the instrument man; this is particularly true of inclined workings, where projections in roof and floor, as well as in the walls, have to be dodged. In passages where traffic is heavy, or where the roof is so low that a projecting spad might be disturbed, stations should be near the wall. In setting a station at which the side auxiliary telescope must be used (Art 4), an additional allowance of space must be left along both sides of both lines of sight.

Fixing stations. In important surveys, and where permanency is desired, stations should be fixed in the rock roof of the workings. For temporary work, stations may be fastened to timbers, or may be set on the ties or rails of a track, or in the floor; but in such cases, permanent roof stations should be placed at frequent intervals. This is best done by drilling a hole in the roof, inserting a wooden plug, and driving a spad into the plug. To save labor of drilling, the hole should be as small as possible; there is no advantage in having it larger than $^1/_4$ in. If the roof is high, or the rock so hard as to require double-hand drilling, a hole of 1 to 1.5 in diameter may be unavoidable. A special drill, 8 in long, $^3/_4$ in diameter, drawn out small at one end and sharpened to a chisel edge $^1/_4$ to $^1/_2$ in wide, used with a 2-lb hammer, is good for this work. In the soft roofs of some coal mines a twist drill will bore rapidly. In any case, the hole should be not less than 1.5 in deep.

In coal mines with thick seams, "jigger" stations are still occasionally employed. A conical depression is drilled in the roof with a pointed steel bar, the other end of which has a device for holding a plumb-bob string exactly at the center of the hole; also a clip holding a paint brush with which to describe a circle around the station.

Plugs should be of soft wood, preferably turned in a lathe, from dry stock, rather than whittled from wet wood; the dry plug is less likely to drop out. Some surveyors soak

plugs in creosote, to prevent decay. Still greater permanency can be secured by using plugs made of soft lead. Plugs should be so proportioned to the size of the holes that they will drive in snugly without mashing, and be flush with the roof.

Spads. The design and composition of spads in general depend upon the importance and permanence of the survey. In a wet mine, especially if sulphur be present, a plain steel spad will not last more than a few weeks; a soft-iron spad will last a little longer, but nothing will resist ultimate corrosion but copper, brass, bronze, zinc, or chrome-steel. A spad should be so designed as to insure that a cord of any size, at any time, will be obliged to hang in exactly the same position. A spad in the form of an open hook is better than one having an eye, because it facilitates the hanging and unhanging of the plumb-bob.

The commonest varieties of spads are (Fig 1): (*a*) Screw-eyes of iron or brass; an iron screw-eye, with a large eye, is objectionable because rust may prevent the cord from hanging always from the same point, while one having a small eye is generally too short on the screw end to hold firmly in the plug. (*b*) Staples and screw hooks; open to the same objections as screw-eyes. (*c*) Finishing nail, with the head bent to form a sharp hook; excellent while it lasts. (*d*) Flat-headed wire nail with a notch filed in the edge; gives accurate position, but it is not easy to adjust quickly the length of a plumb-bob cord when setting up transit. This drawback can be overcome by carrying a short piece of cord with a loop in its lower end, through which the bob cord can be passed; the upper end is wound around the nail. (*e*) Horse-shoe nail, with head flattened, and a hole punched or bored through it; very satisfactory, but subject to corrosion. This spad is improved by making the hole triangular, point down, either by filing, or by using a triangular punch made from a file. The long point of the nail should be cut off, leaving a total length of 1.5 in. (*f*) Flattened horseshoe nail with a notch sawed or filed in edge of head; if sawed, the slit should be made wide enough to allow for rusting. (*g*) Montgomery's spad, sold by survey supply houses, has the advantage of accurate centering and easy manipulation of cord; could be improved by making it of brass, or Cr-Ni steel, instead of soft steel. (*h*) Specially designed spads, as used in the anthracite fields, cast from copper, brass, or zinc, are extra strong and durable, even in acid water. Tinned iron spads of the same design are serviceable. (*i*) Loop of fine copper wire (No 26 B & S) inserted into a $^1/_{16}$-in hole, bored by twist drill, and held up by inserting a shoe-peg; limited to soft roofs, and is not durable nor easily manipulated. (*j*) Floor spad, as used in the Baltic and Champion copper mines, is made from a 3-in wire nail, by drilling an axial hole through the head, large enough to stick a match into. The nail is driven flush into a tie, a match inserted into the hole, illuminated by two candles, and used as a sighting point; subject to the drawbacks of all floor stations, and is specially unreliable when placed in a track-tie. (*k*) A boiler rivet of convenient size and length, split part way by a saw, makes an excellent floor station for chambers so high that roof stations are impossible. A hole is drilled in the solid floor, the rivet is inserted, with a steel wedge to spread it, hammered snug, and the point marked in the head with a center-punch. (*l*) Spad used at Broken Hill South mine, N S W (19), is a strip of brass, $^1/_8$ by $^3/_4$ by 3 in, with notched edges and beveled lower end, through which is a rounded triangular hole, point down; the spad is held in a 1-in hole about 4 in deep by ramming with slightly moistened neat cement, which sets hard enough for use in 15 min; outer end projects only slightly and is well protected.

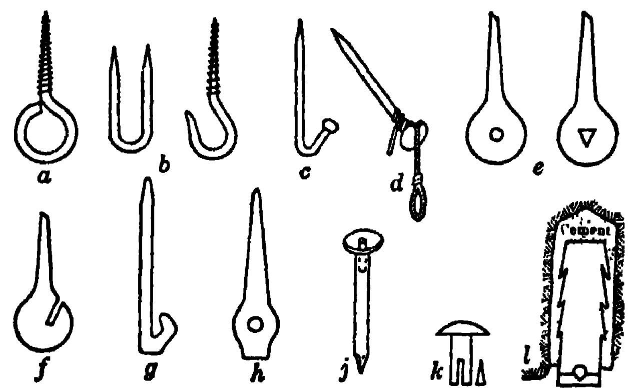

Fig 1. Varieties of Spads

Stations are marked most frequently by red or white paint, applied with a 1-in round brush. A small paint container, holding only enough for one day's work, should be carried, as the paint quickly becomes dirty. The 1-lb carbide container of an acetylene lamp, having a tight screw cover, is excellent for this purpose. Water, mud, or dust should be cleaned from the rock before applying the paint; for this, the flat bristle brush used for cleaning sinks is serviceable. A system of marks will prevent confusion of spads; thus, circles for transit points, squares for benchmarks, crosses for line points, etc. The number of the station may be painted near it, or it may be stamped with steel dies on a tag made of sheet copper, lead, brass, or zinc. When a tag is used, the spad should be driven through a hole in it, rather than to hang the tag from the spad by a wire.

Systematic numbering has many advantages, though some important mines number stations serially in order of setting, and maintain a reference index to identify them. The advantages are: (*a*) Knowing where to go to find a station having a given number. (*b*) Knowing where you are by the number of a station; this also simplifies the notation of samples and assays. (*c*) Being able to identify a station even if its tag or painted number has vanished.

The system must be adapted to the particular mine. In general, it is a good plan to reserve 100 or 1000 numbers for each level; if the workings extend in two general directions, odd numbers may be given to the stations on one side of the shaft, and even numbers on the other. The numbering of stations by their coordinates has been suggested (1), with a letter or Roman numeral to indicate the level. This involves delay until the coordinates have been computed, and the use of unwieldy numbers in the notebooks.

2. ILLUMINATION

Of sighting point. (*a*) By candle or lamp held in back of a translucent screen behind the plumb-bob string. A screen of tracing cloth is good in a dry mine; in a wet mine oiled paper or silk is better. The fabric can most conveniently be stretched smooth by a pair of embroidery hoops, of about 4-in diameter. (*b*) By acetylene lamp, having a 3-in round reflector, or a special reflector with a white enameled face made for this purpose. When using this light, no translucent screen is required, as the reflector gives a bright background. (*c*) Special lamp targets, burning either lard oil or acetylene, used only in connection with the three-tripod method of traversing, described later. (*d*) Plummet lamps, burning sperm or lard oil. These are so constructed (Fig 2) that the point of the bob, and the wick, hang accurately below the station. The hook may be hung directly in the spad, or from a piece of cord, by which its elevation can be adjusted. With long sights in a clear, still atmosphere, the flame affords an excellent sighting point; with shorter sights, the wick tube is bisected. For surveying in gassy coal mines, a plummet safety-lamp has been made on the same principles. (*e*) Specially designed "backsights" of various forms are in use in many mines, their purpose being to economize the services of a man to hold the light. Probably the most satisfactory mechanical backsight is a light tripod, supporting an acetylene lamp, which can be quickly set behind the cord of an ordinary plumb-bob. Instead of a lamp a candle sconce having a translucent screen is often used.

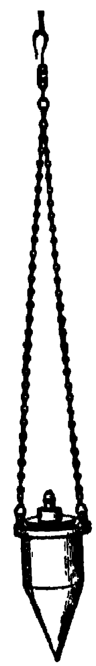

Fig 2. Plummet Lamp

Of cross-hairs. With short sights against an illuminated screen, and even with long sights against an acetylene lamp, no special illumination of the cross-hairs is necessary. When illumination is required, the oblique annular reflector supplied by all instrument makers, for attachment to the end of the telescope, is entirely satisfactory. A similar reflector can be improvised by curling a visiting card and putting it into the front of the ordinary transit sun-shade. Interior reflectors, receiving light through a hollow trunnion of the telescope, are not recommended, owing to their partial interference with line of sight.

Instrument readings are generally made with whatever form of light the surveyor carries. Compass readings must be made with a candle, or a copper lamp. Electric flash lights are convenient for reading verniers. Instrument makers sell a combination electric lamp and magnifying lens for this purpose. If a plain lens is used, it should have a metal case, not celluloid or rubber. For all-round use nothing excels an acetylene lamp, with spherical reflector. The objection of some surveyors that an acetylene lamp, especially of the larger sizes, does not leave the hands free to operate the instrument, can be overcome by hooking the lamp on a tripod leg, or in a button-hole or collar of the coat, or on a strap around the neck.

3. TRANSIT MOUNTINGS AND PLUMB-BOBS

Tripods. For underground work, tripods having extension legs are a necessity. The clamps and rings should be extra loose, to allow for swelling of the extension piece in the mine dampness. The steel points of the legs should be sharpened from time to time, for working on inclined rock floors. Short tripods, allowing the center of a transit to be set comfortably within 30 in of the floor will be found convenient under low roof. For extra low set-ups or in awkward places, as in a timbered stope or a shaft bottom, a trivet (Fig 3) can be set on a firmly fastened plank.

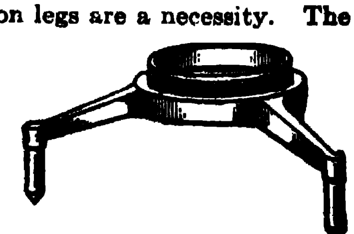

Fig 3. Trivet

Bracket. In timbered drifts, where a tripod would be in the way of traffic, and in constricted places where no tripod can be set, the bracket shown in Fig 4 is useful. A

sound and firm timber must be selected; a hole is bored horizontally at the proper spot, and the bracket is screwed snugly into place with a steel bar fitting through the hole provided for that purpose. The screw-plate is then leveled roughly by the clamp joint, the transit is screwed on, leveled accurately, and brought exactly under the point by the sliding head, the station having previously been fixed with this operation in view.

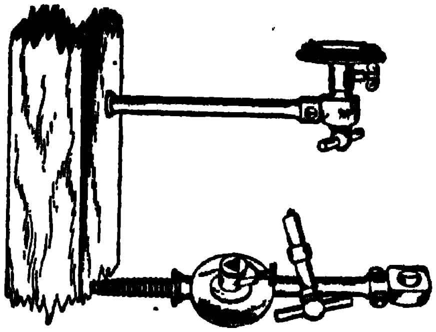

Fig 4. Transit Bracket

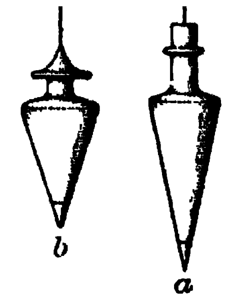

Fig 5. Plumb-bobs

Plumb-bobs. In draughty workings heavy bobs, weighing 14 to 18 oz, should be used. The instrument bob should preferably be of the shape shown at *a*, Fig 5, with a fine point. For sighting bobs the shape shown at *b* is better, as the upper end gives a more definite point to observe on inclined sights when reading vertical angles. Bobs with interior reels are unreliable in underground work, where the cord soon gets wet and dirty; neither are they necessary.

Plumb-bob cord should be braided, not twisted, to avoid spinning of the bob, and raveling at the end; for the latter reason cord having a tubular weave with a core is objectionable. Linen is better than silk for underground work, because a wet knot is easier to untie. When a cord acquires a permanent knot, discard it. Adjusting devices of wood, leather, or buttons, tend towards inaccuracy and serve no useful purpose; a sliding bow knot can be tied in a second, untied by a single pull on the loose end, and readily adjusted with one hand.

4. MEASURING HORIZONTAL ANGLES

By compass. Owing to the omnipresence of steel rails, pipes and cables, trolley wires and electric lighting and signaling circuits, in modern mines, the compass can seldom be relied upon for direct observation of bearings. For accurate work, also, readings to the nearest quarter-degree are not close enough. For less important work the compass can be used for reading an angle by noting the bearings of the two lines converging at the station, and computing it. Local attraction will not affect the accuracy of an angle reading made in this manner. Correct bearings are then computed from the angles, on any desired meridian base. The amount and direction of magnetic declination is immaterial, and need not be set off for underground surveying, unless the compass is being used for supplying details, as in a stope, which are to be tied to an instrumental survey based on true meridian.

The hanging compass (Fig 6) has great utility for traversing through tortuous chutes, or irregular stopes. A strong linen cord is stretched from station to station, which may

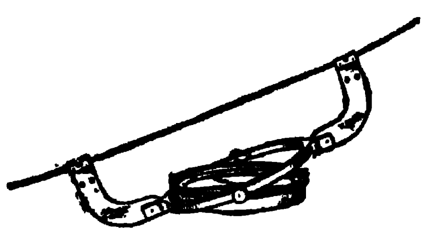

Fig 6. Hanging Compass

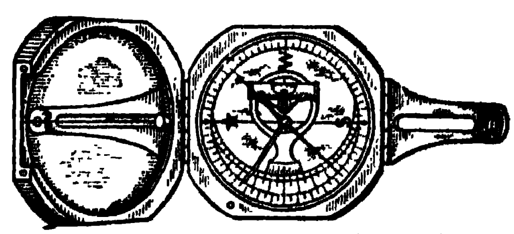

Fig 7. Brunton "Pocket Transit"

be merely of temporary character, like a stick braced from wall to wall. Special brass lugs are provided for screwing into timbers, but a heavy nail answers as well, unless a compass reading is to be taken directly under the station. The compass is then hung at any convenient point on the cord; if the cord is inclined, wooden clips are provided to keep the compass from sliding. For reading angles, where local attraction is suspected, a special hanging appliance is provided, permitting the compass to be brought under the station, to read the bearings of both lines from the same position.

The Brunton "pocket transit" (Fig 7) is a magnetic compass designed for rapid work, usually being held in the hands while taking observations. The cover is hinged perpendicularly to the sighting axis, and has a mirror on its inner side, on which a black line is scratched in continuation of the *N–S* axis; the cover and mirror are pierced with two small

holes on this line, one near the hinge, the other near the opposite edge. On the side opposite the hinge is a folding vane with a sighting slot. In use, the compass is held vertically below the eye, and below the station, the cover opened about 135°, the level tube turned at right angles to the line of sight, and the sight slot lifted to the vertical position. Looking down at the mirror, the operator can then see the reflection of the forward slot and at the same time observe that the instrument is level: the compass is then turned until a beam of light from the other station is seen to pass through the slot and be bisected by the black line on the mirror. The needle is then read. Or the instrument is held on a level with the eye, with the lid open only 45°; sight through the hole near the hinge, and read the needle from its image in the cover. A similar instrument, the Verschoyle "pocket transit," is preferred by some engineers.

The transit is universally employed for accurate work. Any transit having a full vertical circle can be used for mining work involving no vertical angles over 60°, but where underground surveys of magnitude and importance are to be conducted regularly, it is advisable to have an instrument designed for the purpose.

The special features of a mining transit are as follows: (*a*) The construction should be substantial, and not too light in weight, say not less than 12 lb (without attachments). In rough country, for service both above and below ground, and for subordinate surveys in stopes, etc, a light mountain transit is sometimes used, though the small size of its circles and its lack of stability are drawbacks. (*b*) The horizontal circle should be of large diameter, 5 in at least, and should preferably be graduated and numbered from 0° to 360° in one direction only. If graduated in both directions, the figures on the two circles should be inclined to right and left, to indicate in which direction the particular circle is to be read. Graduations should be marked with extra plainness. (*c*) For very precise work, two verniers are desirable on the horizontal circle, reading direct to single minutes; finer graduations are confusing in underground work unless the verniers are provided with magnifiers, which are vulnerable points on a transit subjected to hard usage. Micrometer readers are found on European mine transits, but are not favored in the U S. The verniers should be offset not more than 30° from the *N–S* axis, to avoid necessity of walking around the instrument to read it; also to avoid interference by side auxiliary telescope or its counterweight. (*d*) Compass may well be omitted from a transit intended solely for underground work; it is usually a waste of time to read it, though many surveyors rely upon it to check gross mistakes in vernier readings, and the transit can be made stronger without it. (*e*) Vertical arc should be a complete circle, of same size as the horizontal, and graduated from 0° to 90° and back to 0° in both directions. Two verniers are advisable for the most accurate work. The whole vertical circle should be encased. Edge graduations offer advantages over the more common face graduations on transits likely to be used frequently at difficult or precarious set-ups, as they can be read without shifting position. (*f*) The level tube under the telescope should be extra long and sensitive, and so placed that both ends of the bubble are easily visible when level. (*g*) Striding level on the horizontal axis is recommended for accurate work; its sensitivity should at least equal that of the telescope level, and it should be regularly employed at set-ups involving steep sights. (*h*) Eye-piece should be inverting, to secure better vision where poor illumination is the rule. A prismatic eye-piece is necessary for reading plus vertical angles of 45° or over. (*i*) Stadia hairs are objectionable in a transit intended solely for underground work. If they are retained, oblique hairs intersecting at the center and making an angle of 30° with the vertical hair are advantageous, as serving to identify the middle horizontal hair, and permitting more precise bisecting of a cord on short sights. (*j*) Means of attaching an auxiliary telescope at the side or above the main telescope must be provided, and similar means for attaching the counterpoise. The auxiliary telescope should have magnifying power nearly or fully equal to that of main telescope, so as not to add unnecessarily to the complications unavoidable when using the auxiliary. (*k*) A centering point must be marked vertically above the center of the instrument when the telescope is level; this should be fixed by the maker. (*l*) Illuminating reflectors to fit the ends of the telescopes are advisable. (*m*) An auxiliary lens to be attached outside of the objective, whereby sights as short as 2.5 or 3 ft can be focussed, is often useful in shaft-plumbing operations. (*n*) The interior focussing system with fixed objective, as supplied by certain makers, seems especially advantageous for mine transits; the telescope is permanently water-tight, its balance is not affected by focussing, and collimation errors are more easily avoided. The slight loss in light transmission is compensated by a larger objective.

Importance of transit adjustments. While it is possible, by judicious duplication of readings, to make an accurate survey with a transit out of adjustment, time and worry can be saved by keeping it carefully adjusted; in fact, this is imperative if traverses are to be run by the azimuth method. For methods of adjusting transits see Sec 17, Art 4. For underground work the most important adjustments are: (*a*) Plate bubbles. (*b*) Long bubble parallel to collimation. (*c*) Vertical verniers to read 0° when telescope is level. (*d*) Horizontal axis truly horizontal; this is particularly important because of the prevalence of steep sights. A sensitive striding level attached to this axis is a valuable check on the plate bubbles.

Horizontality of transit axis becomes a most important consideration when taking steep sights. If i is deviation of this axis from horiz and α is inclination of line of sight, the error in the single reading of a horiz angle is closely $\pm\, i \tan \alpha$, which obviously may

be relatively large with steep sights. If lack of horizontality is due only to absence of parallelism between this axis and the upper plate, errors in horiz angles can be fully compensated by doubled readings (telescope direct and inverted); but if it is due to obliquity between the two vertical axes of rotation (upper and lower horiz motions) it can not be fully compensated by doubled readings.

Obliquity between vertical axes can be DETECTED in several ways (14); following are the simplest. (*a*) Level the plate accurately by striding level or telescope bubble, leaving either one of the horiz motions clamped; then loosen this motion and clamp the other; if the plate remains level throughout a revolution, the two axes are either coincident or parallel. (*b*) Sight telescope (not necessarily level) at a distant sharp point and clamp horiz axis. With both horiz motions loosened, slowly rotate the lower motion with one hand, while holding the upper plate stationary with other hand. If line of sight leaves the point, note the approx reading on the horiz circle at which the max vert displacement of line of sight occurs. DETERMINATION of amount of obliquity between vert axes. Clamp upper plate at the reading approx corresponding to max divergence of the axes, as observed by method *b*, above; turning only the lower motion, take reading on a leveling rod held a known distance away and clamp horiz axis of transit; loosen upper motion, turn 180° and re-clamp; turn 180° on the lower motion and read rod again. Difference in rod readings divided by distance to rod is tangent of twice the angle of obliquity between vert axes; it is recommended (15) that this angle shall not exceed 4 or 5 sec in a transit intended for surveying steeply inclined workings.

Setting-up transit. The practice of transferring a roof point to the floor, and then setting over this point, should be condemned. It introduces inaccuracies, wastes time, and is more trouble than setting under the roof point. Hang the plumb-bob so that the cord falls under the center of the spad, not tangent to one side of it. Set the vertical verniers at 0°, to bring centering point into the vert axis of the instrument. Move the tripod under the plumb-bob by shifting and extending the legs, keeping the head of the tripod fairly level and centered approximately under the point, regardless of the transit itself. Level the transit roughly by plate bubbles, adjust the plumb-bob until its point almost touches the centering point on the telescope, and observe the direction and distance by which they fail to coincide. Loosen all leveling screws by the same amount, and shift the transit on the tripod head, without turning it, until the points coincide. Tighten the screws, and level accurately by means of the long bubble and striding level. It may be necessary to repeat the shifting operation once more. If transit has 3 leveling screws, set one plate bubble parallel to 2 screws; this bubble is then controlled by turning these screws in opposite directions, while the other bubble moves when the screws are turned in same direction.

Methods of traversing. The manipulation of the transit, and the several methods of traversing, have been fully described in Sec 17, Art 11. Much uncertainty can be avoided by adopting an invariable rule for observing and recording all angles, whether exterior, interior, acute, or obtuse. It is recommended that angles be read always clockwise, sighting first at the backsight, and invariably recording in the same manner as read. The record that the angle 8–9–10 is 178° can then have but one meaning, namely, that the transit was set on station 9, backsighted on station 8, and turned 178° to the right to station 10. If deflections or azimuths are read, instead of angles, it is understood that the recorded reading refers to the course indicated by the last two numbers. If by force of circumstances it is more convenient to read an angle backwards, that is, in direction opposite to that in which the traverse has been proceeding, the angle should nevertheless be recorded as read; vertical angles, also, should be designated plus or minus, as read, leaving it to the office to compute supplementary angles and transpose signs into conformity with a continuous traverse.

Azimuth traverse. This is the method most commonly employed in underground work requiring only a medium degree of accuracy. For the actual process see Sec 17, Art 11. ADVANTAGES: (*a*) More rapid than other methods. (*b*) Simplifies office calculation and plotting, especially when numerous side shots are taken to locate points off the traverse. (*c*) An error of closure in angles is discovered as soon as final course is read. DISADVANTAGES: (*a*) Accuracy of any one reading is limited to 30 sec. (*b*) Transit must be kept in perfect adjustment by daily inspection, because instrumental errors are cumulative. (This objection can be overcome by taking the backsight with telescope alternately direct and inverted, although, by so doing, each course will be distorted by the amount of instrumental error.) (*c*) If a closing angular error is discovered, there is no sure way to ascertain whether it is cumulative, or occurred at one set-up; nor, if the latter, at which one. The possibility of checking a single error at a station is the only argument in favor of compass readings, but under mine conditions the compass is more likely to be in error than the observer. (*d*) Azimuth traverse is not readily applied in

its simple form where there are steep sights. Since the top telescope can not be sighted either up or down in its transited position, it becomes necessary in a steeply pitching azimuth traverse to use both telescopes at each station. This introduces possible errors of adjustment which would not occur if both sights were taken with same telescope. Also, since faulty adjustments in general produce exaggerated effects on readings at steep inclinations, it is questionable practice to adopt any method for traversing under such conditions that does not permit compensation of instrumental errors so far as possible.

Deflection traverse. The vernier being set at 0°, sight the inverted telescope at the back station with the lower motion; then erect, and bring by the upper motion to point at the station ahead. Record the deflection to R or L. Loosening lower motion, turn instrument back to rear station and clamp. Invert telescope, and turn off the deflection again. Record the final reading, divide by 2, and call this the correct deflection angle. In this manner instrumental errors are compensated, and possible error of each individual reading is reduced to 15 sec. Mistake most likely to occur while traversing by this method is to confuse right and left on very small deflections. If the circle is graduated in clockwise direction only, and deflections to left are recorded as read, the mistake is less likely.

A plan recommended by M. B. Evans (20) combines the azimuth with the deflection traverse and overcomes the chief weaknesses of both methods as follows: In starting a traverse, the vernier (continuous circle) is set at the doubled azimuth of the first course, less 360° when in the 3d or 4th quadrant. At each set-up, the transit is manipulated in same way as for deflection traverse (but with no re-setting of vernier), and the 2 readings, compared with last reading at the preceding station, give 2 values for the deflection angle, of which the average is taken for calculating the azimuth of the course; this should check with half the final vernier reading (plus 180° when necessary). Besides increasing instrumental accuracy of the usual azimuth traverse, this method permits immediate discovery of a mistake in reading.

Angle traverse. By the system of repetition the error of an individual angle reading can be reduced to almost any desired limit. For ordinary mine traversing two sets of four repetitions will give the correct angle with an accuracy greater than can be obtained in the taping of distances, as usually practiced. Method of repeating angles is described in Sec 17, Art 11. Note precautions for recording angles, in previous paragraph on "Methods of traversing." The only drawback to this method for regular and extensive work is that it adds to the burden of office computation, which, however, is often warranted by the higher degree of accuracy attainable.

If a transit is known to have obliquity between its two vert axes of rotation, horiz angles involving steep sights can be read with fair accuracy by following method: Clamp lower motion approx in the position it will occupy when first taking the backsight; center and level accurately by striding level or telescope bubble, while rotating only the upper motion; take a set of repetition readings of the horiz angle, with telescopes erect and inverted. Then turn the lower motion about 90° from its initial position and clamp it; re-center and re-level with the upper motion only, and take another compensating set of readings; average of the two sets should be close to the correct angle. For more precise methods for minimizing or correcting the effects of obliquity see Bib (14).

Three-tripod method requires the use of specially constructed interchangeable transit and two targets. Vertical spindle of the transit is inclosed by a thimble which fits into a socket in the leveling head, and is held there by a clamp and a spring plug engaging a groove on the thimble. Spindles of the targets fit the same socket, and the center of the target is at the same height above the leveling head as the center of the transit. The target standard carries a pair of level bubbles. The method of traversing is as follows: While the transit is being set up, an assistant sets one target accurately under the forward station and one under the back station, the leveling head being set level by the bubbles. The instrument man then reads the angles with as much repetition as he desires, while his helpers are otherwise occupied. Tapings are made from the side center of the telescope to the side center of the target. The transit and the forward target are then interchanged, above the leveling heads, and rear target and tripod are set up at next station ahead. After the interchange, it is advisable to test for centering, and for level. ADVANTAGES: (*a*) applicable to large and high chambers where roof stations are not feasible; (*b*) saves transit man's time in setting-up; (*c*) allows assistants to be engaged in taping, plotting, note-taking, or otherwise, while instrument man is reading angles; (*d*) permits a degree of accuracy in angle reading limited only by the mechanical perfection of the instrument and the personal error of the observer; (*e*) eliminates or reduces liability of error in setting-up, in measuring inclined distance, H I and H S (Art 5), and in reading vertical angles, since all these measurements can be repeated under identical conditions during backsight operations, when a failure to check will be noted. DRAWBACKS: cost of the extra apparatus, and labor of transporting it. For routine surveying in small mines the refinements of this method are unnecessary, and it is used in only a few localities in the U S.

Steep sights. For sighting at an angle exceeding 60° either up or down, when the line of sight of an ordinary transit would be intercepted by the horizontal plate, three expedients are available: Auxiliary telescope; prismatic telescope; eccentric telescope.

Auxiliary telescope may be attached either to the right-hand end of the horizontal axis, or to a lug on top of the main telescope. A counterweight is attached to the opposite point to prevent distortion and unbalancing (Fig 8).

The auxiliary is sometimes described as an "interchangeable" telescope, but this does not mean that it should be interchanged, from side to top or vice versa, at a given set-up, with the idea of saving the calculation of angular corrections. Under conditions requiring its use it is not easy, after setting up, to adjust this telescope with the necessary precision if it is to be depended upon for the single reading of either a vert or a horiz angle, and the difficulties are multiplied if two sets of adjustments have to be made. Therefore, it is much safer to let the auxiliary remain in the same place while reading both horiz and vert angles. Also, because of the exaggerated influence of certain maladjustments in the transit itself upon single observations made at steep inclinations, some method of duplicated readings (direct and inverted) should be followed, in order to compensate unavoidable instrumental errors. This requires that the auxiliary shall be at the side, since a top telescope can not be sighted while in transited position.

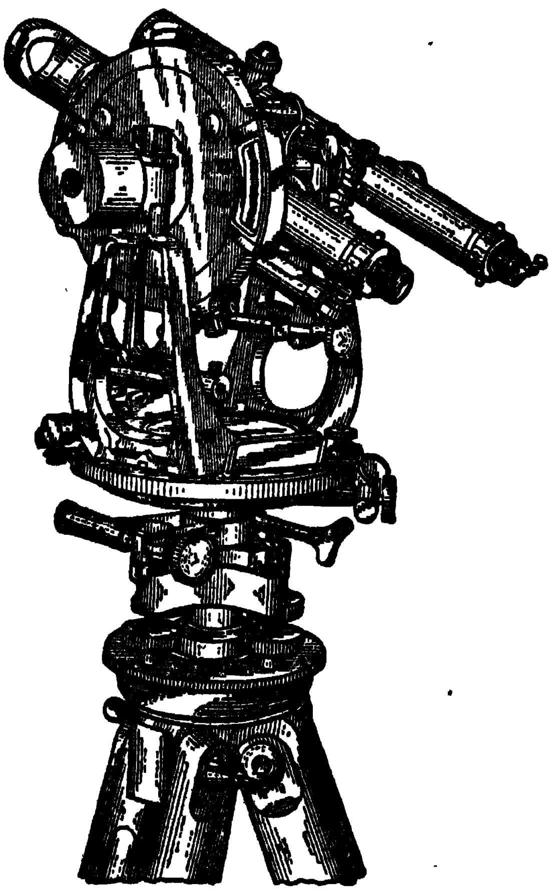

Fig 8. Fully Equipped Mine Transit (C. L. Berger & Sons)

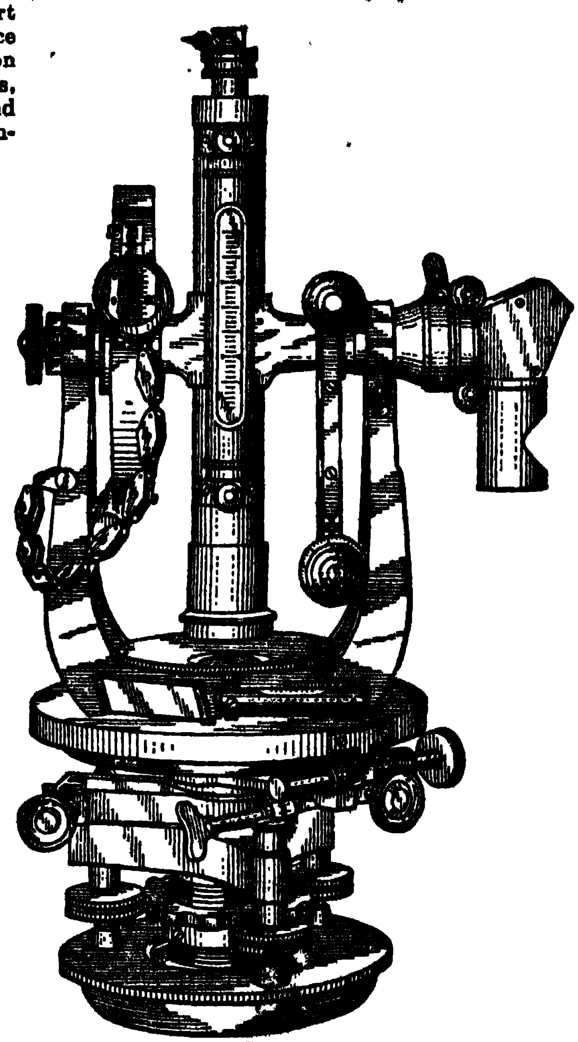

Fig 9. Prismatic and Interior-focussing Mine Transit (Bausch & Lomb)

The following ADJUSTMENTS of the auxiliary telescope must be applied with precision if angles are to be measured by single readings; if compensating observations are to be made, the adjustment becomes largely a matter of convenience only.

To bring the two lines of collimation into the same plane: After screwing on the auxiliary snugly, sight the main telescope at some sharp point and bisect it carefully. Then, with its capstan tangent screws bring the auxiliary to bisect the same point, with its vertical hair if above the main telescope, or with its horizontal hair, if at the side. This adjustment must be made every time the auxiliary is mounted.

To make the two lines of sight parallel: Determine the distance between centers of the telescopes, by direct measuring or by marking the two lines of sight against a wall 8 or 10 ft away. Set a rule, a leveling rod, or a pair of accurately spaced marks, at a distance of 200 or 300 ft, and shift the cross-hairs of the auxiliary until the correct space is intercepted by the two lines of sight. It should not be necessary to repeat this adjustment except at intervals.

Top telescope. When the auxiliary is placed on top of the main telescope, horizontal angles, and azimuths, are read directly on the vernier, as usual. Vertical angles must be

corrected in the manner shown in Fig 10. The amount of the correction, α, is obviously that angle whose sine is equal to the distance between telescopes, c, divided by the inclined distance, d, as taped from the horizontal axis of the transit to the point sighted. If the angle is negative, the correction is subtracted from the angle as read; if the angle is positive, the correction is added.

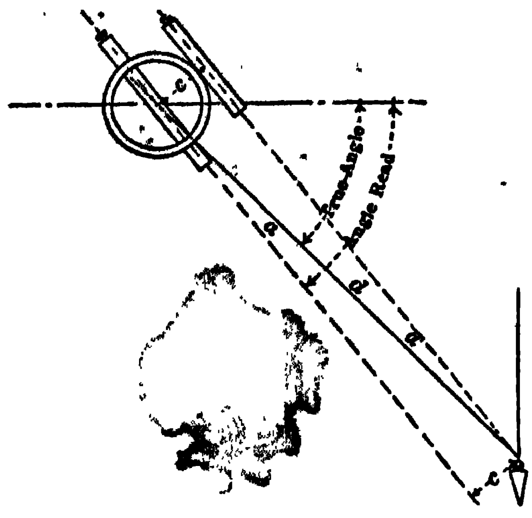

Fig 10. Correction for Vertical Angles

Side telescope. When using this, vert angles are read directly, as usual. In the single reading of a horiz angle, or azimuth, if the backsight is taken by the main telescope, it is obvious by reference to Fig 11 that the correction, β, is that angle whose tangent is c divided by the horiz distance h to the point sighted; this horiz distance, however, is equal to the taped distance d multiplied by the cosine of the vert angle. That is, $\tan \beta = c \div$ (*taped distance* $\times$ *cos vert angle*). If the auxiliary is on the right of the main telescope, and if the angle is read clockwise, the correction must be added to the angle as read. If the side telescope is used for both backsight and foresight in the single reading of a horiz angle, the correction for each sight must be computed separately; from the angle as read (Fig 12) first subtract correction β_1, for the backsight, and then add correction β_2 for the foresight, the auxiliary being on the right, and the angle read clockwise.

The reading of horiz angles with the side telescope can be much simplified, instrumental

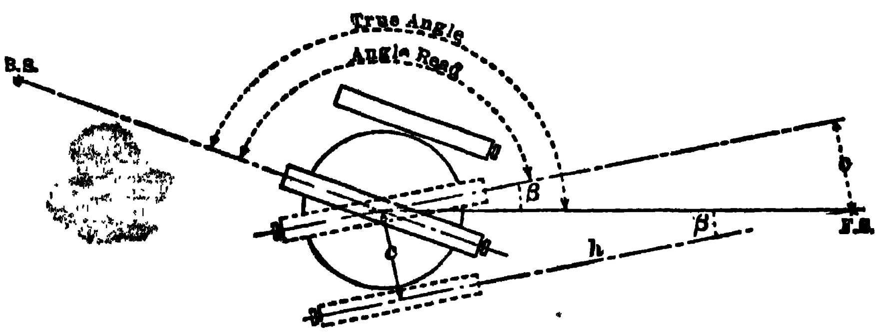

Fig 11. Correction for Single Reading with Side Telescope

errors compensated, and all computation of corrections eliminated in the following manner: Bisect the backsight with either the main or the side telescope, turn the angle and bisect the foresight with side telescope; invert the telescopes and turn the angle again as

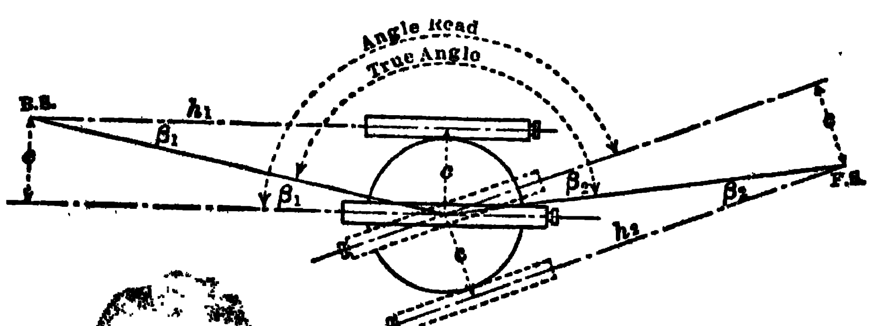

Fig 12. Correction for Horizontal Angles; Both Sights with Side Telescope

before, without resetting the vernier at zero. One-half the final reading will be the true angle. Referring to Fig 12, the first reading = true angle $+ \alpha - \beta$; the second reading = true angle $- \alpha + \beta$; hence first reading + second reading = 2 $\times$ true angle. Instead of making the two readings separately, they are added automatically on the circle of the

transit. There is no object in observing or recording the first reading, since this will not even approximate the true angle unless the horiz distances of the two courses happen to be about equal, that is, unless $\alpha = \beta$ nearly.

If an azimuth traverse is being run, and the use of the auxiliary telescope is only occasionally required, the angles at such set-ups can be quickly determined with the side telescope by the above method, the azimuth computed, and the traverse continued, after setting the vernier at the computed azimuth.

Prismatic telescope. By placing a mirror or prism, which will reflect the line of sight by 90°, on the objective end of the telescope of an ordinary transit, horiz angles of steep

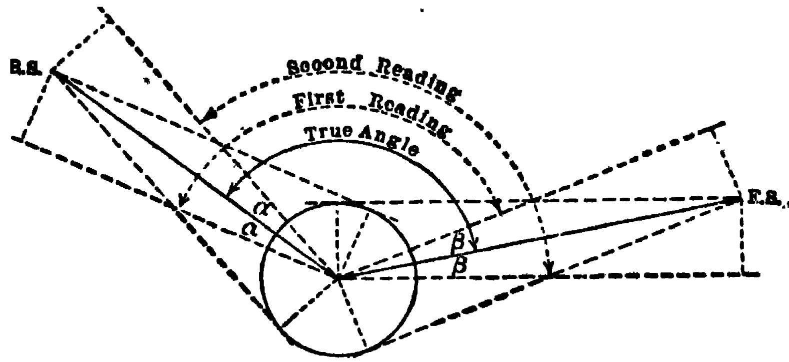

Fig 13. Reading Horizontal Angles with Side Telescope, without Corrections

sights may conveniently be read directly on the horizontal circle. The reading of vert angles by this means involves two difficulties: (*a*) the reflection may not be exactly 90°; (*b*) the movement of the objective, for focussing, alters the degree of eccentricity and thereby the amount of correction to apply to the reading. The Bausch & Lomb prismatic telescope (Fig 14) surmounts both difficulties; first by its "penta-prism," so constructed as to cause an invariable reflection of 90°, and second by its interior focussing device, which renders unnecessary the moving of the objective. The prism may be attached to the main objective, or to a side objective mounted at the right-hand end of the horiz axis, which is hollow. In the latter case the line of sight is reflected a second time by a

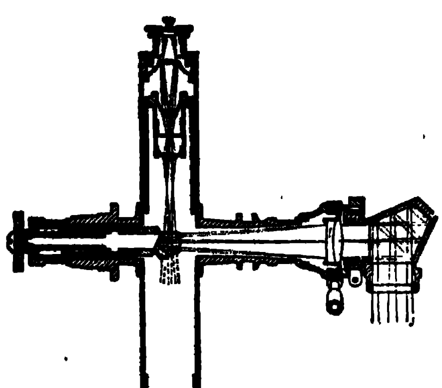

Fig 14. Bausch & Lomb Prismatic Transit. (See Fig 9)

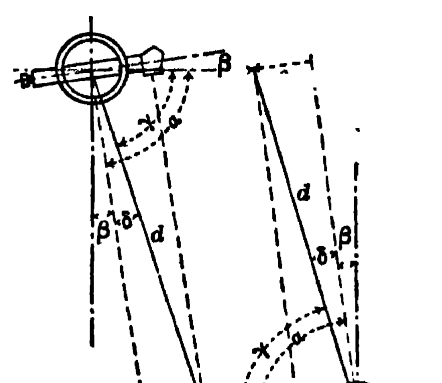

Fig 15. Correction for Vert Angle by Prism on Main Objective

smaller prism which can be inserted, when desired, into the optical axis of the telescope by turning a milled head on the left-hand end of the axis.

Adjustments and corrections. Prism on main objective. Before attaching the prism, sight the telescope on a sharp point at as great an angle as possible above or below the transit point, and bisect accurately with the vert hair; the vert axis of the transit remaining clamped, attach the prism to the end of the telescope, bring the point again into view, and by means of its tangent screw turn the prism until the point is again bisected by the vert hair. Horis angles can then be read directly. The reading of a vert angle by this method involves two computations (see Fig 15). Angle $\alpha = 90° - \beta$, and has the sign opposite to that of the angle β as actually read. True vert angle $\gamma = \alpha - \delta$, and $\sin \delta = e \div d$. If the backsight, for example, is steeply inclined upward from the instrument station, and the foresignt downward, it is more convenient to invert the telescope for

the backsight and read the horis deflection, than to read the actual angle, which would involve adjustment of the prism for each sight.

Prism on side objective. Sight the telescope on a sharp point, and bisect accurately with the horis hair. Attach the prism to the side objective, and bring the interior prism into position. Turn the former by its tangent screw until the point is again bisected. Vert angles can now be read directly. Horis angles are corrected, or corrections may be avoided, in precisely the same manner as with an auxiliary telescope.

Eccentric telescope. Several American manufacturers until recently made special transits on which the main telescope was permanently, or could be temporarily, offset from its central position, though still swinging in same vert plane. They have been discontinued, mainly because, like the top auxiliary telescope, they could not be used for compensating (direct and inverted) readings.

Fig 16 shows two types of transit with permanently eccentric telescopes. *A*, the Whitehead double-telescope theodolite, by E. R. Watts & Son, London, has given excellent service at the Ooregum mines, India, where vert angles of over 80° are common; its usefulness is obviously not confined to steep sights. *B*, by Otto Fennel Söhne, Cassel, Germany, represents a type often

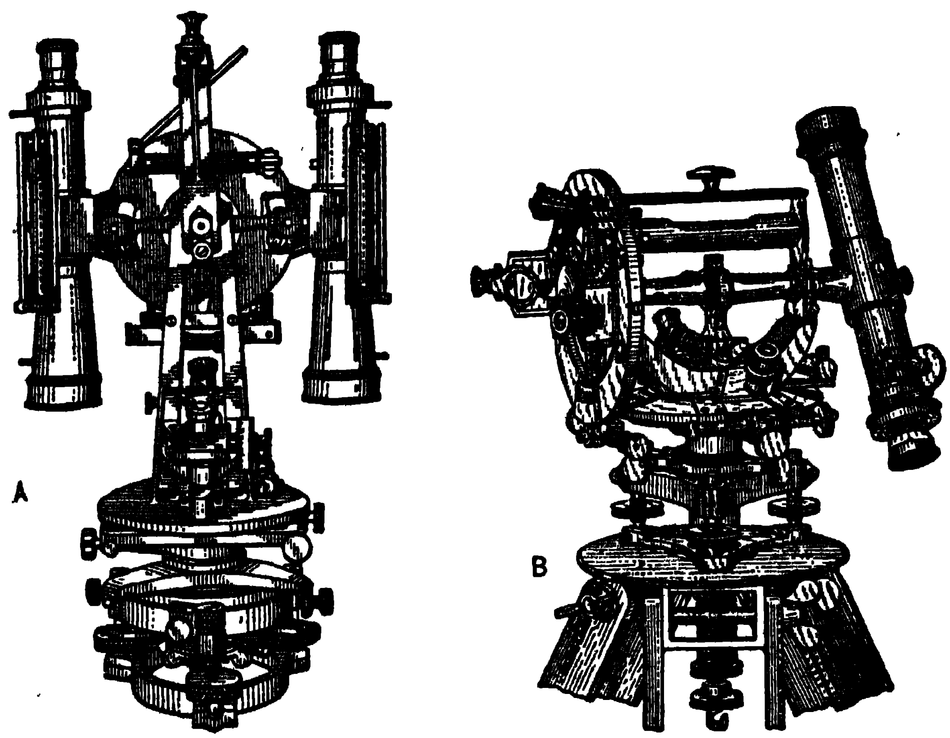

Fig 16. Two Types of Eccentric Transits

employed in Europe, for general work as well as for that involving steep sights. For reading horis angles with type *B* an eccentric target may be used, or the compensation method illustrated in Fig 13 may be followed.

5. MEASURING VERTICAL DISTANCES, LEVELING

In most metal mines, and in many coal mines, vert distances and elevations are obtained by computation on the basis of vert angles; the leveling method is sometimes used, but even then the leveling is often done with a transit. Where much leveling has to be done, it is advisable to use a Y-level, because in important mine problems the respective elevations of various points should be known with no less accuracy than their horizontal coordinates.

Computation from vert angles. Angles below the horis are called negative, and those above are called positive. In Fig 17, if t is the taped distance from the center of instrument at A, to the point sighted B, and α is the vert angle, with its appropriate sign carefully noted in the field, then the vert distance is: $v = t \sin \alpha$, and takes the same sign as α. The height of instrument, $H\,I$, or i, is the vert distance from the center of instrument up to the bottom of the spad, and the height of sight, $H\,S$, or s, is the corresponding distance from the point sighted at up to its spad. The difference in elev between the two spads, d, is thus the algebraic sum: $d = + s - i \pm v$. That is, when the vert angle is positive, add v to s and subtract i; when the angle is negative, add v to i, and subtract s. Sometimes a negative angle will be read, while the actual difference in elevation is positive.

and vice versa, but if the algebraic signs are kept firmly in mind, no confusion will result. Knowing the elev of A, the elev of B is computed by the invariable rule: El B = El $A - i \pm v + s$. In practice it is usually more accurate, and involves but little more office labor, to read vert angles to a definite point on the plumb-bob string (say, the top

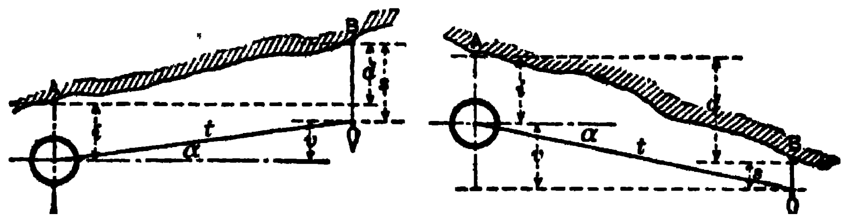

Fig 17. Computation of Elevations from Vertical Angles

of the plumb-bob) just as they come, rather than to attempt to set the sighting point at the same distance below its spad that the instrument is below its point. The $H\ I$ and $H\ S$ are read with a rule, or with a pocket steel tape graduated to feet and hundredths. In measuring the $H\ I$ of a transit it is customary to tape obliquely from bottom of spad to the center of the end of the horiz axis; this does not introduce much error unless the distance is short. The accompanying table gives the corrections to be subtracted from the oblique distance as measured on a transit of which the end of the axis is 0.25 ft from the center of the telescope.

Corrections to Subtract from Oblique Measurements of H I

Oblique distance	Correction	Oblique distance	Correction	Oblique distance	Correction
0.6	0.091	1.1	0.026	1.6	0.012
0.7	0.066	1.2	0.022	1.7	0.011
0.8	0.050	1.3	0.019	1.8	0.010
0.9	0.039	1.4	0.016	1.9	0.009
1.0	0 032	1 5	0 014	2.0	0 008

Clinometer (Fig 18) is a companion instrument to the hanging compass (Art 4), being hung on the same cord before or after the compass has been used. The bob is attached to a fine black hair, which is fastened at the center of the arc. Owing to the catenary sag of the cord, and the weight of the clinometer itself, two readings must be made, equidistant from each end, and as close thereto as possible, and the average taken. If the slope of the cord is not over 10°, a single reading at center of span will give the correct angle. Although not an instrument of precision, the clinometer is useful for subordinate surveys through tortuous, steep, or narrow openings, and in stopes difficult of access, its readings being at least as accurate as those of the compass with which it is usually associated.

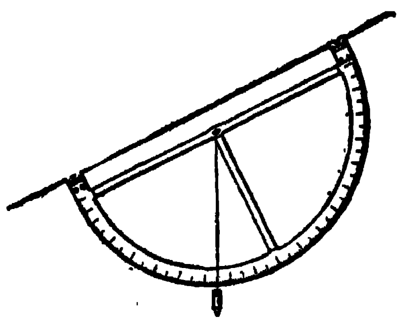

Fig 18. Hanging Clinometer

Brunton "pocket transit" (Art 4), when used to measure vert angles, is operated thus: Open the slotted sighting arm to its fullest extent, turning up its hinged end, containing the sighting hole; also open the lid about 45°. Standing under the station, hold the body of the instrument vertically and sight through the hole in end of slotted arm, and through the round hole in edge of lid close to hinge, to a light at the next station: At same time move the indicator arm carrying the level vial until the bubble, as seen in the mirror, registers horiz. Then read the vernier on the graduated end of the arm. Many other types of hand clinometers, as the Abney, are just as satisfactory for underground as for surface work.

Prismatic and eccentric transits. The use of these instruments for reading vert angles is described in Art 4, in connection with horiz angles, since the correction of one angle usually involves the reading of the other.

Determination of vert angles by transit. Since vert angles can not be repeated, in the same manner as horiz, they must be duplicated and averaged. Every vert angle of a traverse of any importance should be read at least twice, once with the telescope normal and once with it inverted, and the average taken, in order to eliminate zero error of the vert vernier. For important work it is advisable to read both verniers, in both positions, and take the aver of the four readings; this further compensates any eccentricity error in the vert circle.

While traversing by repetition angles, or by double deflections, no time is lost by reading vert angles with the telescope in both positions. On an azimuth traverse, the only check is to read the vert angle on the backsight as well as on the foresight, making two complete sets of readings of taped distance, the *H I*, and the *H S*. This checking of an azimuth traverse can be simplified by adjusting the *H S* at both foresight and backsight to correspond with the *H I* at instrument station, although this practice is not altogether recommended for the more precise methods of traversing. The auxiliary telescope, when attached to the horiz axis, gives vert angles direct; when on top of main telescope, a correction must be applied (Art 4).

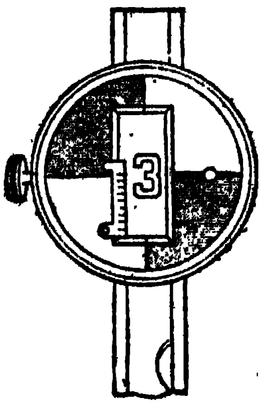

Fig 19. Underground Target

Underground leveling is performed in a manner the reverse of that employed on the surface. The zero end of the rod is pressed upward against the bottoms of the spads, or other desired points; backsight readings are thus negative in sign, and foresight readings are positive. (Compare Sec 17, Art 18.) Elev of a point on the floor is obtained by holding the rod right end up and recording the reading as negative.

Form of notes and method of computing elevations are otherwise exactly like those used on surface work. A self-reading rod can not usually be employed, unless the air is clear, the sights short, and a strong light is available. The target for underground service should have a 1/4-in hole and a 1/32-in slot cut on the horiz line, behind which a light is held (Fig 19). A 3-ft rod, extending to 5 ft, is convenient for mine work. Hooks or other devices for hanging leveling rods from survey spads, to relieve the labor of holding the rod in inverted position, are open to criticism since a spad may be dislodged by a weight for which it is not designed.

6. TAPES AND TAPING

Underground conditions require a tape to be light in weight, because measurements are usually made with the tape unsupported between the two points; strong and durable, to withstand unavoidably rough treatment and sometimes acid water; and its numerals to be as large and distinct as possible, to avoid mistakes of reading in a poor light.

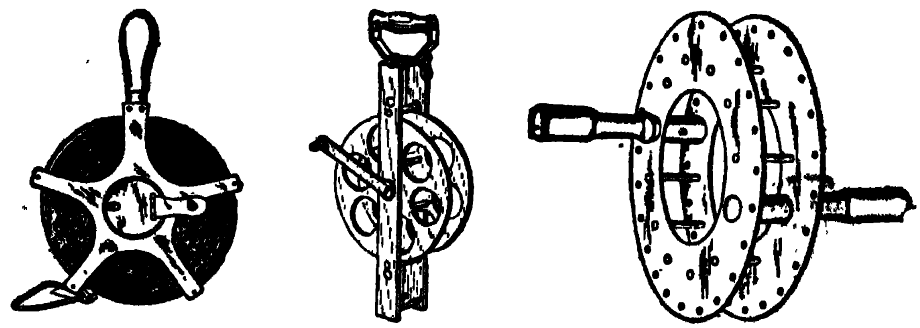
If the graduations are marked on copper or brass sleeves, these should be soldered in place, as well as clamped, to keep the water out. Riveted sleeves are not recommended. Nickel-plated, bronze, and stainless steel tapes are most resistant. A steel tape, plated with white metal and having its graduations, at every foot, stamped on thin bosses of babbitt metal, is on the market. Tapes should be standardized for a constant pull, say 20 lb, and for constant temp, say 62° F. It is seldom necessary to apply corrections for temp, because mine temperatures are fairly constant, although not necessarily corresponding to the standard temp of the tape. Temperature may, however, become a noteworthy factor in correlating surface and underground surveys. For catenary and temp corrections see Sec 17, Art 11. It is rarely possible in mine surveying to tape a distance exceeding 300 ft, and for general purposes a length of 100 or 200 ft is satisfactory. A clamp handle for gripping the tape anywhere along its length adds to convenience as well as to the accuracy of the work, besides avoiding sharp bending of the tape.

Graduations are commonly at 5-ft intervals. Exact distances must then be ascertained by marking on the tape with a pencil, or by holding the thumb-nail on the point, and measuring to nearest 5-ft mark with a pocket tape. This is troublesome, and likely to be inaccurate. The difficulty can be lessened by having the zero mark of the tape 5 ft from the end, the outer length being graduated to single feet. The foresight man then holds the nearest 5-ft mark at his point, and the transitman measures the exact distance with a 6-in rule, graduated by hundredths from 0 to 0.5 ft on one side, and from 0.5 to 1.0 ft on the other, for convenience in reading in either direction to nearest foot-mark. Inaccuracies in reading can be best overcome by using a steel ribbon tape graduated to feet and hundredths throughout. These are more expensive than flat-wire tapes, and require more cautious handling. Practically the same convenience is secured with a cheaper tape graduated only to single feet, and having an extra foot at one end graduated to hundredths backwards from zero point.

Taping practice. Distances should ordinarily be taped along the line of sight, from the center of the horiz axis to the point sighted for reading the vert angle, usually the top of the plumb-bob. An exception is in the case of nearly horiz drifts, where elevations are subsequently to be obtained by leveling; the tape may then be stretched on the floor. At Cerro de Pasco (30), where elevations are determined by leveling wherever possible, the unsupported tape is stretched horizontally by noting, on the cord of the sighted bob, the point level with the transit; this makes measurement of vert angle, *H I*, and *H S* unnecessary, and leaves the telescope in the correct position for the next set-up. For unsupported taping, a steady pull of 20 lb should be given, a spring balance being used

until the operators become expert at judging the pull. For surveys demanding high accuracy, and permitting or requiring taped distances much in excess of 100 ft, the catenary correction for the tape used should be ascertained by referring to accurately established reference points. In general, taping as usually practiced is more subject to error than angle reading and, especially if there are long spans, the error tends to accumulate.

Tape reels for underground work should be larger and stronger than for surface work. If the type shown at *a*, Fig 20, be employed, for a ribbon tape 100 ft long, the reel should



b *c*

Fig 20. Tape Reels

have a capacity of 150 or 200 ft, to prevent clogging by dirt. Type *b* is preferred for long flat-wire tapes. Type *c* is as simple and satisfactory a reel as has been devised. It is made of sheet metal, preferably brass; in the turning of the shoulders on the spacers, plenty of metal should be allowed with which to form the riveted heads. The two wooden handles should be fastened by screws to prevent them from turning inside the ferrules and wearing small enough to drop out. A reel of this type, of 10 in diameter and 2 in width, will hold 500 ft of flat-wire tape. So much of the tape as is not needed for constant use is tied to the reel by cord or leather thongs.

Care and repair of tapes. Tapes used underground should be cleaned, dried, and oiled every day. When a tape breaks, it is not necessary to send it to the maker for repairs. Obtain a few pieces of soft sheet brass, about $^5/_8$ in long and of a width sufficient to wrap around the tape with a double lap on one side ($^1/_2$ in is about right for a flat-wire tape). These pieces are tinned on one side, and then folded as shown in Fig 21. Straighten and clean the broken ends of the tape, apply zinc chloride solution, and tin with a soldering iron for a distance of $^1/_2$ in on both sides of the break. Fit the broken ends closely together inside one of the brass sleeves, close the latter with pincers or by hammering, apply more flux, hold a hot soldering iron on the sleeve until the solder flows, add a little more solder at the ends of the sleeve, and finally wash off carefully any excess of zinc chloride, to prevent rusting. A neater job can be made by cutting out the 5-ft length in which the break occurred, and inserting in its place a 5-ft length cut from an old tape, then stamping the figures on the new sleeves. This plan avoids multiplicity of brass sleeves.

Fig 21. Brass Sleeve for Repairing Tapes

7. UNDERGROUND TOPOGRAPHY

By offsets. This method is best suited to rooms, entries, drifts, and narrow stopes. While the tape is stretched between stations, either before or after the distance has been measured, lay it on the floor in a straight line approximately under the two points, with the zero end preferably at the instrument. At every 5- or 10-ft mark, or at any other intermediate points opposite salient features of the walls, such as corners of pillars, chutes, etc, measure the distance at right angles from the tape to the walls on both sides, using a rod, a rule, or a linen tape.

If the object of this work is to compute excavated volumes, as a basis for payment of wages, for example, the widths should be read to the nearest tenth of a foot, and considerable care should be exercised to measure at right angles to the line of the traverse. For less important work, measurements need be only to nearest foot. If all offsets are measured at about waist height, errors due to irregularity in the walls will compensate themselves in the long run. The readings may be plotted immediately to scale on the right-hand page of the note-book, which should be ruled coordinately, with a center-line corresponding to the line of sight. Or the readings may be recorded to the right and left, opposite their appropriate points on the center line. Another way is to record the readings thus: 50 $^3/_5$, meaning that at the 50-ft point the right wall was 3 ft and the left wall 5 ft from the line. Distances to roof and floor are taken at instrument points by direct measurement, and at intermediate points by a leveling rod sighted from the transit, the target being bisected at each point by the line of sight. Roof and floor notes are best recorded in the form of fractions, as above, but should be distinguished from wall notes by drawing a circle around them.

Radiating offsets. Where more detailed information is desired as to the complete cross-sectional profile of an opening, as for example in estimating for a masonry or concrete lining, the principle of Heller & Brightly's SUNFLOWER is serviceable.

As used many years ago in N Y aqueduct tunnels, the "sunflower" was a brass disk, 14 in diam, graduated around its edge, and having a centrally pivoted arm which served as guide for a measuring stick long enough to reach all points on the perimeter of the section. The disk, mounted vertically on a tripod, was brought into the center line or traverse course and its elevation adjusted or observed by transit at the nearest station; distances to the roof, walls, and floor were then recorded at as many radiating angles in the plane of the disk as desired.

For smaller-scale work in a metal mine the same principle can be adopted in simpler manner, *viz.*: a light board, about 12 by 14 in, is held vertically at an adjustable height by clamping to a leveling rod or other easily portable device, which acts as a supporting column when braced between floor and roof or between walls. A pad of durable paper is tacked to the board and a thin finishing nail driven part way in at the center. After adjusting the board so that its center is on the line of sight between two stations, or otherwise determining its position, a light wooden rod graduated to feet and tenths is rested on the center nail and its zero end brought against the walls at as many points as desired; its position is scribed directly on the paper and the corresponding distance noted. The distances are then reduced to scale and the profile is sketched in somewhat like a plane-table survey, using a fresh sheet of paper at each set-up.

By angles and distances. This method is applicable to broad open chambers, and lends itself particularly to the azimuth method of traversing. Having set up at a station and oriented the lower plate by a backsight, take sights to a light held at as many points as desired, recording the azimuth, the vertical angle, and the distance to each. As these notes are commonly plotted by protractor, duplication of angles is not necessary. After all the sights have been taken, observe the azimuth and distance to the next station, and proceed. If the traverse is being run by deflections, or by angles, the method of taking the side shots is the same, but in plotting the notes the protractor must be separately oriented at each station.

By tape alone. This is suitable only for large open chambers unobstructed by pillars or timbers, in which all of the points are nearly in one plane. From each of two traverse stations measure the distances to each desired point, and plot by swinging intersecting arcs from the plotted stations. This gives the situation of the points, referred simply to their own plane; to project on the horiz plane, an observation must be made on the prevailing slope.

By angles alone. Two traverse stations are required, from both of which all the desired points can be observed. With the vernier at zero, set up at one station and sight the other station with the lower motion. Then read angles, both horiz and vert, successively to each of the desired points. Set up on the other station and read angles to the same points, having the zero directed to the first station. Time is saved by using two instruments, sighting simultaneously at the same point. Plot with protractor, by intersecting lines. Labor of plotting with protractor may be reduced if, instead of observing angles as just described, each transit is oriented to same meridian and azimuths to the several points are recorded. If elevations are required, they can be computed by multiplying the horiz distances, scaled from the map, by the tangents of the vert angles.

If the points in the chamber are inaccessible for the man holding the light, the following expedient has been found successful. Two transits are required, set up at two traverse stations commanding as much as possible of the excavation, and having their zero points oriented. Take the ground-glass plate out of the back of a camera box, and hold in its place an acetylene lamp. This will throw a narrow beam of light through the lens, which can be projected against the roof and walls of the chamber, the bright spot being observed simultaneously by the two transits. Plot and compute as above. A third transit at another station may insure a more complete capture of all the points in the chamber.

The Tonnesen method (2) was devised for estimating stoped areas in the Transvaal gold mines, where the slope is often regular for long distances, and wages are based on area excavated. It aims to reduce the office labor involved in first converting inclined distances to the horizontal basis, and then reprojecting to the inclined plane the areas thus calculated. Tonnesen's instrument, the "stereometer," is based on the same principle as the nautical sextant, and reads angles in the plane of the three points. At least two accurately located points are set in the stope, in convenient positions, and the side shots to the faces of the stope are taken either by angles and distances from one station, or by intersecting angles from both stations. Or, a traverse may be run, in the plane of the stope, close against the face, offsets being measured to the solid ore. If the uniformity of slope is interrupted by faults or folds, the area is divided into panels, each having a uniform slope, and each is separately measured.

8. SHAFT PLUMBING

Wires used for shaft plumbing are of iron, steel, copper, brass, or phosphor bronze. In any case, the size of the wire should be as small as will safely carry the weight of the bob; B & S No 20 or 24 is convenient. Iron wire is easily obtainable, and its ductility permits the bob to stretch out its kinks without breaking. If much plumbing has to be done, at intervals, iron wire is liable to deteriorate by rusting. Steel wire (piano wire)

is much stronger, but is not always easy to procure, must be handled cautiously to prevent kinking, and is subject to rust. Copper wire is easy to get, is ductile and non-corrodible, but as a fine copper wire will not carry much weight, and therefore can not be stretched tight, its position in a shaft is more subject to disturbance by air currents and falling water. Brass wire is stronger than copper, but is subject to kinking, and if it breaks under tension its springiness makes it troublesome to untangle. Phosphor-bronze wire is strong, durable, and not too springy. In general, iron and copper wires are more suitable for shallow shafts free from rapid air currents and falling water, while steel and phosphor bronze are better adapted to deep shafts and troublesome conditions.

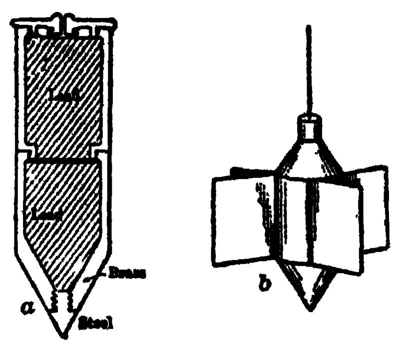


Fig 22. Shaft-plumbing Bobs

Bobs range in character from flat-irons and sash weights to carefully turned and centered instruments, and in weight from 10 to 125 lb. Irregular-shaped weights are objectionable because in twirling they impart a wobbling motion to the wires, which adds to the difficulty in determining their mean position. Cast-iron bobs have been suspected of being susceptible to magnetic influences, tending to deflect them from their true position. This was once observed in a case where a pile of steel rails lay in the magnetic meridian, with their ends close to an iron bob. Ordinarily, magnetic influence on iron bobs is probably negligible. Lead bobs, used in connection with copper wires, are wholly free from this

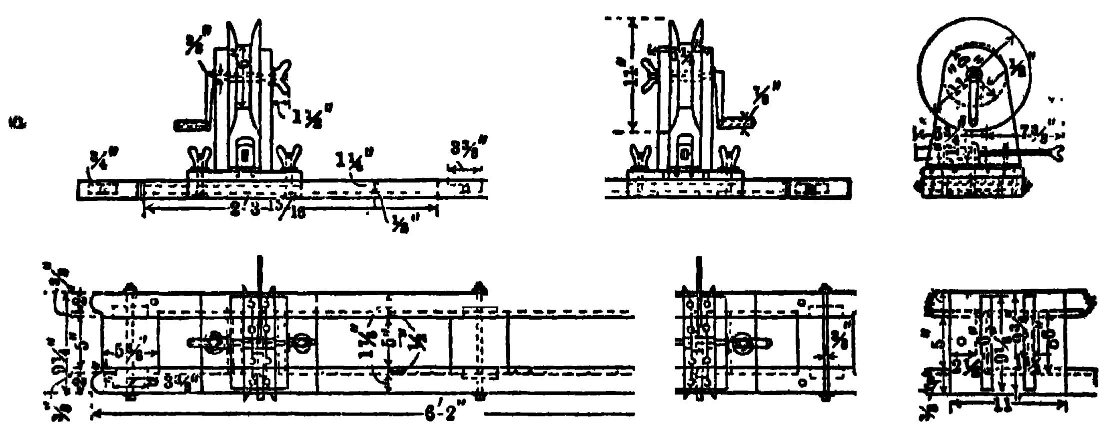

Fig 23. Shaft-plumbing Board, Butte, Mont

suspicion. The Handley (3) sectional bob has a brass shell, accurately turned and centered, with threaded connections, permitting a bob of any desired weight to be put together (Fig 22, *a*). The brass shell is poured full of lead, each section weighing 10 lb. An iron bob fitted with fins to reduce twisting and vibration, when submerged in a bucket of liquid, is shown at *b*. The fins are soldered to a tin-plate jacket closely fitting the bob. An excellent bob can be turned from a piece of steel shafting; additional weight, if desired, can be obtained by making it hollow and filling with lead or mercury.

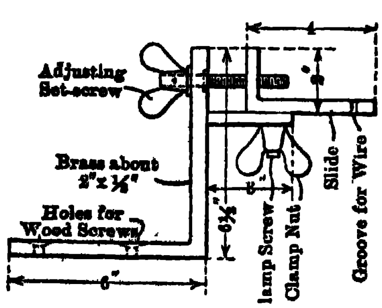

Fig 24. Shaft-plumbing Bracket

Supporting wires at top. If the shaft survey is only an isolated case, the simplest means will suffice for fixing the position of the wires at the surface. The wires may hang over notches in the edge of a board or in the head of a nail, and the excess wire may be kept on a spool. If the plumbing operation is likely to be repeated frequently, it is well to provide better designed and more durable apparatus. It is a convenience to support wires in such manner that their position can be readily shifted to bring them into line, or to vary their distance apart; also to keep the excess wire on a reel, where it can not be injured. The apparatus used at Butte (4), is shown in Fig 23. A type of adjustable bracket is shown in Fig 24. Another type, and the reel used in connection with it, are shown in Fig 25. Still more elaborate forms have been used, but are not necessary for ordinary cases.

When two vert shafts with connecting workings are available, only a single wire in each shaft is needed, preferably hung near the center. Having determined the coordinates of the two wires by a closed surface traverse, set up underground at a station as far from wire No 1 as it can be plainly seen, and sight the mean position of the wire. This operation need not be performed with such extreme precision as when only a single shaft is available, since the base-line for the underground survey may be several hundred or thousand feet long. Assume any bearing for the line from the wire to the first station, and carry the traverse on that basis through the workings to wire No 2. From the underground notes, calculate the length and bearing of a straight line connecting the 2 wires (see Art 9); this length should correspond closely to the similarly computed length on the surface, as a check on the underground work. Compare the computed underground bearing of the closing line with its true bearing as determined on the surface, and correct all underground bearings accordingly.

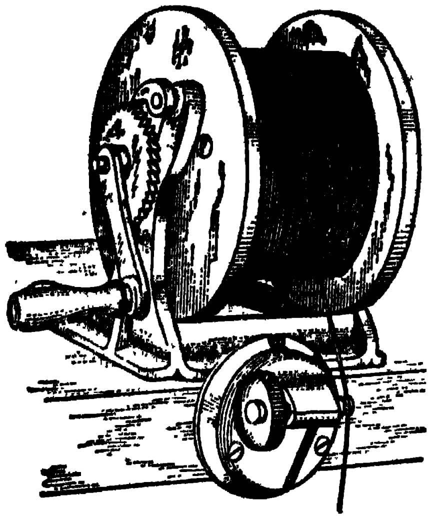

Fig 25. Shaft-plumbing Bracket and Reel

Hanging two wires in one shaft. If only one vertical shaft be available for connecting an underground survey with the surface, two wires must be hung as far apart as possible in this shaft, and their connecting line used as a base for the underground survey. Extreme care is therefore necessary in every detail of the work.

It has been found by experiment (5) that wires are liable to deflection if air is traveling faster than 100 ft per minute in the shaft. The amount of deflection is proportional to the veloc of the current, but whether the direction is up or down the shaft is immaterial. A wire hung in the corner of a rectangular shaft is more strongly deflected towards the long side of the shaft; hence, if two wires be hung in opposite corners, their deflections will be in opposite directions and the bearing of the line connecting them at the bottom will be doubly displaced. This is a more serious source of error than a mere divergence of the wires. It is therefore recommended that in a shaft having a strong current of air the wires should be hung at about the middle points of the ends, rather than in the corners. If possible, the ventilating current should be reduced or stopped while shaft plumbing is going on. If this is not feasible, for important work, board flues can be built from the top to near the bottom of the shaft, and the wires lowered inside of them; these will afford protection also from falling water. A light bob should be used for lowering the wires, and the heavy bobs attached below; a snap hook facilitates interchanging. Freedom of a wire from obstructions can be ascertained: (*a*) by watching, from above, a light slowly rotated around the bob; (*b*) by comparing the swing period of the bob with the correct period computed from the known length of the wire; (*c*) by wrapping a little ring of wire loosely around the plumb wire at the top, and letting it drop; (*d*) by causing the point of support to be moved a definite distance and direction at pre-arranged intervals of time, noting whether corresponding movement occurs at bottom. Adjusting wires in a deep shaft is nervous work; it may be greatly facilitated if telephone extensions can be provided at top and bottom, or a 2-wire cable installed with push-button and buzzer for transmitting signals.

Three-wire system. As a means of detecting angular displacement of the line connecting two plumb-bobs in the bottom of a shaft, it is recommended (6) that three bobs be hung, and that no angles be read until the three wires at bottom are precisely the same distance apart as at the top. If this be the case, since it is highly improbable that all three bobs would have been displaced by exactly the same amount, and in the same direction, the angular positions of the bobs can be accepted as correct. At Hollinger and other deep Canadian mines (21) the third wire is used, not merely for the purpose just described, but as an additional sighting point, both above and below ground, thus permitting a check on position of any one wire by calculations based on 2 or 3 independent sets of observations. Following paragraphs assume that instrumental observations are confined to 2 wires.

Observations at top of shaft. It is usually convenient to bring the transit into line with the wires; if not, their respective positions may be triangulated as described below. Having hung the wires approximately in position, set the transit on a point from which both wires can be seen. If the position of the wires is adjustable, they may be brought into line with the transit by sighting first at one and then at the other; if the wires are

fixed, the transit must be brought into line with them, by the shifting head. The micrometer head shown in Fig 26 is a help in this operation. All being set, measure the distances from wire to wire, from the nearest wire to the transit point, and from the transit point to the last traverse station. Also measure, by repetition, the angle from the last station to the line of the wires. From these data compute bearing of the line of wires, and the coordinates of either or both wires. Before leaving the transit station, both it and some other point accurately in line with the wires should be permanently marked for future reference.

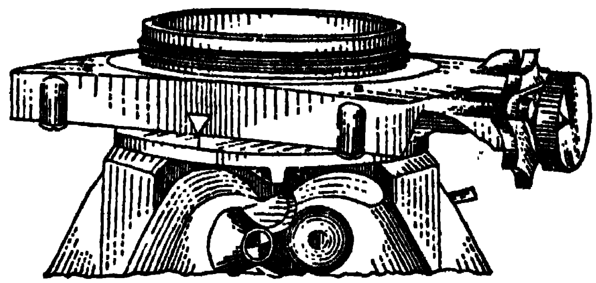

Fig 26. Micrometer Head

Observations at bottom of shaft. If a suitable instrument station can be found at the right spot, the transit may be lined in on the wires; if not, their position must be triangulated. European engineers generally favor the triangulation, or Weisbach, method, with angles as small as 1 to 3 min (preferably not exceeding 25 min) subtended at the transit by the wires, even when the alinement method could be used.

Compensation of instrumental errors by repetition can probably be made more readily when triangulating than when alining on the wires. Methods for increasing the precision of alinement practice are given in Bib (16). For an alinement method permitting check calculations from observations at both top and bottom, see Bib (29).

If the shaft is not deep, and is free from air currents and falling water, sights may be taken on the free wires; otherwise, the mean position of each wire must be ascertained, and the wire held in that position, at least until tapings are finished; for reading angles the ascertained mean positions of the wires can be used for sighting points. In any case an illuminated screen or scale must be fixed behind each wire.

Alinement is obtained by a series of approximations, as at top of shaft. The micrometer head is particularly helpful for this purpose. If distance from transit to the nearer wire is not much greater than the distance between wires, it is possible to focus a sharp image of the farther wire even when both wires are exactly in line with the transit (16). Hence it is not necessary to insert rings or chain links in the nearer wire, unless the transit must be set farther away.

Triangulation. First measure the distance between wires. If this indicates a divergence of the wires, it is highly probable that the line connecting them is also deflected in azimuth, and all necessary means must be used to reduce interference of air currents and falling water. Set transit on a point as nearly in line with the wires as convenient, and as close to one of them as focussing permits. Measure distance from transit to both wires, and to next underground station; also the angle from each wire to that station, and the angle between wires. These measurements are not all essential, but serve to check one another.

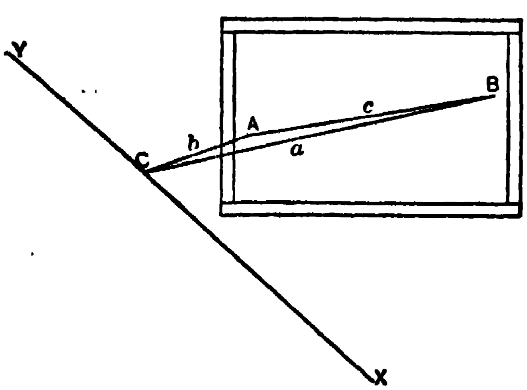

Fig 27. Triangulation at Bottom of Shaft

In Fig 27, if A and B are the wires, C the instrument point, and a, b, c, the sides opposite the angles, the known parts of the triangle are C, a, b, c. Angles A and B can be computed in several ways:

1. $\sin B = b \sin C \div c$ and $\sin A = a \sin C \div c$. As a check, $A + B + C = 180°$

2. $$\tan {}^1\!/_2 (A - B) = \frac{a - b}{a + b} \tan {}^1\!/_2 (A + B) = \frac{a - b}{a + b} \tan (90° - {}^1\!/_2 C)$$

$$A = {}^1\!/_2 (A + B) + {}^1\!/_2 (A - B) \quad \text{and} \quad B = {}^1\!/_2 (A + B) - {}^1\!/_2 (A - B)$$

3. $$\sin {}^1\!/_2 A = \sqrt{\frac{(s - b)(s - c)}{bc}}, \text{ where } s = {}^1\!/_2 (a + b + c)$$

$$\text{Also, } \sin {}^1\!/_2 B = \sqrt{\frac{(s - a)(s - c)}{ac}} \quad \text{and} \quad \sin {}^1\!/_2 C = \sqrt{\frac{(s - a)(s - b)}{ab}}$$

Eq 1 gives more precise results for small values of C; hence the advantage of setting the transit closely in line with the wires; a further advantage is that the error caused by inaccurate measuring of distance is slight. Accuracy is further gained by keeping the ratio of AC to AB as small as possible, preferably not exceeding unity. Eq 2 should be used when it is not possible to set up on a point nearly in line with the wires. Eq 3 is independent of angle C, but inasmuch as the transit must be set at C to read the angle to next station, angle C may also be read. Knowing bearing of $A-B$ from the surface survey, compute the bearing, first of $A - C$ or $B - C$, and then of $C - X$, and finally the coordinates of C and X.

While occupying Sta C (by whatever method determined) and sighting Sta X, it is advisable to set another point accurately on this line, as at Y, particularly if Sta C has not already been permanently marked as a triangulation point; point Y then serves as backsight when continuing the traverse from X.

Sighting on the free wires. Amplitude of oscillation and amount of local vibration can be reduced by immersing the plumb-bob in a pail of water, oil, or molasses. At Anaconda (7) they use a pail 18 in deep and 10 in diam, having a $^1/_4$-in pipe through the side, near the bottom, with its outlet 2 in below top of pail. The pail is filled with water to this level, and $^1/_2$ in of engine oil is poured on top to prevent splashing of falling water. Further protection is given by a split conical lid with a 2-in hole. Fig 28 shows a pail used at Broken Hill South (22) designed to hang from timbers at the corner of a shaft.

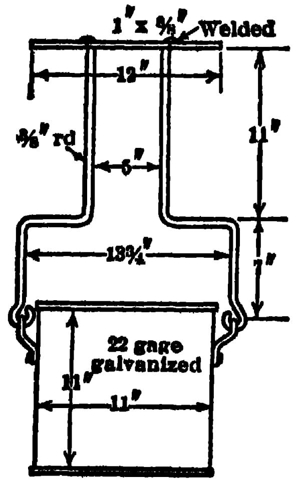

Fig 28. Plumb-bob Damping Bucket, Broken Hill, N S W

Determining mean position of wire. (*a*) If period of swing gives enough time, the wire may be followed with the upper tangent motion of the transit, the extreme right and left position being noted on the vernier. The aver of a series of readings will give the mean position. (*b*) If the transit has oblique cross-hairs, these, in connection with either of the stadia hairs, will serve as a guide in bisecting the amount of max displacement of the swinging wire, after which the mean position can be marked on the timbering. (*c*) Fix a strip of clean wood behind the wire, approx at right angles to line of sight of transit, and mark a succession of extreme positions; bisect these and set a fine nail at the mean position. (*d*) Instead of a wooden strip, a graduated rule may be used, the extreme positions being read through the transit and the mean calculated. (*e*) Draw a graduated scale on a translucent screen placed behind the wire, and read deflections as above. (*f*) A graduated slide for inserting in the eye-piece of the telescope, as in microscopic work, has been suggested.

Note.—In all the above methods involving the use of a scale to calculate the mean position, it is important to take a large and an even number of readings; 100 or more are not too many in a deep shaft, with air currents and falling water. Due to local vibration the bob seldom makes a complete swing. Prof. H. S. Munroe suggested that observations at regularly timed intervals would give the mean position with accuracy. To obtain the exact mean point for purposes of taping, the preceding methods all require 2 sets of observations on each wire, from positions giving lines of sight as nearly as practicable at right angles. One set of readings can be made on each wire from a first position of the transit, which will then be set up at another point for the second set; or, any kind of a telescope can be fixed at the second point, and the readings made simultaneously. Another method (*g*) obviates use of scales and telescopes. Bore a 1 to 2-in hole in a board, and fix it horizontally so that the wire passes through nearly the center of the hole. Cause the bob to swing in various planes and mark points of contact with circumference of hole, indicating which marks correspond. The usual pail of liquid should be omitted. Remove the wire, set a plug flush in the hole, draw lines to connect corresponding points, and set a nail where the majority of these lines intersect. (*h*) An elaborate system is the Roberts' "Shadow Method," used at East Geduld mine, Transvaal (23).

Fixing the wires. It is generally advisable, and, if sights are to be made on them at upper levels of the mine, it is essential to fix the wires in their mean positions. A simple method, under favorable conditions, is to bring the wire gradually to rest against the edge of a board so set in the timbering as to be brought forward gently against the wire. The board is then nailed fast, and the wire tied to it. If the mean position is known, from observations made as above, any simple combination of boards, tacks, and strings will serve to fix the wire.

The Schmidt apparatus (Fig 29) is useful when much work of this kind has to be done.

It is screwed to a board having a 1 1/2-in hole, set in the shaft timbers. The mean position of the wire is calculated by observations on the two scales. The bob is then disconnected, and the wire threaded through a fine hole in the brass plug screwed into the square block; the latter is then placed between the adjusting screws and shifted by them until the wire is seen to occupy its mean position, the bob having been attached again. This operation can be simplified by having a slot sawed to the center of the square iron block, the brass plug being unscrewed and threaded on the wire before the plumb-bob is attached; this saves trouble of removing the bob and then replacing it. Or, if no observations have to be made at higher levels, both bob and wire may be laid aside, and a needle inserted in the fine hole to serve as sighting and taping point after being adjusted to mean position. One advantage of retaining the wires is that all tape measurements can then be made horizontally, from transit to both wires, and some computation thereby eliminated.

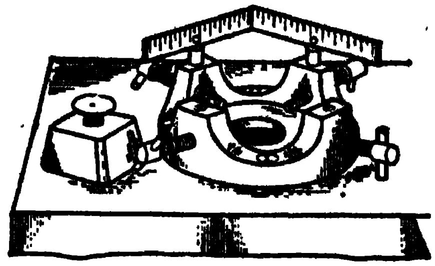

Fig 29. Schmidt Shaft-plumbing Apparatus

A method for bringing a plumb-bob gradually to rest in its mean position and holding it there as long as needed has been suggested (17), though not yet tested in practice; it would obviate both the instrumental determination of mean position and the fixing of the wire by mechanical aids. A can or small pail, only large enough to give the swinging bob clearance on all sides and only deep enough to submerge lower half of bob, is rigidly fastened by cleats and wedges to a plank nailed across shaft timbers. A warm solution of agar-agar (1.5 oz per gal thoroughly dissolved by boiling) is poured into this receptacle; as solution cools it slowly increases in viscosity and at ordinary temperature sets to a jelly rigid enough to hold the bob securely. The receptacle must be protected against falling water. If desired, the jelly can be dried out and used again.

Instrumental methods of plumbing. The side or the top telescope of a transit may be used to project the meridian of a survey with great accuracy down a vertical shaft; special eccentric transits (Art 4) are particularly useful for this. A plumb-bob must also be lowered, to give the coordinates at bottom, but as a slight error in coordinates is not so serious as one in the bearing of an underground base-line, the combination of instrumental observation and a single plumb-bob has great advantages. Observations may be made from either top or bottom.

Transit at top of shaft. Set the transit on heavy timbers in such a way that it can see to bottom of shaft. Sight along a line having a known bearing; then sight down the shaft. Stretch a wire across the shaft on the bottom level, as nearly as can be estimated under the transit, and in same plane as the telescope. The wire should have a weight on one or both ends and at each end it may be laid in the thread of a long screw mounted horizontally on a heavy trestle; by turning these screws manipulate the wire until it is bisected by the transit throughout all its visible length. This wire then gives a bearing on which to start the underground traverse, and a single plumb-bob gives coordinates of a starting point, which may be situated anywhere in the shaft. Instead of a wire, a plank having an illuminated sighting point at each end may be shifted by repeated trials into the plane of the telescope, the two points then being used as the underground base-line (8). In all work of this kind repeated observations should be made, with the telescope normal and inverted.

Transit at bottom of shaft. A method exactly similar to the preceding may be employed, stretching the adjustable wire across top of shaft, the bearing of which will be ascertained later. Or, the wire may be fixed in known bearing, and the transit brought into same plane with it by repeated trials. It is not necessary for the transit to be vertically under the wire, provided the latter is horiz; it may be tilted by its leveling screws until the wire is seen to lie in plane of rotation of the telescope, even though this plane is not vert. If then two points be fixed in the workings *at equal elevations*, whether above or below center of transit, the line connecting these two points will be parallel to the wire at the top, and its bearing can be used for starting the underground survey. Coordinates must be transferred, as before, by a single plumb-bob.

Measuring depth of shaft. (*a*) By direct measurement with tape along the timbers, made by two men, one on the roof of the cage, and one on a seat attached to the hoisting rope about 100 ft above the cage. It is well to have a third man on the cage to give signals promptly. Direct measurement is relatively simple if the shaft has a manway. (*b*) By measuring a plumb-bob wire. Place a small pulley in the head-frame so that the wire can pass over it while hanging freely in the shaft, with plumb-bob attached. Set one mark (*A*) close to the shaft and another (*B*) at any convenient place on the surface, but exactly 100 ft from *A*; the two points should be as nearly as practicable in line with the

pulley. Having noted the elev of the bob with respect to a bench-mark at the shaft bottom, fasten a marker on the wire opposite point *A* and walk with it to point *B*, when another marker is to be attached at *A*. Continue reeling up the wire, measuring off every 100 ft and the final fraction, until the bob arrives at surface and can be referred to a bench-mark. This method compensates for variation in stretch of the wire, due to its diminishing weight as it is drawn out of the shaft.

9. NOTES AND COMPUTATIONS

There is no best form of notes, and every engineer is entitled to his own preference, so long as his system is equally clear to him and to the engineering staff. In general, it is advisable to use a printed form, with headings printed or written in, having no more columns than necessary. The transit man can then tell at a glance whether every item of information pertaining to each set-up is recorded, before proceeding to the next station. If a certain measurement is not required at a given set-up, a check-mark should be made in the appropriate space, to indicate that it was not overlooked. The following headings are suggested for ordinary underground traverses.

Azimuth Traverse

Course	Azimuth	Tape	Vert angle	H I	H S	Remarks

Deflection Traverse

Course	Deflection		Double def	Tape	Vert angle	H I	H S	Remarks

Angle Traverse

Angle	First reading	Second reading	Tape	Vert angle	H I	H S	Remarks

In the form for deflection traverse the narrow column under "Deflection" is for entering initials *R*, *L*. After dividing the doubled deflection (or angle) by 2, the final value may be entered in first column, on line below. If duplicate readings of any measurement are taken they may be entered one below another in same column; it does not pay to economise note-book space. Side-shots, entered one after another in regular order, following the traverse data taken at that station, are preferably lettered to distinguish them from numbered traverse stations. In case of an angle traverse by repetition it is well to devote a whole or a half page to each set-up. Angle readings may be recorded thus:

Angle 7–8–9

	First reading			Fourth reading			Final value		
	°	′	″	°	′	″	°	′	″
Vernier *A* at 0°............	—	—	—	—	—	—	—	—	—
Vernier *A* at 180°...........	—	—	—	—	—	—	—	—	—
	Average...			....			—	—	—

The data relating to courses 8–9 and 8–7 would then be entered lower on the page in their appropriate columns. Sketches and remarks are made on the right-hand pages, which should have coordinate ruling.

Loose-leaf systems. Among the advantages are: (*a*) Pages are kept cleaner, since a particular page need not be kept more than one day underground. (*b*) It is possible to file together all the notes relating to a given section of the operations, though they may have been taken by different engineers at different times. (*c*) A complete record of all notes is constantly on file in the office. (*d*) While working at a distance from the office, the notes can be sent in daily for computation and mapping.

The forms should be printed on bond paper cards, say 5 by 7 in, punched to fit the clasps of a leather or aluminum cover, which should be large enough fully to protect the edges of the sheets. Duplicate copies are sometimes desirable, in order that the engineer may have a complete set as

well as the office. One way to make these is to have white envelopes ruled and punched exactly like the cards, into which the cards fit snugly. One card and a carbon copy are put into each envelope, and a number of envelopes are put into the cover for the day's work. The engineer then retains the empty envelopes, and returns the carbon copies to the office.

Computations. The first step is to convert azimuths, deflections, or angles, into bearings, as in Sec 17, Art 11. Next, reduce inclined distances to their horizontal and vertical components, multiplying by the cosine and sine respectively of their vertical angles. Gurden's traverse tables or mechanical calculators are great helps in this operation. Next compute latitude differences and departures of all courses, or take them from traverse tables. If a closure can be made, compute and distribute the error in proportion to the length of the courses alone. From the balanced latitudes and departures, compute the coordinates of the stations. If no closure can be made the coordinates are calculated from the unbalanced latitudes and departures. Lastly, compute elevations of the stations, from the vertical distances, the H I and the H S, as described in Art 5. The following form will be found convenient for assembling the data and the computations.

Course	Azimuth	Bearing	Inclined distance	Vertical angle	Horizontal distance	Latitudes		Departures		Corrected latitudes		Corrected departures		Coordinates		Vertical distance	Height of instrument	Height of sight	Elevation	Station	Remarks
						+N	−S	+E	−W	+N	−S	+E	−W	Lat	Long						

The whole aim and object of a mine survey is thus to determine the coordinates and elevations of as many points as possible. If the whole system, above and below ground, be based on the same set of coordinate axes, nearly every problem in mining engineering can be readily solved by the application of the principles of trigonometry, or analytical or descriptive geometry. (See Sec 36 and references 9 to 12 in the bibliography.) To minimize the possibility of error in computation it is well to take as the origin of coordinates a point well to the south and west of the entire workings; negative coordinates are thus avoided. For the same reason elevations should be referred to a plane well below the deepest workings.

The following problems are the ones most frequently encountered in laying out new mine workings.

To establish the line connecting any two points. If x_a, y_a, z_a are respectively the longitude, latitude, and elevation, of station A, and x_b, y_b, z_b are the corresponding data for station B:

1. Bearing of the line A–B is that angle whose tangent $= (x_a - x_b) \div (y_a - y_b)$; inspection will indicate in which quadrant the bearing lies.

2. Horizontal distance $A\text{–}B = \sqrt{(x_a - x_b)^2 + (y_a - y_b)^2}$.

3. Difference in elevation between A and $B = z_a - z_b$.

4. Vertical slope of the line A–B is that angle whose tangent $=$

$$(z_a - z_b) \div \sqrt{(x_a - x_b)^2 + (y_a - y_b)^2}.$$

5. Inclined distance $A\text{–}B = \sqrt{(x_a - x_b)^2 + (y_a - y_b)^2 + (z_a - z_b)^2}$.

Starting at Sta A, run a traverse by the shortest available route to Sta B; if this traverse does not form part of a closed circuit, it can be made to close by returning by the same route, but using different stations. A serious error of closure should be investigated, by repeating the work, if necessary, but a reasonable error may be balanced. This gives the coordinates and elevations of A and B. Calculate bearing and slope of the connecting line A–B by Eq 1 and 4, above. Set the transit at either A or B; orient

by sighting on a traverse line with the lower motion; set the horizontal vernier to read the computed bearing or azimuth, and the vertical vernier to read the required slope, and fix two points from which the mine boss can hang sighting cords.

To locate corners of a vert shaft to connect with a winze or raise. From an underground station near the winze or raise, measure bearings and distances to the corners, and compute coordinates thereof. Run a traverse to a station on the surface near the site of the proposed shaft, and compute its coordinates. Calculate bearings and distances from this station to four points having the same coordinates as those observed underground (Eq 1 and 2 above). With the transit set on this surface station turn off successively the computed bearings, and measure the corresponding distances to the four desired points.

To compute point at which a given line will intersect another line, for example, the end line of a claim. The known data (Fig 30) are the bearings of $B-C$, or a, and $D-A$ (which is also that of b), and the coordinates of the points A and B; required, the distance $A-C$, or b. Compute bearing and distance of c by Eq 1 and 2. From the bearing of c compute angle B, by reference to the known bearing of a; also angle C in the same manner. Then $b = c \sin B + \sin C$.

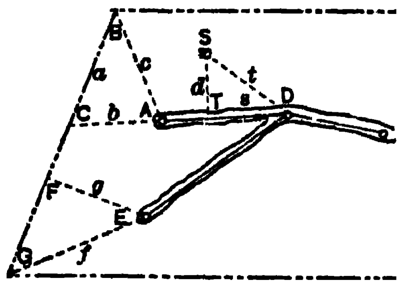

Fig 30

To establish the shortest line from a given point to meet a line of known bearing. The required line will obviously be perpendicular to the given line; hence its bearing can be computed and set off at once by a transit on the given station. If the length of the connecting line is desired, the coordinates of some point on the given line must be known, as G; whence compute bearing and distance $E-G$. In the right triangle EFG, the side f and the angle G are now known; whence $g = f \sin G$.

To determine the point on a given line from which to make the shortest connection with a given point, as, for example, to drive a crosscut from the drift $D-A$ to the bottom of the shaft S. The shortest line will obviously be perpendicular to $D-A$; hence its bearing is known, as are also the coordinates of D and S (the latter from a surface survey). Compute bearing and distance of $D-S$, or t, from Eq 1 and 2; whence compute angle S. Then $s = t \sin S$.

The above are given only as suggestive examples. In general, the shortest solution of a problem will become apparent by the simple method of plotting the known factors.

10. MAKESHIFT METHODS

Circumstances such as (*a*) lack of most suitable equipment, (*b*) absence of a helper, (*c*) difficulties in carrying out an instrumental survey by precision methods, (*d*) need for a quick survey without high accuracy, have led to numerous ingenious applications of trigonometry or descriptive geometry.

One-man survey may be necessary in examining prospects and small mines; it should not be attempted if work requires climbing old ladders or going into unventilated stopes. Brunton "transit" (Art 4) is the usual instrument; a light tripod with telescopic legs aids accuracy but is not essential, since a box or a piece of timber will serve as a mounting when hand-held readings are unsatisfactory. Candle ends serve for station points. Linen tape manipulates easier than steel; at the zero end, tape can be anchored by a cord to a rock, timber, or track tie. A 6-ft folding or semi-flexible rule is better than tape for short measurements.

Traversing steep workings without auxiliary telescope. Method described by C. Ferguson and K. J. Benner (24) is limited to slope lengths of 100–150 ft (steeper the slope, greater the permissible length); it assumes a traverse station with known coordinates and elevation near upper or lower end of the inclined opening.

Stretch a fine wire tightly between permanent or temporary supports at top and bottom, so as to leave as much as possible of the wire visible from the established station; heavy spike with notched head serves well in timbered workings. On this wire, set 2 marks (as by pinching on it short bits of soft copper or solder wire) as far apart as they can be seen from the transit station; read azimuths and vert angles, and tape the inclined distances from transit to both points (head of the supporting spike may serve as one mark); then calculate coordinates and elevations of both. Further calculation (Eq 1 and 4, Art 9) gives azimuth and slope of wire. Tape the distance from either mark to a similar mark at other end of wire, coordinates and elevation of which are now computable. Set transit under the last mark, backsight on the wire or a plumb-bob hanging from it, and continue traverse.

String surveys, requiring no direct angular measurements, have given sufficiently accurate data for plotting steeply inclined and tortuous raises, winzes, and narrow stopes in parts of the North Broken Hill mine, N S W (25).

In Fig 31, A–A' is a traverse course through a drift, details of which are known; plumb-bobs are hung at A and A'. B–B' is a wire or strong cord stretched tightly between temporary fastenings, the position of that at B' being recorded by measurements to roof, floor, and walls. Under conditions as in Fig 31 (a), a plummet is hung from B–B' at C and brought by eye into line A–A'; point D is also marked in line A–A'. Measure (horizontally) C–E, C–D, D–E, and A–C or C–A'; also inclined distance C–B'. Inclination of B–B' is obtained by hanging a plumb-bob at either end (Fig 31 (d)), measuring the length of cord B–H, and distances H–J and B–J (not safe, in this case, to assume that H–J will be measured horizontally). Cases (b) and (c) require setting of 2 temporary points C and D on line A–A', usually also light plummets at E and E'; the dotted lines

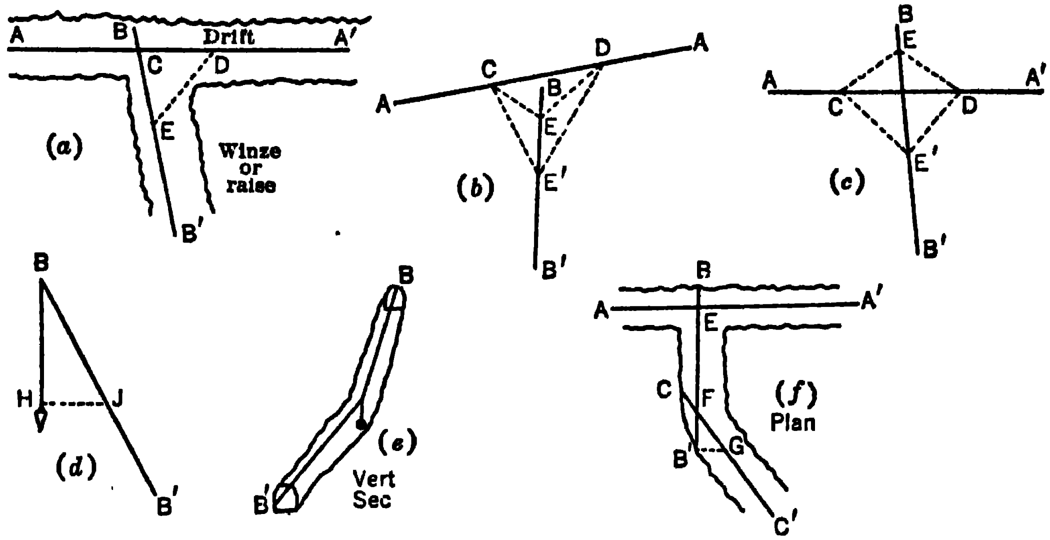

Fig 31. String Surveys, North Broken Hill Mine, N S W

indicate horiz measurements to be made. If the opening turns vertically, as at (e), enough weight is attached to make the cord clear the roof, length and inclination of both segments then being observed. At a horiz turn, as at (f), 2 cords, B–B' and C–C', are mounted, almost touching at F; horiz measurement of B'–F, B'–G, F–G then fixes the horiz angle at F; inclined distances E–F, F–C', with their corresponding vert angles, will locate C', and so on. At the Broken Hill mine, graphic solutions of angles and bearings, at scale of 1 in = 1 ft, have given sufficient accuracy; or, each case shown above can be solved trigonometrically from the indicated data, by Eq 3, Art 8.

Projecting azimuth down inclined shaft. In this case (26) the only available transit had prismatic eyepiece for main telescope, but no auxiliary telescope; hence, could sight only upward. Shaft, 5 ft wide between wall plates, pitched 85°; stations at 80 and 180 ft depth. A short piece of brass angle, with a notch at exact middle of one edge, was fastened to the upper-inner edge of the hanging-wall plate (Fig 32), and a plumb-bob with as long a cord as possible was hung from this notch; bob was damped in a pail of water on footwall side. Surface survey station, 20 ft on footwall side of shaft, was an iron pipe capped with a plug, turned and center-marked by lathe; diam of round plug was same as length of brass angle. Two parallel cords were stretched around this plug and the ends of the brass angle, their azimuth being known from surface survey. At an underground station on hanging-wall side, the transit was then adjusted by trial until the space between the cords was bisected throughout its visible length by the plumb-bob cord; telescope was then in vert plane of known azimuth.

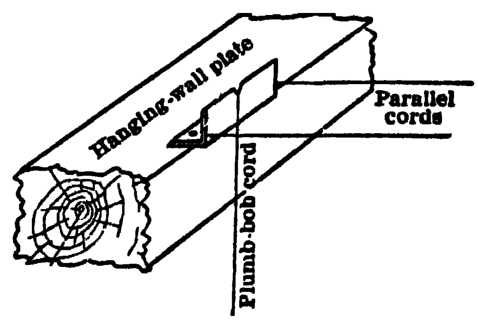

Fig 32. Transferring Azimuth down Inclined Shaft

Graphic solution of inclined raises (A. D. Rood, 27), is useful for alining the inclined and branched raises commonly required for block-caving into chutes (Sec 10, Art 80); for raises up to 125 ft long, accuracy of plotting is commensurate with that of observations by Brunton compass and tape.

Knowing coordinates and elevations of points A, D to be connected (Fig 33), procedure follows: On coordinate paper, and at scale of, say, 1 cm = 5 ft, plot positions of A and D in plan. A protractor then gives bearing A–D. Lay out a vert scale (same scale as horiz) adjusted to show D at

its proper elev. (In Fig 33, coordinates are shown at bottom and right; elevations at left.) Transfer the horiz projection of *A–D* to a vert plane passing through both points by swinging arc *A–A′* and projecting *A′* downward to *A″* at elev of *A*. Inclination of *A″–D*, by protractor, is slope of connecting line *A–D*. If the raise gets off line, a Brunton and tape survey gives bearing, slope, and inclined distance to face *B*. From *A″*, plot this slope and inclined distance to *B″*; project *B″* vertically upward to *B′* and swing arc *B′–B*, to intersect line *A–B* drawn by protractor at its observed bearing. When the face has advanced to *C*, a set of measurements at *B*, with similar construction starting from *B″*, locates *C* in vert and horiz planes. *C–D* then gives the bearing, and *C″–D* the slope and length of the closing line. In this example, note that 3 different vert planes are involved, all containing point *D*.

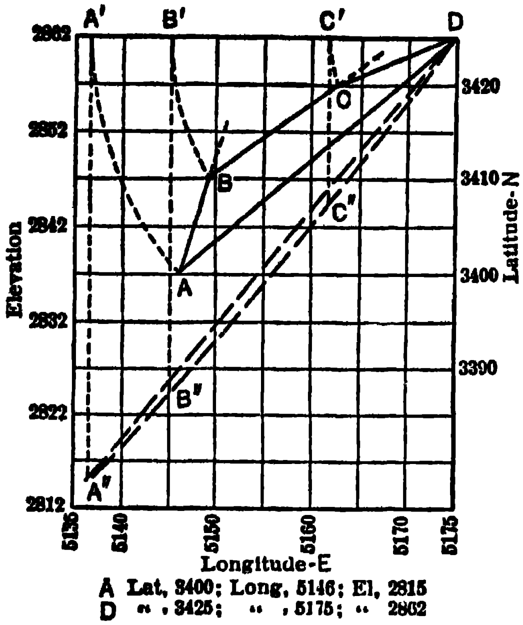

Fig 33. Graphic Solution of Inclined Raise

Survey of glory-holes at Fresnillo, Mex (Sec 10, Art 99) was formerly done by stadia (Sec 17) when walls were at max slope of 45°–50°, and vert angles at transit rarely exceeded 30°.

With increasing depth and steepness, the following methods were applied (28): (*a*) A 4-in steel ball on end of a rope was repeatedly dragged across the pit and its successive horiz and vert positions were observed simultaneously by transits on 2 previously established stations on the rim; position in plan was plotted by intersecting azimuths, and horiz distances to each station were measured by scale; these distances, × *tan* of corresponding vert angles, gave check on elev at each position. (*b*) For slope distances under about 50 m, a steel tape was attached to the ball, in addition to the rope; a transit on a rim station then gave horiz and vert angles, and the tape gave inclined distance to each point, sufficing for its computation. A third suggested plan requires setting of rim stations (not all of which need be monumented) at opposite ends of as many section lines as desired. The ball is brought into positions along each section line by 2 ropes (long enough to reach clear across) manipulated from corresponding stations on rim. Position of ball is observed by horiz and vert angles from a transit on a station at end of pit; positions are plotted in plan by intersections with section line, and elevations computed from scaled horiz distances × *tan* of vert angles.

11. MINE MAPS (See also Sec 19)

The map of a growing mine should be drawn on muslin-backed, tough paper, in a roll long enough to accommodate the most extended workings. The scale 1 in = 100 ft is as small as should be used for a map required to show details; and a larger scale is better if the map can be brought within the available paper.

Sectionalized maps are preferred for mining properties of large extent, to cover which on a scale as small even as 1 in = 100 ft would demand an unwieldy single roll of paper.

At Butte (18), the Anaconda properties are mapped on standard 18 by 24-in sheets, with 1-in margin. An area 20.8 miles E–W by 15.1 miles N–S is divided into 100 sections both ways, each block being plotted on the standard sheet to scale of 1 in = 50 ft. Each level is separately plotted at that scale, these maps being kept closely up to date and serving as the main working diagrams of the respective mines. Additional maps of same size are plotted at scales of 1 in = 100, 200, and 600 ft, with diminishing amounts of detail, the last carrying only triangulation lines and the most important surface features.

The first step is to rule the paper with fine, light-blue lines into accurately constructed squares of 4, 5, or 6 in, depending upon the scale to be used. Number these coordinate lines along margins of the paper. Plot all traverse stations by coordinates only; inasmuch as the coordinates are already computed, no time is saved, and avoidable errors are introduced, by using the protractor for any of this work. Indicate each traverse point by a small red circle, and write its number and elevation in black. It is not advisable to write the coordinates, as the figures would be crowded, and the coordinates are quickly available in the office records; it is advisable, however, to write the elevations to give a better three-dimensional idea when inspecting it. Connect traverse points by fine red lines, stopping at the circles.

Plot the outlines of the workings by offsets from the traverse lines, by intersections, or by angles and distances (reduced to horiz), as the case may be. A protractor is allowable for this work. A paper protractor of 24 in diam, with a semicircular opening cut out of its interior, is nearly as accurate as more expensive instruments. Many special forms of protractor designed for this work are in the market. Those carrying a scale on the rotating arm are excellent where much mapping

on the same scale is to be done. A special device described by J. J. Bristol (13) diminishes the labor of plotting by mechanically reducing inclined distances to horiz. Draw the outlines in black, freehand. If the mine workings lie vertically under one another, on only 3 or 4 levels, colors may be used to distinguish them. If more than this number, it is better to make a separate map for each level, all oriented and coordinated alike. To get a combined view, tracings of the several levels can be superimposed. Conventional designs to indicate various underground features are shown in Sec 19, Art 1.

Finally, a complete map should contain: (I) A title in simple lettering, and in a uniform position (lower right-hand corner recommended) stating: (*a*) name of mine or portion thereof (the words "map," "plan," etc., can be omitted); (*b*) names of surveyor and draughtsman; (*c*) date of survey and plotting; (*d*) scale, indicated thus: 1 in = 100 ft, not 100 ft to the inch. (II) An arrow indicating the true (or assumed) meridian, and another indicating the magnetic declination, if this is of interest. (III) A simple border.

Methods of making maps in glass, wood, etc., are described in Sec 19.

SECTION 19

MINE GEOLOGIC MAPS AND MODELS

BY

RENO H. SALES

GEOLOGIST TO THE ANACONDA COPPER MINING CO, BUTTE, MONTANA

MINE GEOLOGIC MAPS AND MODELS

1. MINE GEOLOGIC MAPS

Geologic study and mapping are especially useful in complex or faulted veins. Work of this nature, in conjunction with mine development and exploitation, is undertaken chiefly by large mining companies, though similar study is proportionately important at small mines. The surface and underground notes and sketches are transferred to office maps, omitting less important notations from field books, which would tend to overcrowding. Where structure is complicated, geologic plans may be supplemented by vertical sections or by models. For other data on Mine Maps, see Sec 10, 18 and 25.

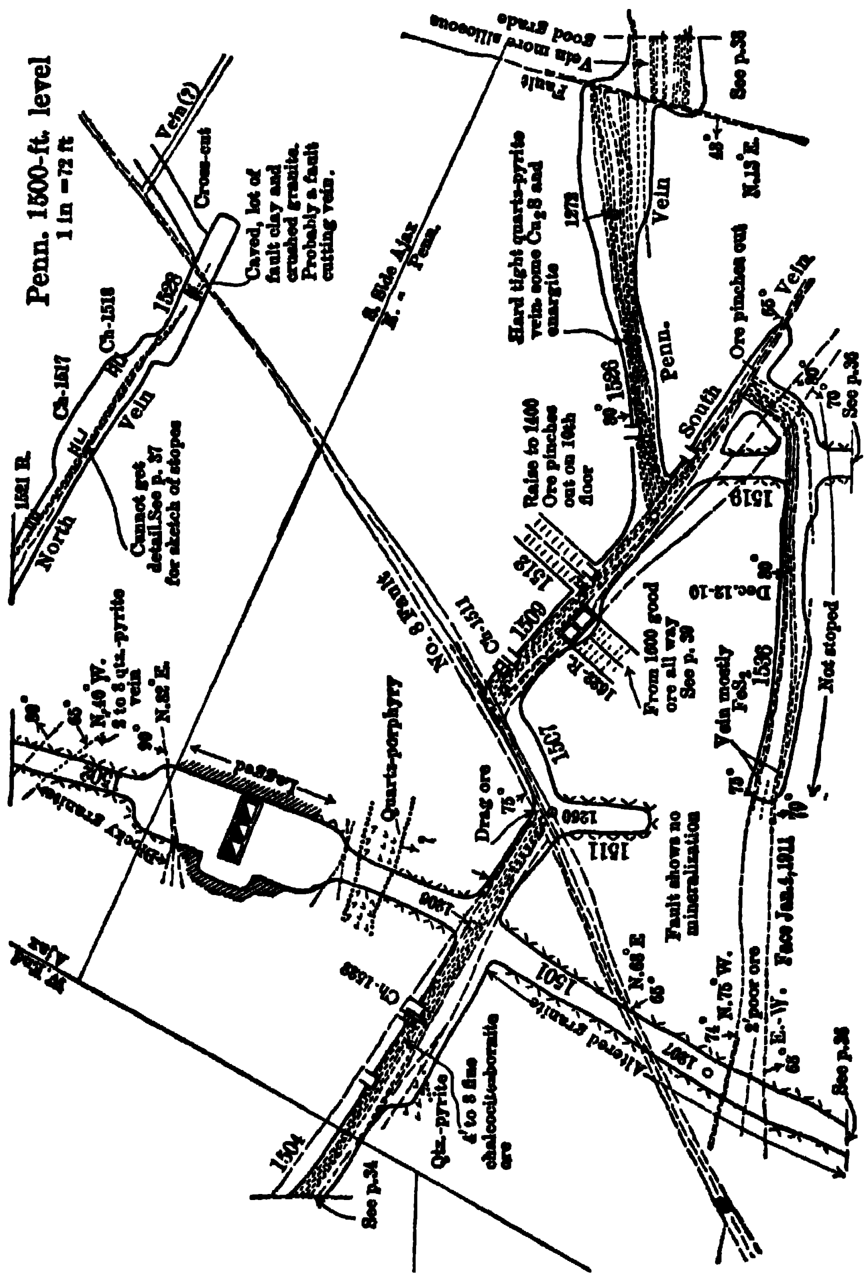

Fig 1. Example of Field Notes

Underground observations are best made in new workings on freshly broken rock and ore. In wet ground, the surfaces soon become coated with black slime, derived from moisture, dust, and products of explosives, which conceals mineralogic characteristics and adds to the difficulty of correct geologic deductions. In shifting or faulty ground, also,

inspection of workings should be made immediately after blasting and before timbering. Important information is frequently found in wet or heavy ground. Prompt geologic mapping is always desirable, to enable those in charge to direct work properly, and avoid the waste of misdirected exploration. Observations should not be confined to level workings, but should cover stopes and all other openings. In vicinity of faults, sill-floor workings in wide veins become heavy, and either cave or are closely lagged. Plans and cross-sections must then be made of the stopes above (Fig 4). Frequently, when engineer or geologist is called on to map mine geology, much of the ground has been stoped and no information as to nature of vein is obtainable.

Each ore-deposit presents its peculiar problems; in taking notes the observer should keep in mind the purpose of his work, and the point of view of the mine owner. In complicated vein and fault systems structural features demand special attention; in other cases, mineralogic associations are paramount. It is important to distinguish essential from non-essential geologic data.

Field notes are best recorded in loose-leaf notebooks, with aluminum covers. Leather will not stand hard underground usage, and sketches in bound books become blurred; with loose-leaf system, only the sheets covering workings visited need to be taken underground. Also, with bound books, growth of the mine soon causes overcrowding of notes and sketches, or scattering of them in several books. Loose-leaf records can be arranged as desired, and made easily accessible in office by a simple filing system. Scale and size of paper depend chiefly on character of deposit; sometimes on scale of mine maps, or the kind of notebook available. If minute details be necessary for proper interpretation of geologic data, use scale not less than 20 ft to 1 in. For sketches, and for use in wet or hot places, a 6 by 8-in page is desirable, ruled with pale blue or green indelible ink in 5-ft squares, with every fourth line emphasized. For more favorable conditions, an 8 by 11-in page is preferable for clear delineation of structural relations. Maps on white-print paper, or cloth, may be used underground instead of notebook, but are unwieldy and liable to be torn or soiled. When possible, begin by transferring the workings direct from mine maps to notebook, orienting them on the pages. See Fig. 1.

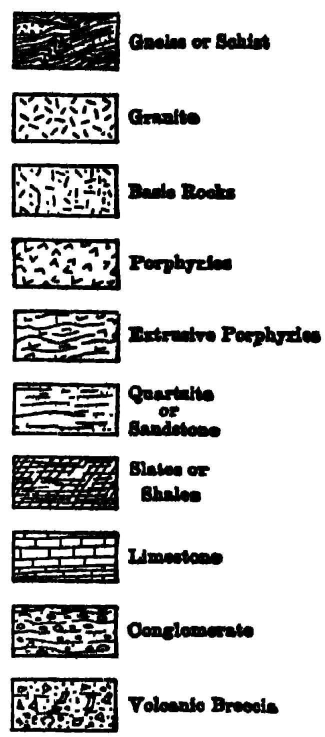

Fig 2. Conventional Signs, Rocks

Underground sketching. Colored pencils are used to denote certain geologic features, thus: red for vein minerals, and blue for faults and other dynamic effects. In representing vein matter by red, distinction between poor and rich ore is left to side notes. Too many colors are confusing, and for mixed minerals differentiation of varieties is impossible. Country rock, except narrow dikes, is best designated by conventional signs (Fig 2). Chief object is to emphasize veins or faults, as contrasted with the less important wall rocks. Vein structure is difficult to represent correctly in notebooks, and given conditions are seldom interpreted alike by two observers; hence careful, accurate sketches are essential. Observer must remember that, as others may have to interpret his notes and sketches, wrong inferences of serious nature may result from inaccuracy. Clear-cut sketches indicate clear understanding of the structure; muddled, mussy sketches denote confusion of ideas.

Facts to be sketched and noted include, in general, everything having present or future bearing on life of mine. Fig 1, 4 and 5 are typical examples of field notes from files of a mining company employing a mine geologist. Conventional signs (Fig 3) are placed along margins of sketches. In crosscuts, drifts, stopes, and raises, all veins, faults, slips, and dikes are plotted, with side notes at intervals respecting strike, dip, and mineralogic character, with their changes, if any; all being accurately located by tape measurement with relation to a mine survey station, or other fixed point (Fig 1 and 4). Pacing is excluded, except as rough check, or for unimportant details. Keep sharp lookout for cross-faults, strike-faults, and splits in vein. At intersections, or unions of veins, note change, if any, in mineralogic character; also, influence of faults and direction of "drag" along the fault. Avoid too copious notes, a common fault of inexperienced observers; note essentials briefly. Base generalities on careful weighing of available facts.

Certain matters are of scientific interest, even if not of immediate practical importance, such as: rock alteration, paragenesis of minerals, depth of oxidation and weathering, and presence of water in vein and country rock.

Instruments are pocket compass and tape. Brunton pocket transit is widely used; Verschoyle transit, Attwood clinometer, and ordinary sighting compass are also good. Metallic linen tape (Sec 17) is accurate enough for most purposes; in dry mines steel tape may be used. For notebook plotting a 6-in transparent celluloid protractor scale, graduated same as office maps, is recommended; or a common scale and protractor will serve.

Safety precautions. Geologic maps are rarely made of a mine in its early development. Hence, the geologist is usually obliged to examine many workings abandoned wholly or in part. Such work is hazardous. A common source of danger is bad air in dead ends, and in old workings lacking ventilation. Enthusiasm in pursuit of information should not lead to taking unnecessary risks. If bad air or deadly gases are known or suspected, get all possible information before entering workings. If air is such that a candle will not burn, do not force matters by using electric or acetylene lamps, both of which will burn in air too poor in oxygen to support life. Other dangers in old workings are: open stopes and winzes, rotten and loose ladders, the latter being frequent in presence of copper or acid water. In freshly broken faces, examine for missed holes or loose slabs before using pick. Always watch for open manways and chutes, loose rock, loose planks in stope floors, trolley wires and trains of cars. Geologists often work singly, but, as their work is hazardous, the practice is unwise.

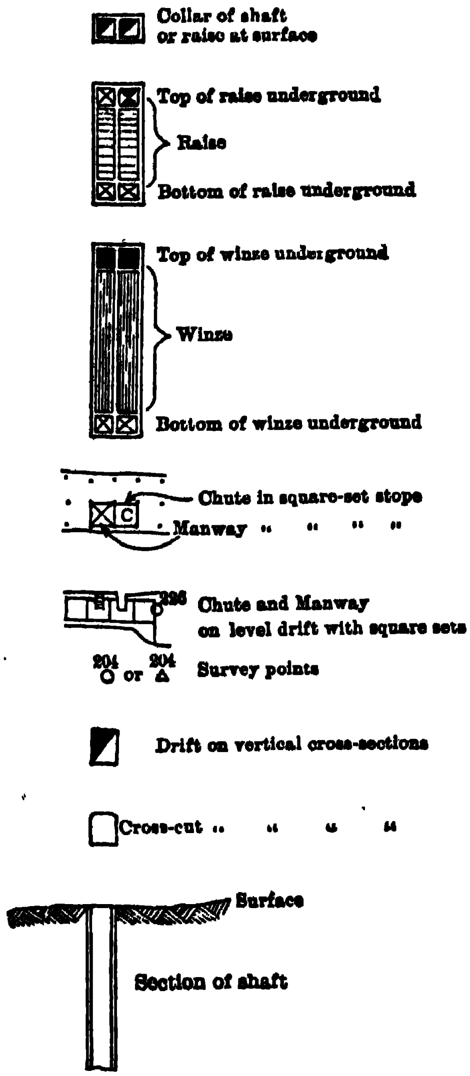

Fig 3. Conventional Signs, Workings

Office records. For a small mine, one set of geologic plans, with one or more cross-sections, or a glass-sheet model, will suffice, except in cases of complex structure. For large concerns, operating more than one mine, maps may be duplicated, furnishing to the superintendent generalized small-scale maps of two or more adjoining mines, and to the foreman detailed maps of mine under his direction. Vertical sections (Fig 5) are essential in conjunction with plans. Sections are taken at regular intervals, and as nearly as possible perpendicular to strike of principal veins; all openings are outlined.

Making the maps. Tracing cloth is in general use, having many advantages over opaque material, like drawing paper or unprepared blue-print cloth. A set of maps comprises surface map and separate sheet for each main working level. Extra sheets for intermediate levels or stopes are added when necessary for correct interpretation of geologic structure. Surface sheet shows property lines, contour lines, and all surface openings; but surface structures are admissible only for reference, and are indicated by light lines. Vein and fault outcrops must be accurately plotted. Approximate positions of concealed outcrops, determined by projection from known points in mine, are indicated by dotted lines. Mine-level sheets (Fig 6) are coordinated, and made to register with surface sheet and with one another. Each horizontal section sheet should show all openings intersected by that section. Claim lines are put on each level sheet, to show relative position of a working or of a certain geologic feature on any level.

Name of mine, with number and elevation of level shown, is placed at lower right-hand corner of each sheet. If mine numbers are used, place them along their respective openings. Raises, winzes, and stope chutes are shown along the drifts. Geologic features are plotted from field books, closely to scale, with colored pencils or ink, corresponding with those used in field work. In map construction, however, wider latitude in colors is permissible, and different veins or faults may be drawn in different colors. Assorted colors are advantageous when veins or faults are not of same geologic age. Veins or faults developed on higher or lower levels, but not intersected by any working on the level under consideration, are projected in their probable positions. Reasonably accurate projections of geologic data on unopened levels assist the superintendent in planning future development.

Scale of map depends on area covered, nature of deposit, and complexity of structure. To avoid necessity of reducing or enlarging, it is convenient to use same scale as for mine survey maps. Except for special uses, tracings should not be larger than 36 by 42 in, though it is advantageous to include on one sheet as much of a mine level as possible, and some allowance should be made for future extension of workings. For simple structure a scale of 100 ft to 1 in may be used; for large areas, 200 ft to 1 in. But, on small-scale maps, accurate drawing is required, little side notation is admissible, and it is difficult to give due prominence to veins, stringers, faults, and slips. The relative importance of

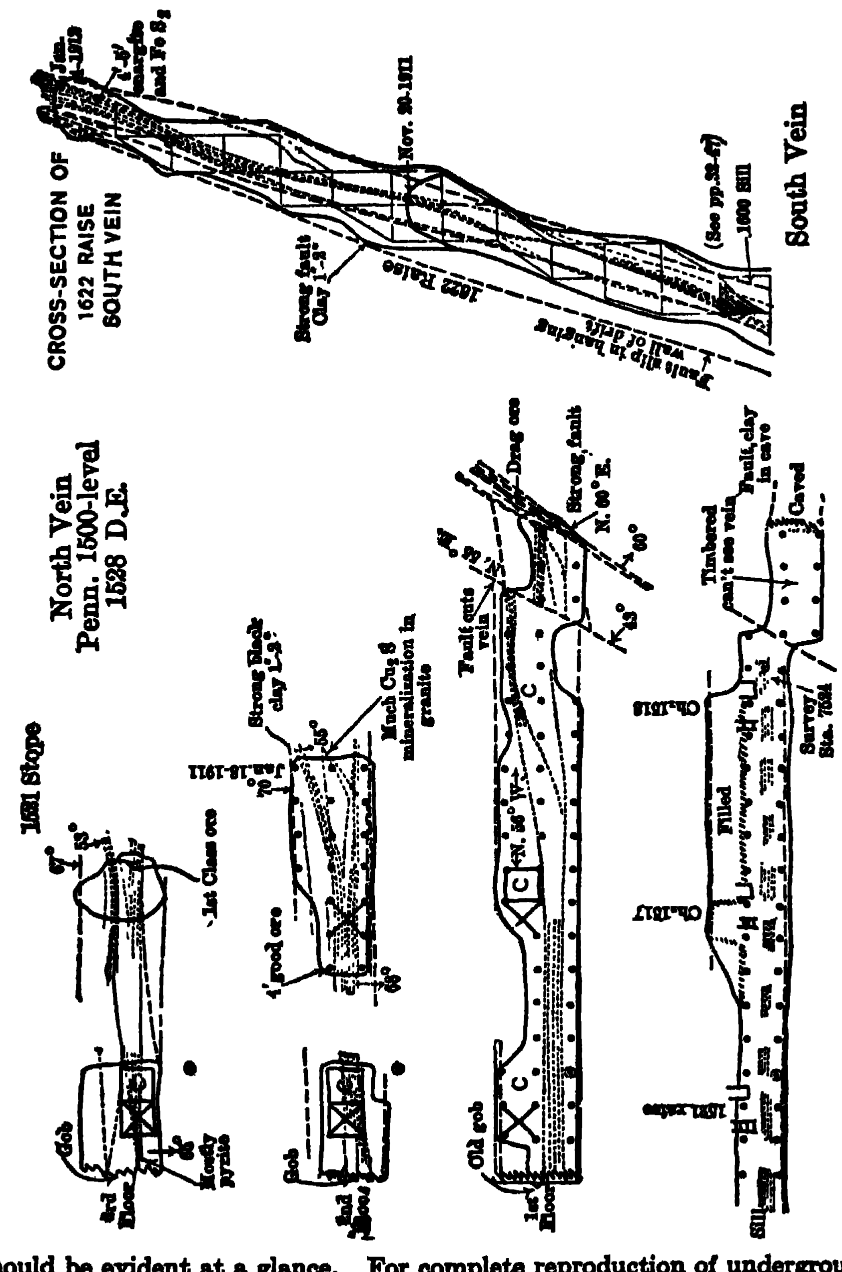

Fig 4 and 5. Examples of Field Notes

veins should be evident at a glance. For complete reproduction of underground notes, a large scale is necessary. If a single sheet does not embrace the whole mining territory, the area may be divided into blocks, with a set of geologic sheets for each. In general, a scale of 40 ft to 1 in is good for average conditions. Accurate field work, followed by careful transfer of notes to maps, is essential.

Filing maps. Wear and tear on geologic maps are excessive. Tracings become wrinkled, dirty, and opaque, and hence less useful. Tearing or rolling of corners and edges may be prevented by a $^1/_2$-in binding of unprepared blueprint cloth; made by cutting cloth in 1-in strips, folding to cover map edge, and stitching with a sewing or carpet machine (Fig 6). Maps should be laid flat in filing cases or drawers, never folded, nor

rolled if it can be avoided. The Shannon spring-arch file serves well for level maps, attached at one edge in pairs to compo board or to thin pine board, cut 1 in larger than map.

Thus mounted, tracing cloth soon tears out where punched. Reinforcement may be supplied by punching the holes in the map binding, or by pasting a patch of blue-print cloth where hole is to be made. Maps are held flat by a light cover board, same as filing board, with slot to go over the Shannon arch. For geologic cross-sections, and other less used maps, the Beck filing case is good for sizes up to 36 by 42 in.

Vertical cross-sections are on planes perpendicular to strike of vein; or, in case of two or more veins or faults, section lines are taken where structural relations will be best brought out. In bedded deposits, section lines may be taken perpendicular to strike of stratification planes, to show relation of deposit to inclosing strata. All workings cut by a section plane are accurately plotted; stope openings are specially important, to exhibit relation of advancing stope to geologic features of level above.

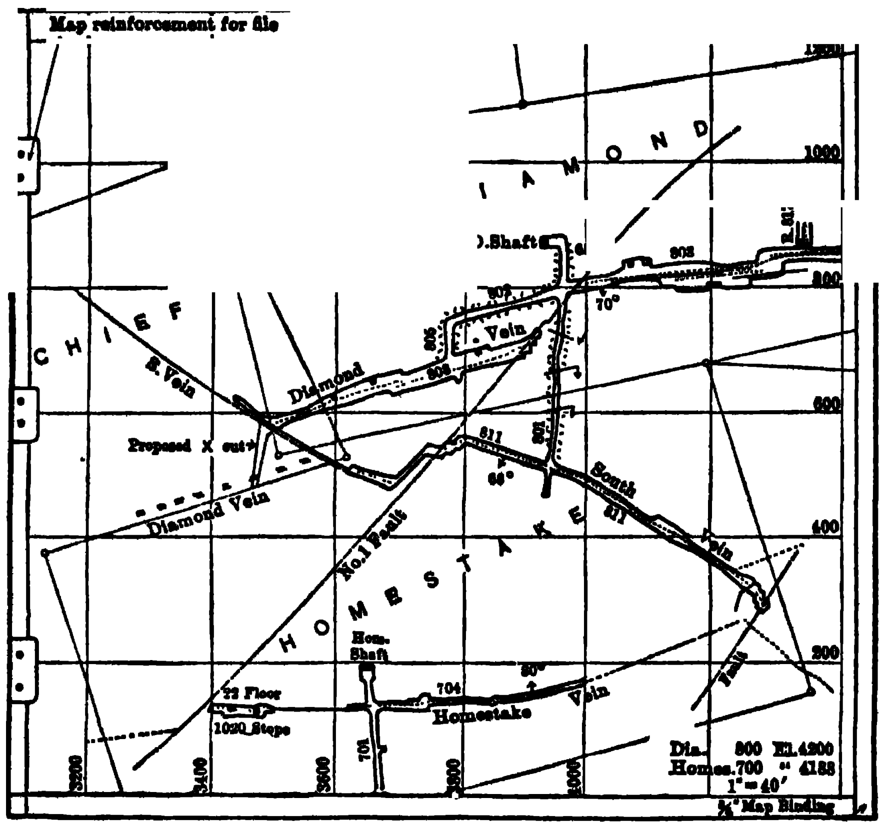

Fig 6. Working Geological Sheet (on Tracing Cloth with Edge Bindings)

In Fig 7, assuming projection of unknown features to be fairly accurate, the prospecting and development of the faulted vein segments are readily planned for minimum cost. Vertical sections are especially useful for projecting veins, faults, dikes, or rock strata, through considerable distances on dip, to determine possible intersections or unions; also to locate vein apices with reference to claim boundaries, under law containing the "extra-lateral right" provision (see Sec 24).

Longitudinal vein projections determine structural relations within plane of vein or fault along the strike. All workings should be shown; whether in vertical projection, or on a plane approximating true dip, must be decided in each case. Principal use of longitudinal sections is to show extent of stopes. In geologic work, intersecting veins, faults, or changes in country rock are the only structural features that can be represented. The pitch or general trend of orebodies occurring in shoots or irregular shapes is well shown. A cross-fault, not exhibiting large horiz displacement on plan, often causes considerable vertical displacement in plane of vein (Fig 8). Longit sections bring out clearly the influence of junctions or intersections of cross-veins, faults, or changes in wall rock.

Practical use of geologic maps: (*a*) to assist in reducing mining costs; (*b*) to lengthen life of mine; (*c*) to preserve a geologic record of mine for future use. A thorough understanding of the mine geology by the superintendent, *in advance of exploration*, is of prime importance for avoiding useless underground prospecting. Where geology is complicated,

it is rarely possible for the mine staff to comprehend intricate structural relations of veins and faults, however familiar they may be with the mine workings. Best results are obtained by combined use of plan and vertical-section geologic maps, possibly aided by glass-section models. Veins and faults are projected on strike and dip, and probable positions indicated by dotted lines.

Such advance interpretation of geologic structure assists superintendent and foreman in planning the larger development of mine, and in searching for new veins or faulted segments of known veins. Level workings intended as permanent openings for drainage, air or haulage ways, shafts, pump stations, and raise connections should, if possible, be laid out to avoid faults and heavy ground. Maintenance costs of mine openings are directly affected by nature of ground encountered; hence the value of carefully prepared maps, showing probable areas of heavy ground. To have the structure well in mind, the geologist must follow closely the advance of mine openings, so that when a vein is cut off by a fault or dike, no money is wasted in search for the lost segment. Mine foreman and geologist must therefore work in harmony, so that, in beginning search for faulted vein, the first round of holes may be properly directed. When fault zone is wide, or composed of more than one fissure, its entire width should be penetrated before search for faulted segment is begun. Owing to irregularities in ore-deposits and frequent tendency of vein fissures to branch, or change dip or strike, the mapping of smaller structural details often assists in keeping an exploratory drift on the important branch or fissure; and the proper subsequent procedure for exploring other branches readily suggests itself. If the deposit be in sedimentary rock,

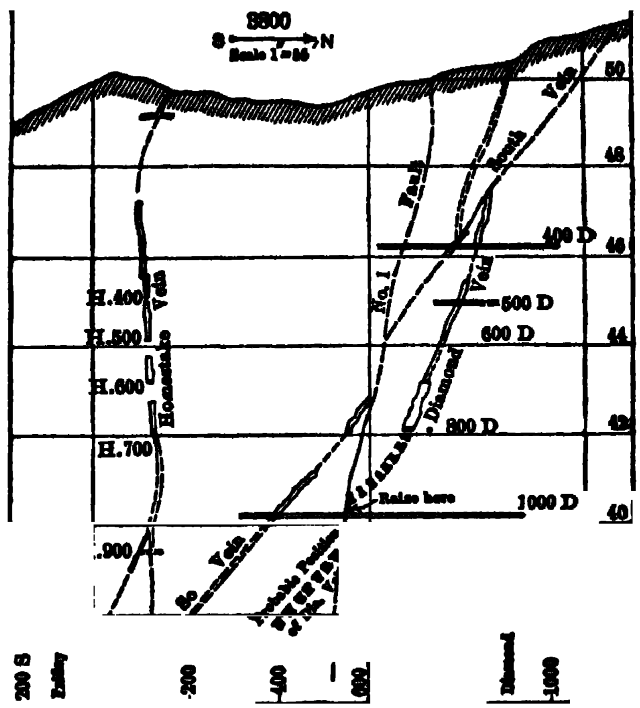

Fig 7. Vertical Cross-section on Coordinate 3800 of Fig 6

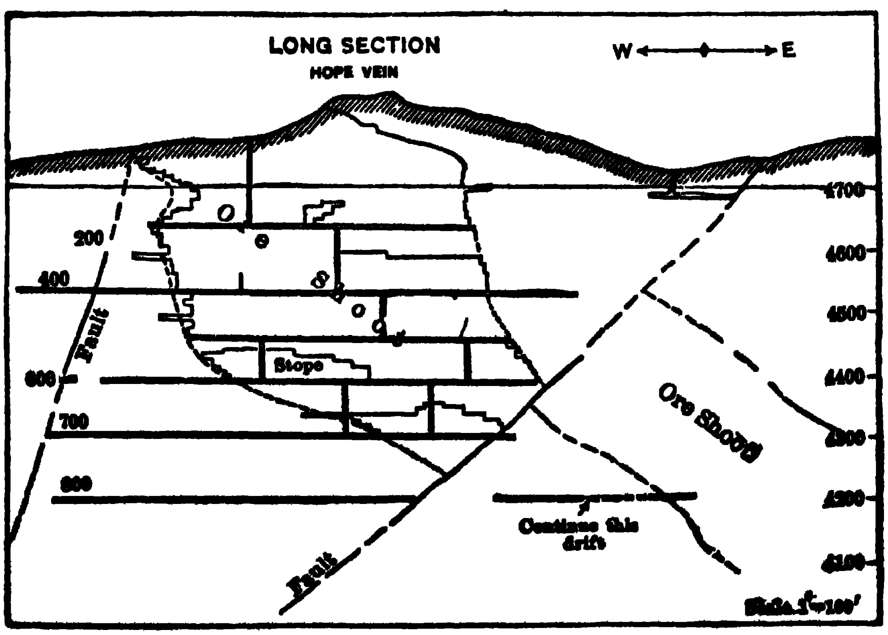

Fig 8. Vein Map, Longitudinal Projection

mapping often discloses structural or genetic relations, if any, between ore and certain rock strata. Relations of ore occurrences to minor fissures, bedding, or cleavage planes may also be revealed by close study of recorded observations.

Comprehensive knowledge of the geology of a mine has a direct bearing on its length of life. The period of profitable operation may be extended by recovery of faulted segments of veins; or new orebodies may be discovered by study of the mine geology and of the workings of contiguous properties. Geologic investigation often reveals the nature of factors controlling ore distribution. When a mine shows signs of failure, through faulting, or impoverishment with depth, those in charge must decide on future course; whether the conditions call for a shut-down, or a further expenditure based more on hope than on sound judgment.

Geologic maps are valuable in case of apex controversies. It may be of the greatest moment to have detailed records of geologic structure, and of mineralogic character of exhausted orebodies and parts of mine which have become inaccessible through caving. Such maps and records, supplemented by models, may constitute the chief court exhibits in mine litigation. When a mine is to be abandoned and allowed to fill with water, accurate maps, brought to date at time of closing, are of scientific value for subsequent geologic study of district, and of vital importance for future work in adjoining properties. Each mine geologic record is also useful in advancing knowledge of the science of ore-deposits.

2. MINE MODELS

Classification. *A*. Working models, to supplement mine maps and elucidate complex vein or fault structure. *B*. Court exhibits in law suits. *C*. Models for exhibition purposes, or for those who are unfamiliar with underground conditions or lack facility in comprehending maps. A model may be intended chiefly to illustrate a mining method, geologic structure being neglected or broadly idealized; in this case the scale must generally be so large that only a part of the mine can be shown. At the other extreme is the model exhibiting the ore-deposits with reference to boundary lines, as for court use, in which geologic features are made paramount. An intermediate position is occupied by types like the glass sectional models, which combine detailed geologic structure with correct portrayal of the mine workings. According to type of construction, there are 5 classes: (*a*) skeleton working models; (*b*) vein models; (*c*) models of mine timbering; (*d*) solid models; (*e*) glass models.

Choice of design. Important features of a model for mine use and to illustrate geologic structure are: ease and rapidity of construction; facility of making additions to bring model up to date; durability of construction; preferably not requiring services of specially skilled mechanic; reasonable cost. For court use, designer must remember that the model is chiefly for information of laymen, not engineers. Hence, design is simple, to emphasize important features, and on a scale large enough for court and jury to see model clearly. Exhibition models need not be built with regard to future use at mine, nor convenience of making additions. Beauty of design may be given more attention and there is usually more latitude as to cost.

Skeleton working model, based on mine maps, is a small-scale reproduction, in wood or other substance, of shafts, drifts, stopes, etc, which are modeled to scale and supported in true relative position by light iron or wooden trusses. Metal trusses are best, being less bulky and not easily confused with working parts. If shafts extend to base of model they are usually of steel, to serve also as structural supports. The principal workings (other than stopes) are of strong, tough wood, like maple. Stopes are best made of pine, for readily cutting into irregular shapes. Level workings are cut in the rough with jig-saw, shaped with chisel or knife, and fastened together with brads, wooden pins or glue. The trusses are supported by a smooth, wooden base, on which are drawn the claim lines and coordinates of the mine system. Each working is given its true gradient, by previous determination of many elevations, for showing relations to adjacent shafts or mines.

The skeleton model, not intended for geologic study, may be painted one color, preferably light gray. For portraying geologic features, also, the ore-deposits and faults are painted in contrasting colors, like red, blue, and yellow. Trusses and other supports are painted black. Names of shafts and veins, and working numbers are lettered with waterproof ink, or by pasting on printed labels. Surface topography may be shown by: (*a*) iron wires, each bent to represent a contour and fastened at intervals to those next above and below, and all held in position by a light metal frame, attached to supporting trusses; (*b*) ordinary wire window screen, or a sheet of gelatin, shaped to topography. Proper scale of model depends on dimensions of mine: 40 ft to 1 in is good for average conditions; 60 ft to 1 in is too small, and 10 ft to 1 in generally too large.

Skeleton models are not satisfactory for illustrating geologic structure, unless there are many continuous workings in the ore-deposit. They are excellent for court use, if ore-deposit is well stoped out and not excessively faulted. In absence of connections between levels, vein continuity can be indicated by wires, strings, celluloid or gelatin sheets. Cross-faults, or slightly developed veins, the position of which can be approximated, may be shown by glass or celluloid sheets.

Vein models are made to scale from cross-section and level maps, which show vein boundaries. The vein is built of solid wood, beginning with lowest level; or the level sections are made separately and afterward combined. If vein be regular, the whole, or large portions of it, may be shaped from a single piece of wood. Mine workings are outlined with ink on the vein. Topography and claim lines are shown as for skeleton models.

By combining vein model with skeleton model, the position of vein referred to mine openings is shown. Though well-designed vein models may exhibit effects of vein intersections, faulting, and changes in strike and dip, they have little practical value. To build them requires a skilled cabinet maker, and for solving geologic problems they are inferior to sheet-glass models. When much of vein is undeveloped, large portions must be idealized, giving definite thickness and form where these factors are wholly unknown.

"Peg" models are commonly used for tabular deposits like the disseminated coppers proved by vertical drill holes.

Claims (and sometimes surface geology) are drawn to scale on enameled surface of a board or table, in which are small holes corresponding with the drill holes on the ground. In the holes are set 1/8-in pegs. Surface of table represents a certain elev above sea-level, and lengths of pegs are such that the top of each represents the surface elev at corresponding drill hole. Different formations cut by the drill holes are shown by painting the pegs different colors: thus barren capping, white; oxidized ore, green; sulphide, black; sulphide ore below commercial minimum, gray. Strings may be run between transition points in adjacent holes.

Mine timber models are possible only where square-sets are used and accurate stope records kept. Drawbacks: high first cost and cost of keeping model posted up to date, expert workmanship needed and difficulty of making additions. Chiefly for exhibition and court use, but if on large scale, method of timbering is well shown.

Solid glass models consist of superposed plate-glass sheets, in which are cut openings corresponding to those in mine. Accurate stope plans or sections are required at 8-ft intervals, each glass sheet corresponding to a plan or section. Outline of each opening is marked on glass, sawed out as in scroll-sawing, and inner surfaces of openings painted any desired color. Plates are cemented together by Canadian balsam. These models are costly, and can not be altered nor extended.

Solid wood models are of wooden sheets, 1/2–2 in thick, each representing a vert slice through mine. From maps, the workings and geologic structure are drawn on the wood; sometimes openings are cut to correspond with mine workings. Lower edge of each sheet rests on the base, upper edge shaped to represent topog of the slice. After assembling, claim lines, outcrops, buildings, etc, are drawn on upper surface. For ready access to any section of model, the slices may be hung on hinges. To illustrate surface features only, as in RELIEF MAPS, wood, clay, plaster of paris, and composition materials may be used. Concrete has a limited application, for large-scale models of sections of mines, to show methods of timbering; or for topographic models, where but one cross-sec is desired; concrete is too heavy except for permanent exhibits, as in museums.

Glass section models, consisting of horizontal or vertical sections, are the cheapest and most effective for geologic study in connection with mine development. The horizontal-section model is made by transferring the mine level workings to glass sheets, so spaced in

vertical arrangement as to show the workings in true vertical and horizontal relations. Accurate mine maps and geologic maps (or field notes) are prerequisites. The workings are outlined on the glass by a mixture of black oil paint with gold size and turpentine, of a consistency to flow readily from a right-line pen, but not so thin as to spread or make sharp lines impossible. (Waterproof ink does not adhere well, nor stand washing and dusting.) For showing the geology, use tube paints, of colors corresponding to those of the mine maps. Put working outlines on upper side of glass; geologic features on under side, traced

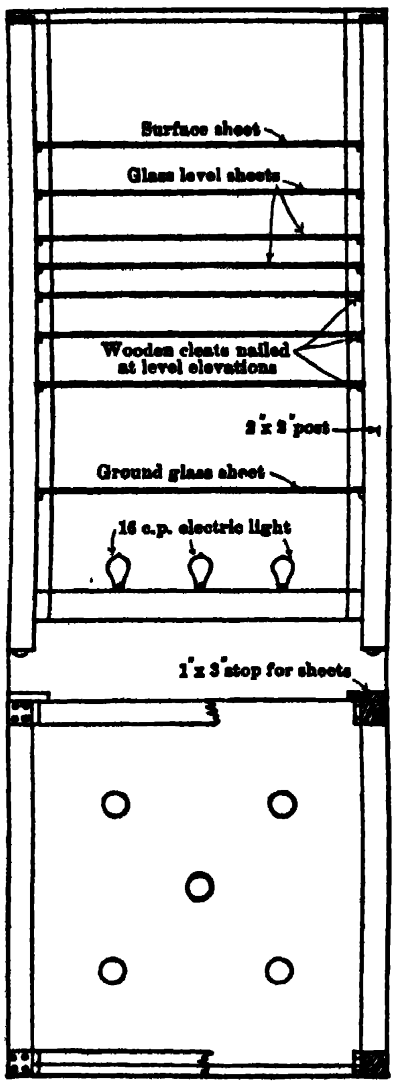

Fig 9. Glass Model, Front Elevation and Plan

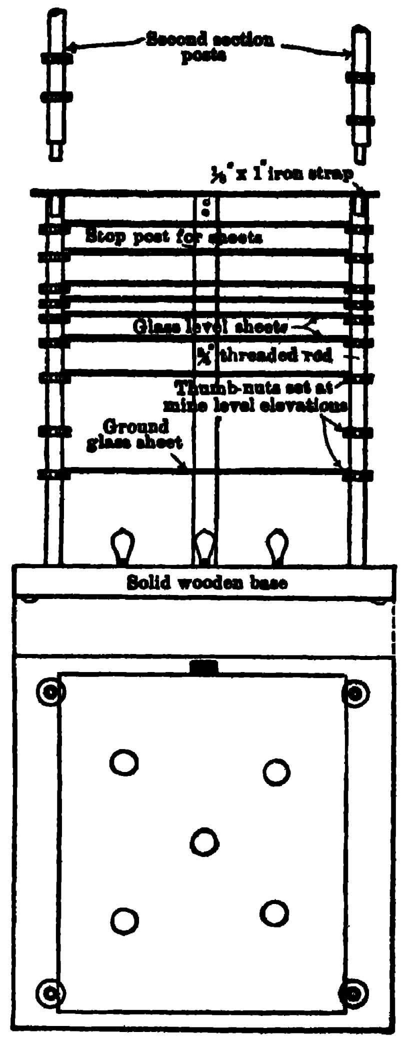

Fig 10. Modified Gl___ Model, Front Elevation and Plan

directly by placing the glass on the geological map. Additions may thus be readily made. Dips of veins and faults may be added, but side notes are omitted. Property lines are drawn on each glass sheet, so that all will show true horiz relations. Put names of claims on uppermost sheet only, together with vein apices, surface openings, and shaft names.

Size of glass. Greatest dimensions should not be over 42 in, on account of weight and danger of breakage. Work is facilitated by using same scale as that of mine maps. Otherwise, where geologic structure is not complex, a scale of 100 ft to 1 in is satisfactory, permitting large area to be shown on a small sheet. Ordinary window glass will do, though picture glass is better, being freer from flaws and more uniform in thickness. Plate glass is heavy and expensive. FOR PERMANENT CONSTRUCTION the sheets are spaced vertically in model frame, to correspond with mine level elevations. Fig 9 shows the older type of construction, the sheets being carried on cleats. In another form, the sheets are supported in grooves; to avoid breakage of glass by possible spreading of sides of frame, metal runners may be nailed flush with bottom edges of grooves. FOR TEMPORARY USE, instead of 4-post frame, sheets may be set up with 2-in wooden blocks between them, of heights equal to differences in elevation of the successive mine levels. When no longer needed, the sheets may be cleaned of paint and used again. A difficulty in using ordinary glass sheets for deep mines

is that, not being perfectly transparent, where there are many sheets, light is cut off from those near bottom. A partial remedy is to set electric light bulbs on base of model, or instead of wooden base use a sheet of ground glass. The geologic details are also confused where there are many levels.

Modified glass model for deep mines. The difficulties mentioned above are successfully met by a design used by the Anaconda Copper Mining Co (Fig 10). Model is built up in sections similar to those of a sectional book case. Sections are of 12-, 18-, and 24-in sizes, each holding a certain number of level sheets. The sections are used independently, or may be built up to any desired height; all are of identical construction, except base section, which provides support and means of illumination.

Mounted vertically on corners of wooden base are four $^3/_4$-in threaded rods. Nuts of 2-in outside diameter are threaded on rods, for supporting the level sheets. Small sheets may rest directly on nuts, but, when larger than 30 by 30 in, large washers are placed on nuts. The rods are held rigidly by 1 by $^1/_8$-in straps across their tops. Alongside of each rod is a $^1/_2$-in square wooden scale, free to revolve, and graduated to different scale on each side. The level sheets are spaced at their respective elevations by the nuts and scales. Each sheet is slid into position from the front to contact with an upright stop at the back, running from base to horizontal straps connecting tops of corner rods. For high and heavy models, an outer wooden frame is added. Succeeding sections are same as base section without the base. The lower ends of the vertical rods of upper section are turned down and threaded to fit into sockets in tops of rods of first section. Additions are also made to the scales, furnishing a continuous graduation to top of model.

Advantages of sectional glass model: (*a*) adaptable to maps of any scale; (*b*) same frame may be used for any mine, new glass only being necessary; (*c*) glass geologic sheets may be filed away like maps, until needed; (*d*) model easily dismantled and stored; (*e*) with slight modification the upper sections can be stood on edge for holding vertical sheets, forming a vertical section model with supplementary level sheets.

Vertical-section glass model supplements the horizontal type, for showing vertical relations of structural features of the deposit. The sheets are spaced according to planes of section, and set in grooves in a wooden frame. Claim lines and intersected workings are shown, as on the horizontal sheets. For a mine more than a few hundred feet deep, a scale of 100 ft to 1 in is satisfactory. Size of glass should be sufficient for making additions, as mine becomes deeper. This type is especially useful for study of deposits having large lateral dimensions, as compared with vertical extent, such as the disseminated copper deposits. Horizontal relations of geology and workings may be shown by drawings on strips of glass, fitted between vertical sheets.

Modifications of glass section-model are generally designed to show geologic and working continuity from sheet to sheet. The following construction is excellent: model in wood the raises, stopes, and other intermediate openings; paint workings same color as that given to vein in which they are made; attach to the glass sheets by "Caementium," which readily adheres to wood or glass. This model, a combination of the glass-sheet and skeleton types, is unsurpassed for indicating vein continuity between levels, where there are raises, but no extensive stopes. THIN GELATIN SHEETS may also be used to represent vein and workings between levels; when slightly warmed, they are readily cut and molded into any desired shape. The gelatin sheets are placed in position between the glass sheets, following variations in strike and dip, and fastened to glass with glue or cement. Thus, width of each gelatin sheet equals distance measured on dip between levels. Areas removed by raises, winzes, and stopes are marked in ink or painted on the gelatin. This construction is not entirely satisfactory for two or more closely spaced veins, or in cases of complicated faulting; otherwise, it combines in a thoroughly practical manner the longitudinal stope-map and the glass-sheet geological model. VERTICAL GLASS SHEETS fitted along section lines BETWEEN HORIZONTAL SHEETS may also be used to show vein continuity and workings between levels. Workings intersected by the plane of section are drawn on the vert sheets, with the geologic facts disclosed. As a substitute for both horiz- and vert-sheet models, this combination is of doubtful value. Though the vert strips furnish some support for large horiz sheets, they restrict the view of observer. For small models, the vert sheets may be continuous, horiz relations being shown on narrow strips between them; but the tendency of narrow horiz strips to sag is not easily overcome.

Dust-proof construction of the supporting framework is desirable for all models, especially for glass-section type, the sheets of which soon lose transparency because of dust. Complete glass cases may be supplied for large permanent models; or a loose wooden box cover of light construction, for models used only at intervals. Cloth covers are not dust-proof.

SECTION 20

MINE ORGANIZATION AND ACCOUNTS

BY

J. R. FINLAY

CONSULTING MINING ENGINEER

REVISED FOR 2ND AND 3RD EDITIONS BY

ARTHUR NOTMAN

CONSULTING ENGINEER

Note. Numbers in parentheses in text refer to Bibliography at end of this section.

MINE ORGANIZATION

Introduction. A full discussion of this subject would be lengthy, covering all the relations between the objects of the business and the field of technical knowledge and practice. The aim here is to exhibit methods of mine organisation and management chiefly by means of concrete examples. The examples given are to some extent interrelated. Thus, the daily reports given under Cost-keeping (Art 4) will throw light upon the discussion of Mine Records (Art 5), and both subjects are supplemented and amplified by the extensive series of cost tables in Sec 21.

1. BUSINESS MANAGEMENT

Essentials of efficient operation are: correct understanding of the producing possibilities of the mining property; good technical methods and operating skill; adoption of correct methods of finance. The foundation upon which the working organism rests is the stockholders, who are responsible for the conduct of the business. In the case of the large corporations, now common, actual control is usually exercised through leadership of a few active stockholders. Such a situation sometimes results in abuse and mismanagement, because the body of stockholders feel that their votes have little or no effect on the conduct of the business. Controlling groups sometimes bribe the stockholders by paying unearned dividends. Conduct of the business by a single owner or by a small group of partners is usually more efficient, though not necessarily so. In large corporations the management comes to lie in a practically self-perpetuating committee of stockholders, called the "Board of Directors" (see below). This board usually has power to buy and sell the company's properties and products, to dispose of its funds, and to borrow money; it can expand or contract the business, it is the mainspring of efficiency of the enterprise, and in it lies success or failure.

Mining companies may be divided into two groups: (*a*) those which limit their expectations to working a given property, and when that is exhausted to wind up the business; (*b*) those which contemplate perpetuating the business; these do not depend on a single mine, but by constantly setting aside part of their earnings, or from time to time obtaining new capital, or both, provide for purchase and development of new mines. The second type of corporation has a more aggressive policy, and the Board of Directors is usually composed of men expert in some branch of the mining business, to whom organization of mining operations is a matter of vital personal concern (2). Examples follow.

American Smelting & Refining Co is an example of the second type of corporation. It is the central organization of a group of companies engaged in mining, milling, smelting, refining and selling of copper, lead, zinc, gold, silver and other metals, derived from ores, concentrates and scrap, produced from mines owned, leased or managed by the company, or treated on toll contracts, or purchased outright from other sources. A combined capital of about $175 000 000 is represented by fixed investments and working capital in different forms. There are many thousands of stockholders and probably 100 000 employes. Annual dividends approx $12 000 000 (1938), and large sums are set aside annually to buy new properties to replace old ones. Its general business has steadily grown. The Board of Directors comprise 21 members, of whom 11 might be described as investors or capitalists primarily. The remaining 10 are distinguished employes who have been and still are experts in mining, transportation, metallurgy, accounting, executive work and the law. The Executive Committee consists of 12 of the most active directors. The Finance Committee consists of 2 of the members of the Executive Committee and 8 other directors. There are 17 general officers; President, 8 Vice-presidents, including General Counsel and Treasurer, and a Secretary, Comptroller, Assistant Comptroller, General Auditor, Assistant General Auditor, Assistant Treasurer and Assistant Secretary. Seven of these general officers are Directors. The Vice-presidents are executive heads of the principal departments. There are also 25 minor department heads and consulting engineers. Minor departments comprise sales of metals, purchasing agency, heads of important groups of mines and smelters, traffic and insurance managers. The entire group of 56 business heads, financiers, executives and directors are responsible organizers of the business. Subordinate to them are the managers of mines, mills and smelters.

St Joseph Lead Co, Missouri, is another example of the second type. There are 13 directors, 8 general officers, President and Chairman, Vice-president and Sales Manager,

Vice-president and Treasurer, and two other Vice-presidents, a Secretary and 2 Assistant Secretaries. The operating divisions are in charge of managers and superintendents, with a staff of mining and metallurgical engineers, geologists, and attorneys.

2. TECHNICAL MANAGEMENT

General features of this part of mine organization are illustrated by the description of the American Smelting & Refining Co (Art 1). For smaller organizations, the plan is similar, on a reduced scale, generally with a smaller proportion of staff officers.

Organization data: Total number of employes of an elaborate organization are shown in Table 1. The operations comprise: (*a*) exploration by vertical diamond drill holes from surface; (*b*) development from existing workings to orebody; (*c*) mining without timbering by blasting in horizontal or breast stopes, shoveling ore into cars (between 50% and 60% of the ore is loaded by mechanical shovels), hauling to shafts by trolley and storage-battery locomotives, hoisting by skips in double compartment shafts, there being one shaft at each mill and no surface haulage of ore, all electric pumping; (*d*) primary and secondary crushing by gyratories and rolls, to a maximum of about 7 mm; (*e*) concentration by jigs and tables, with flotation of the slimes and reground middlings; (*f*) transportation of concentrates to smelters; (*g*) roasting, smelting in blast furnaces, refining; (*h*) transportation of pig lead to market.

All the mining and milling divisions are completely electrified and the entire load is carried by one central power station with a capacity of about 35 000 kw. All the steam is generated by large boilers with pulverized coal firing. The load is usually carried by two 12 500-kw turbines, equipped with surface condensers. For condensing purposes the hard mine water is treated by both Booth and Permutit systems before being circulated. The operating cost per kw-hr is, approximately, 0.6¢. This company operates 4 mills and 1 smelter. Normal output is about 15 000 tons of ore per day, and the whole operation is under a Gen Mgr. Each mining and milling division has a supt and there is a supt for each mill. There are also engineering, legal, employes' service and medical departments.

Table 1. Example of Organization Data, for Month Ended Mch 31, 1926

	Employes		Employes
General	108	Prospecting	82
Mines	1 620	Construction	141
Mills	429	Operating	99
Machine shops	195	Power	3
Carpenter shops	35	Heating plants	6
Electric shops	48		
Yards	85	Total shifts for month	2 872
House repairs	8	Total tons " "	15 228
Steam plants	13	Aver tons per man in mines	9.4
		Aver tons, total employes	5.3

Daily mine records. Contrary to a common idea, the daily mine reports are more important in securing results than the permanent records. A mine is a series of working faces, under constant attack, and constantly presenting new conditions to be met from day to day. A manager who waited for monthly costs and production statements as a basis for making changes in his stopes might find that many or all parts of the mine had become unprofitable before he got his information. Since the chief problem is to make the mine yield a profit all the time, any work which has ceased to pay must be stopped immediately. To determine this, the manager must know from day to day the rate of production and the cost of each part of the work (7).

Daily estimates of profit. For these, formal statements are unnecessary. The manager can usually calculate them readily, if he knows the number of men employed and the tonnage produced. Then, total cost of operation, divided by number of shifts of labor employed, gives cost per man-day. In a specific case, the total cost charged for mining, milling, freight, general expense, etc, for one month was $54 302; number of man-shifts, 9 391. Cost per shift was therefore $5.77. So long as the mine continues to work on same basis, this cost is practically constant, and may be counted upon with confidence for daily calculations. With a labor tabulation showing 400 men at work on a given day, the manager of this mine can instantly calculate his expenses: 400 × $5.77 = $2 300. Then, if he can calculate that the ore will yield say 150 oz gold per day, he at once figures his daily income at about $3 100, and his profit, $800. This illustrates the principle underlying the daily records.

Calculation of daily yield, however, is only approximate. For a gold mine, the records may appear somewhat as follows:

Working place	Tons	Grab sample assay, ounces per ton	Total ounces
A............	26	1.06	27.56
B............	19	1.96	37.24
C............	110	0.32	35.20
	155	0 61	100.00

From this tabulation, the ore apparently is worth about $12 per ton. But experience proves that grab samples, as a rule, run high, and that it is safe to figure on only 75% of their value; in this case, $9 per ton. Furthermore, if the 110 tons from working place *C* assays only 0.32 oz ($6.40 per ton, of which 75% = $4.80), and if the working cost is $6 per ton, stope *C* is plainly losing money, and it should immediately be investigated.

Daily Statements. Some simple process of calculation can be established for each mine, and for each important working place in it. Referring to Table 1, the men employed in each subdivision might be entered upon a daily statement, which can be made on a horizontal line of a form ruled with one line for each day in the month. By filling it in daily, the number of men is exhibited in any desired detail; also the daily product from the working places for all the preceding days of the month. Information of this kind is needed also by superintendents and foremen, for their several departments. Though the interpretation of daily reports can be based intelligently only upon the complete periodical cost statement, yet the daily activities of manager, superintendents, and foremen are intimately connected with them (fuller details given in Art 4). The formal monthly statements are regarded as past history by active men, who receive them with only a mild interest and use them chiefly to check conclusions drawn from the daily reports.

Mine maps. Sec 19 gives details of mine maps and models, from the mine geologist's standpoint. Geology of a mine is an indispensable part of the information conveyed by maps; but maps also exhibit engineering features, namely: location of workings; depths, dimensions, and volumes of ore; position of boundaries and approach to areas of disputed title; opportunities for more effective handling of ore, timber, waste rock, filling, etc. A good set of maps is an important aid in attaining efficiency of operation. A system of maps, from which dated blue-prints are made at intervals, and filed for record, furnishes the history of the development of a mine and the best means of forecasting its future. Lacking a comprehensive system, much valuable information may be lost. In working a mine, details accumulate rapidly and are difficult to correlate unless they are recorded at once and made parts of a broad scheme. In general, the maps should be made in following order:

1. Property maps, showing ownerships, boundaries, and monuments.
2. Surface maps, showing topography, roads, buildings, streams, pipe lines, etc.
3. Surface geologic maps.

Note. A single map may cover functions 1, 2, and 3.

4. General maps of workings, showing: (*a*) areas explored; (*b*) areas worked; (*c*) general geologic facts.
5. Detail maps, showing: (*a*) underground geology; (*b*) occurrences of ore; (*c*) diamond-drill records; (*d*) assays; (*e*) depths and elevations; (*f*) other pertinent facts.
6. Detail maps of stopes, developments, workings (drifts, crosscuts, raises and winzes), tracks and ore chutes; also detail assay maps for individual working places.

If necessary, maps can be made conveniently uniform in size, by adopting different scales according to the amount of detail required; and all should be systematized for ready reference from one to another (11, 12, 17). Their utility is determined by the ease with which they yield the desired facts, and display the critical mining conditions.

MINE ACCOUNTS

3. PRINCIPLES

Two methods, broadly speaking, are adopted for keeping accounts of mining companies. In one, expenditures are charged to production at the time they are made; in the other, certain expenditures are carried as "Capital Accounts," to be written off as

depreciation (8, 14, 15, 21, 22). Since enactment of the Federal Income Tax Law (Sec 24) most companies use the latter method, or a modification of it (see following statements).

A. Annual Statement of Mohawk Mining Co, Mich, for 1913

Received from 5 778 235 lb copper @ 15.36¢		$ 887 618.50
Working expense at mine, as per statement	$601 890.77	
Smelting, freight, and N Y and Boston expense	67 263.17	669 153.94
Profit		$ 218 464.56
Expense for construction	$ 66 972.17	
Strike expense	27 652.87	94 625.04
Net profit (balance over all expenditures)		$ 123 839.52
Total surplus, Dec 31, 1912 (balance of quick assets)		897 316.40
		$1 021 155.92
Dividends paid, 1913		500 000.00
Total surplus Dec 31 1913 (balance of quick assets)		$ 521 155.92

B. Mohawk Mining Co, Statement of Income and Profit and Loss for Year Ended Dec 31, 1924

Sales: 17 908 506 lb of copper at 13.5147¢ per lb		$2 420 275.35
Cost of sales:		
Copper on hand Jan 1, 1924	$ 572 139.18	
Operating expenses at mines	1 403 403.06	
Smelting, freight and N Y expenses	281 221.68	
Taxes	61 271.16	
	$2 318 035.08	
Less copper on hand Dec 31, 1924 at cost	204 842 52	
Net cost of copper sold		2 113 192.56
Profit on sales		$ 307 082.79
Miscellaneous income:		
Interest and dividends	$ 21 284.09	
Rents received, etc	32 817.69	
	$ 54 101.78	
Less interest paid	19 330.01	34 771.77
Profit for the year before providing for deprec and depletion		$ 341 854.56

C. Ray Consolidated Copper Company. Operations for the year ended Dec 31, 1925

Operating revenue:		
Copper produced, 142 076 711 lb @ 14.075¢	$19 997 848.94	
Gold " 5 054.7655 oz @ $20	101 095.31	
Silver " 4 116.06 oz @ 70.3¢	2 895.47	$20 101 839.72
Operating expenses:		
Mining, including stripping and development	$ 6 216 944.68	
Ore delivery, mine to mill	906 286.67	
Milling	4 198 532.35	
Treatment, freight and refining	4 183 602.73	
Selling expense	177 588.50	15 682 954.93
Profit from operations		$ 4 418 884.79
Miscellaneous income		215 463.37
Total income		$ 4 634 348.16
Charges against income:		
Depreciation	$ 914 096.64	
Loss on property retired, etc	281 728.06	1 195 824.70
Net income to surplus acct		$ 3 438 523.46
Balance, Dec 31, 1924		$13 478 177.45
Net income for year (without deduction for depletion) as above		3 438 523.46
		$16 916 700.91
Charges against surplus:		
Additional federal income tax for 1918 and adjustments of surplus in connection therewith		1 043 503.17
Balance, Dec 31, 1925		$15 873 197.74

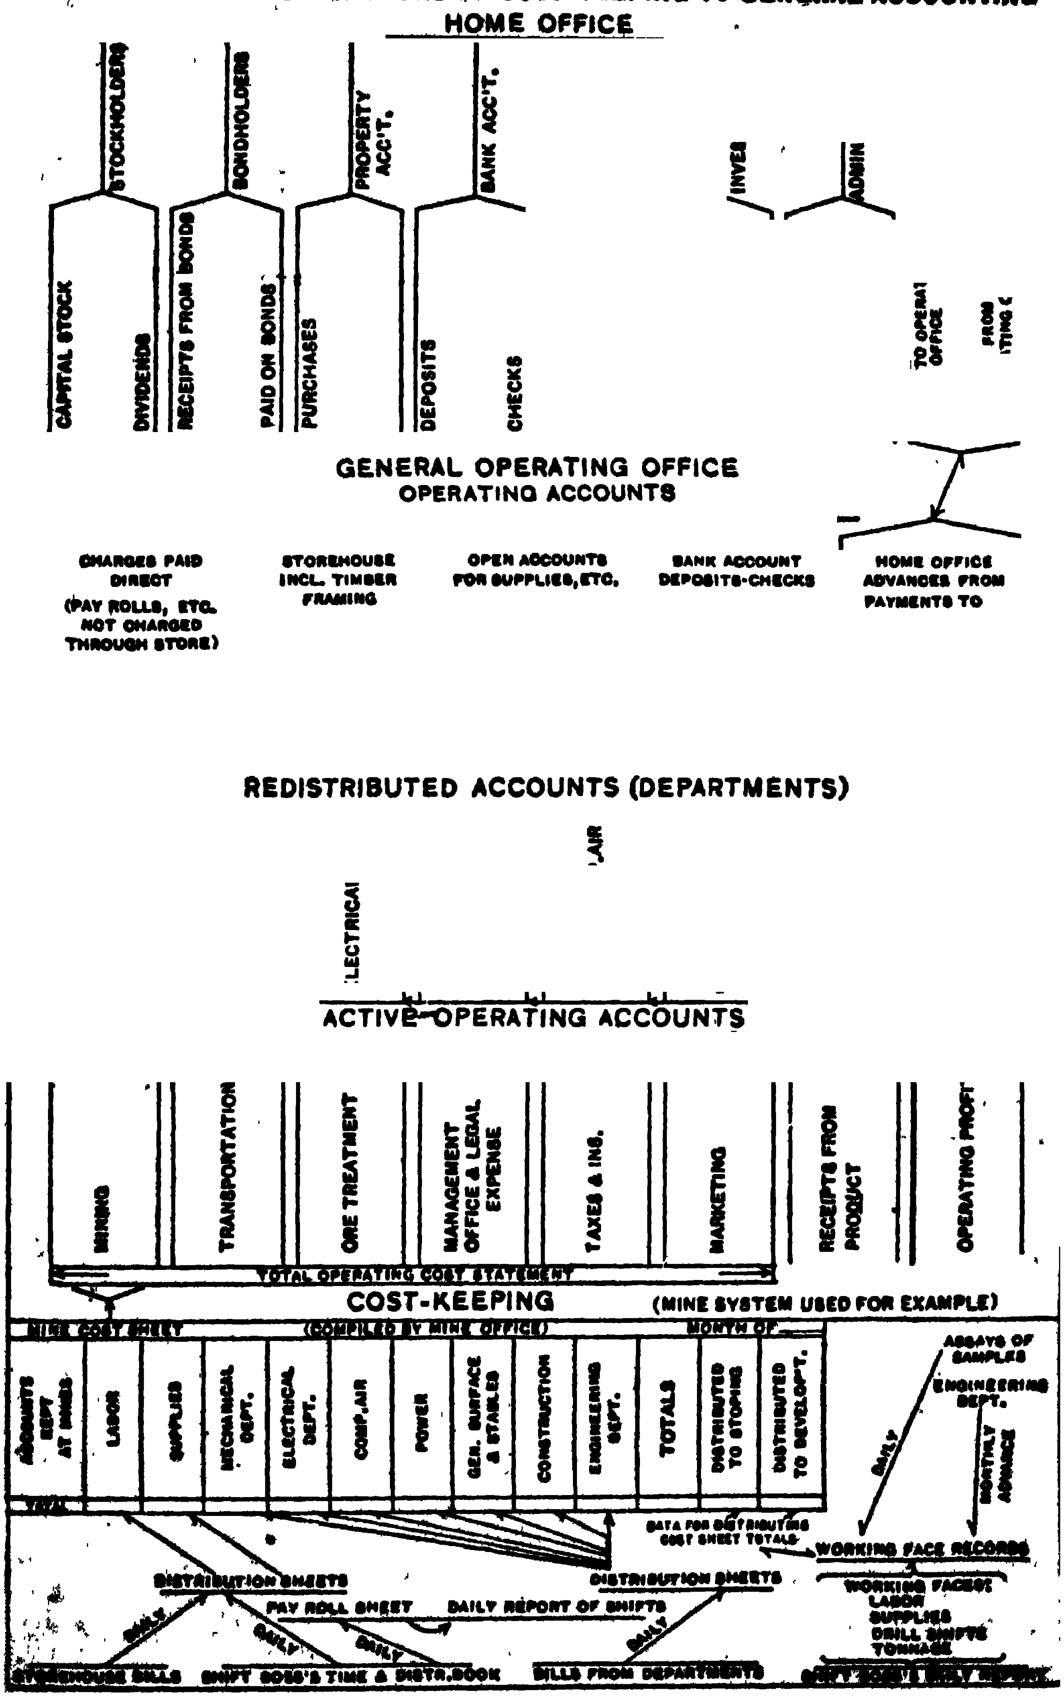
4. COST-KEEPING

General. Table 2 shows that detailed cost-keeping is not essentially a part of the financial records of a mining company, but is a system of costs and data kept separately by each department, the total cost represented on cost-sheets agreeing with total cost shown on operating books. General accounting furnishes a financial record for the management, while cost-keeping provides data for the operating heads, to enable them to regulate expenditures (see Art. 2).

Cost-sheet. Accounts kept by the mining department for its cost records vary according to the mine (14, 21, 22). In any case the final cost-sheet should be brief and deal with totals carried forward from detailed daily records. Many accounts can not be

Table 2

DIAGRAM SHOWING RELATIONS OF COST-KEEPING TO GENERAL ACCOUNTING



directly distributed to working faces each day; therefore, on the mine cost-sheet it is desirable to deal only with general accounts. Referring to Table 2, under the head of cost-keeping, the accounts may be as follows: For DEVELOPMENT direct: miners, muckers, trammers, and timbermen. For STOPING direct: miners, shovelers in stopes, trammers, timbermen, and expense for filling. For GENERAL ACCOUNTS: hoisting, pumping, machine drills, explosives, sampling and assaying, surveying, watchmen, mine office, superintendent, foremen, shift bosses, blacksmithing, repairs and renewals to buildings, repairs and renewals to machinery, mine and shaft repairs, general surface expense, new construction, new machinery, tools, miscellaneous iron and steel, heating. To these accounts the charges are made in the vertical columns of cost-sheet. The total of the mine accounts is apportioned to two general accounts, development and stoping; in some cases a third account, prospecting or exploration, is added. It is not necessary to keep a set of books for a cost system. Best method is a system of daily reports, distribution sheets, and loose-leaf record sheets. To facilitate filing, all reports are preferably in loose-leaf form.

Besides the mine accounts, the following division of costs may be made from WORKING FACE RECORDS (Table 4), after cost-sheet totals have been apportioned to development and stoping. For EXPLORATION: trenching, test-pits, shafts, diamond drilling, churn drilling. For DEVELOPMENT: shafts, drifts, crosscuts, raises, winzes, shaft stations, ore-pockets. For STOPING, the account may be divided according to the different methods of stoping employed. Extending the system further, these accounts may be distributed to each working face, the totals agreeing with cost-sheet total (14, 21, 22).

RICHARD DOE,
Shift Boss

5. MINE RECORDS

Working-face records (Table 4) are compiled from the SHIFT-BOSS REPORT (Table 3), which gives for each working face and for each shift: number of miners, muckers, shovelers, trammers, timbermen, and men engaged in filling, drill-shifts; also dynamite and caps consumed (fuse may be averaged per cap used), amount and description of timber used, and tonnage of ore and waste hoisted. In addition to the explosives and timber reported on shift-boss report, any other supplies shown by requisition to be chargeable directly to a particular working face may be entered on this sheet. Assays of ore and face samples are also entered, as reported from assay office. The columns of estimated cost are worked up when desired, by using previous general account averages (14).

The above data give: direct charge for labor (which for cost-sheet may be taken from payroll distribution); direct charge for supplies; production figures, assay records, and advance made. Hoisting is apportioned on basis of tons reported, and total machine drill cost on basis of machine shifts. These are the only charges that may be distributed directly. The remaining general charges of the cost-sheet may be made in proportion to the totals of the direct distribution.

Working No, 401 stope

Note. The 4 parts of Table 4 are continuous horizontally on one large sheet; the first column containing days of month from 1 to 31.

Labor records. When a man is hired he should be given an employment slip, stating character of his work. This slip furnishes to the timekeeper proper authority for putting the name on the payroll. A file of identification cards should be kept, giving name, signature, local address, and address of family, for each employe.

Table 5 is a shift-bosses' loose-leaf TIME AND DISTRIBUTION BOOK, found to work satisfactorily at a property where it had been impossible, before its introduction, to get the shift-bosses' daily reports of working faces to balance with time book. By first making the distribution in time book, the daily report is readily filled out. A daily distribution of payroll can be made by the time-keeper from the shift-boss time books. Entries are also made from these books to the monthly PAYROLL SHEET (Table 6), which serves as a full receipt for wages paid. To check the shift-boss time books, brass checks, corresponding to the number in first column of payroll, may be given to the men to deposit

in a box when coming off shift. Employes may be identified by the paymaster by asking their number and by reference to the identification card. The number in the last column of the payroll is for the pay check, which also serves as a receipt.

Supply records. Distribution of supplies is a comparatively simple matter, if all supplies are kept in a central storehouse, and treated as a separate business. Requisitions should be drawn only for quantities needed for immediate consumption. Requisitions should show the distribution of supplies ordered, and storekeeper makes note of this distribution on the bill, which is sent to the mine office. These bills are entered on a SUPPLY DISTRIBUTION SHEET, to such accounts as are kept for the cost-sheet, the totals of the distributions being checked with a monthly storehouse statement. Slight differences will occur between supplies purchased and supplies shown on shift-boss daily reports, owing to small balances on hand, but these differences should balance themselves from time to time (6).

Department charges, for services and power rendered, are billed and distributed as for bills for supplies. Detailed costs of power, compressed air, cost-sheets, and department distributions should be kept by the department concerned. At properties where scale of operations does not permit a subdivision into departments, it is desirable at least to keep these costs on separate records.

6. MAJOR AND MINOR OPERATING UNITS

Major units can be divided into smaller, or MINOR UNITS, still more or less independent. Thus, the mining plants consist of the mines, the mills, and the power plants. Carrying subdivision still further, the mines may comprise a number of shafts (with workings), which may be quite independent of one another, but are dependent upon the power plant and a concentrating mill, and each may have a choice of several mills for treatment of its ores (Table 2).

Economy demands that each major unit be run at full capacity. If a mill can treat more ore than is sent to it, part of its equipment and first cost is being wasted. Conversely, if more shafts are operating than are required to supply the mill, they are obviously being worked at reduced capacity, and one or more of them should be shut down. Major units wholly dependent on one another are illustrated by the items of a shaft equipment. Hoisting engine, pumps, haulage plant, shaft timbering, etc, must be kept up and in repair, whether the output is large or small. Therefore none of these elements should be developed out of proportion to the others.

Efficiency engineering consists of a study of units, in order to secure maximum output from each. Hence, ascertain which units are effective and which are only relative.

Example. The object of a machine drill is to mine ore cheaply; the units comprised in its operation are: labor, cost of the machine and repair parts, compressed air, explosives. The total cost per shift, for breaking say 12 tons, is about \$8.60, comprising: wages, \$5; repairs, \$1.48; compressed air, \$0.80; explosives, \$1.32. Economy lies in getting a large output for the cost. It

might be uneconomical to emphasize any of the minor units without reference to the influence of the others. Thus, by reducing wages, inefficient men would produce poor results; excessive economy in repair parts might cause costly delays; cutting down supply of compressed air would result in feeble drilling; reducing quantity of explosive might necessitate an excessive footage of drilling. It would be clearly uneconomical to reduce the cost of operating a drill from $8.60 to $7.30 per shift at the expense of decreasing the tonnage broken from 12 to 10. Conversely, it would be good economy to raise the cost per shift if the output could be increased in greater proportion. Hence, a true unit cost for machine drilling is the total cost per ton of breaking ore, and not merely the cost per drill-shift. This line of reasoning leads to effective management and cost-keeping.

SECTION 21

COST OF MINING

BY

J. R. FINLAY

CONSULTING MINING ENGINEER

REVISED FOR 2ND AND 3RD EDITIONS BY

ARTHUR NOTMAN

CONSULTING ENGINEER

Introduction

The tables of First Edition of this book, prepared by Heath Steele, along the lines of Finlay's "Cost of Mining," present typical examples of costs, and illustrate systems of account keeping. Three distinct conceptions were adopted: (*a*) Total net expenditure, not including dividends, sums loaned out, nor mere book entries. This includes all money spent on property, construction of plant and for financial and legal transactions; (*b*) Amount spent in operating mines and mills, but omitting expenditures on plant, financial transactions, etc. These costs take the form of averages, calculated for long periods, which, when added to operating expenditure, give total costs. These costs will never, except by chance, agree with expenditure for any one year, but should approximate aver expenditure for a number of years; (*c*) Amount spent on operation, omitting all other expense. This cost will always fall far below total expenditure.

In many of the tables the business as a whole is first exhibited, followed by successive subdivisions, until the details are as minute as practicable. The first table for a given mine gives total expenses by departments. Thus, Example 2, Table 3, shows operating results of Goldfield Consol Mines Co: (*a*) Total expenditures are checked by showing the total outgo, plus a gain, or minus a loss, in quick assets for each year; (*b*) Expenditures in Table 3 are given under 19 different headings, of which only 3 fall directly under mining and milling operations. The cost of Mining is shown as a lump sum (details in Table 5); (*c*) In Table 5 are the mining operations for 3 years, the cost being segregated as labor, supplies, power, and general charges; (*d*) Here reference is made to Table 7, where costs are divided into 32 items at each of 4 shafts, with their averages.

Mining costs per ton differ much less in detail than in total. To do exactly the same thing in different places involves no differences in cost other than those due to procuring labor and supplies. But total costs per ton show great differences, because one ore may require a process of five steps, while another may require fifty. In general, the examples exhibit results obtained on a large scale by successful organizations. It should not be assumed that these costs can be duplicated by small-scale operators.

To enable the reader to compare present-day costs with those of former years, some of the older and fully detailed tables, dated 1909 on, are retained in this Third Edition. To convert pre-war costs to a post-war basis, an approximation can be reached by adding, say, 75% to pre-war costs; or, the latter can be compared with figures for 1924 and 1925, as in some of the original examples, or with costs in the new examples. Much of the information comes from public reports, and all is authentic.

Though the examples are representative of different kinds of mining, the plan has necessarily been modified by the question of availability of information in different fields. Information is freely made public in non-competitive business, like gold mining; but, as competition becomes vital, as in mining low-priced staples like coal and iron, operators are more secretive. This is especially true of the highly integrated organisation of the iron and steel industries. Hence, the number and fullness of the examples are not in proportion to the importance of the individual fields covered.

The Report of the Federal Coal Commission contains an exhaustive analysis of Coal Mining costs; from it are taken Tables 60 to 64. For Iron Mining, no recent representative figures were obtainable. The vertical integration of the iron and steel industry in past years has been so complete that published reports afford little opportunity to segregate costs of producing the raw materials from costs of finished products. Table 55 contains broad facts relating to Michigan iron mines, in form of averages for entire districts. Favored properties in each district do cheaper work. Current costs are not obtainable (see statement preceding Table 55.) For general discussion of iron-mining problems, see Finlay's "Cost of Mining."

Undoubtedly, the proper way to discuss mining costs would be to adopt a unit basis, which has never been done in a broad manner. Having defined and tabulated the steps in mining, milling, and metallurgical processes, the labor, supplies, and power required for each could then be ascertained, the total cost being the sum of those of a given amount of each element at a given place.

EXAMPLES OF COSTS

Example 1. Homestake Mining Co, South Dak

Table 1. Summary of Operations for 1925

	Per ton milled		Per ton milled
Cost of mining	$1.65	Less discount, interest and rents	$0.05
" " milling	0.26	Net cost	$3.42
" " cyaniding	0.19	" Dividend from current earnings	0.35
Freight on bullion	0.01	Bullion yield	$3.77
Indirect costs	0 52		
Total operating cost	$2.63	Total ore milled	1 589 701 tons
Depreciation charged	0 47	Development work	9 765 ft drifts
Depletion charged	0.37		3 105 " raises
Total cost	$3.47	Total development	12 870 ft

Table 2. Operating Results, Homestake Mining Co., 1934-1937 Inclusive

Tonnage mined, 5 598 557; ounces gold produced, 2 129 083, capitalization, 2 009 280 shs, $12.50 per sh

	Totals	Per ton	Per share	
			Total	Annual aver
Bullion revenue	$74 517 938	$13 31	$37.09	$9.27
Other income	1 271 844	0 23	0.63	0.16
Total income	75 789 782	13.54	37.72	9.43
Working costs, administration, etc	22 623 024	4.05	11.26	2.82
Profit before taxes	53 166 758	9.49	26.46	6.61
Taxes	9 091 318	1.62	4.52	1.13
Net income	44 075 440	7.87 (a)	21.94 (a)	5.48 (a)
Dividends	32 188 182	5.75	16.02	4.00
Balance	11 887 258	2.12	5.92	1.48
Decrease in net current assets, Dec 31, 1933 to Dec 31, 1937	733 032			
Balance to be accounted for	12 620 290	2.25	6.28	1.57
Increase of book value fixed assets	865 996			
Increase in consolidated surplus	2 559 407			
Total	3 425 403			
Balance: Capital expenditures and additional taxes	* 9 194 887	1.64 (b)	2.57 (b)	0.64 (b)
Net profits after capital expenditures (a minus b)	....	$6 23	$19 37	$4.84

* This balance was expended for a new 4 000-ft shaft, steel lined, equipped with the two largest hoists ever built in America, a new mill, dismantling of two old mills, a new cyanide plant, refinery, change house, and steam-turbine power plant, additional compressors, and substantial improvements to the townsite; also, certain minor amounts for tax adjustments.

It is unlikely that capital expenditures for next few years will exceed $400 000 per annum (20¢ per share); real earnings should therefore approx $5.25 per share on current tonnage, ore-grade and costs. By including actual capital expenditures over a period long enough to secure a representative annual aver, a more accurate measure of costs is reached than by including the annual write-offs for deprec and depletion. The latter charges are unavoidably affected by exigencies of the tax laws.

The following figures, for the Goldfield Consol Mines Co (Tables 3-12), although out of date, are retained because they illustrate the amount of detail needed in cost accounting to maintain sound, intelligent control over extended operations (see p 02, par 4).

Example 2. Goldfield Consolidated Mines Co (a Gold Mine)

Table 3. Summary of Operating Results

For year ended Oct 31	1909	1910	1911	14 mos to Dec 31, 1912

Tons of ore shipped	1 515	487	12 426

The operating costs given in Table 5 cover operations during periods when the 100-stamp mill was the only mill in operation. The company operated a 20-stamp mill up to the end of 1909. Briefly, the operations in this mill consisted of: crushing by 8- by 12-in Blake crusher; conveying by 14-in by 165-ft belt, running on a 20° incline to stamp bins; stamping, 1 250-lb stamps, 109 $6^1/_2$-in drops per min, through 12-mesh screen; amalgamation, tube milling, reamalgamating; separating to sands and slimes; concentrating; leaching sands and agitating slimes; filtering through Butters' filters; zinc pre-

Admin and gen	0.29	0.36	0.26	0.27	0.23	0.34	0.37	0.36	0.36	0.36
Total per ton	$4.47	$5.32	$4.47	$4.61	$4.23	$4.74	$4.20	$4.36	$3.85	$3.83

To the end of 1912, it had cost this company approx $5 per ton of annual capacity to construct and maintain its plants. Total charge for plant, equipment and maintenance, to end of 1912, was about $1.50 per ton of ore produced.

In Table 3 construction and other items for 1909 were charged to capital account and not shown in costs reported. Of this amount for 1910, $445 864 was for construction; in 1911, $137 831, the greater part of the remainder being evidently spent on outside properties; in the 14-month period, construction costs were $87 395.

The following data, to the end of Example 2, furnished by Albert Burch, Gen Mgr Goldfield Consol Mines Co, cover working conditions and costs during 1913.

The orebodies occur very irregularly as to value, shape, and persistence, in fractured zones in dacite and latite. The dip of the fracture is usually about 40°; in a few instances dip is as flat as 20°, and in a few practically vertical. Country rock is soft, frequently

swelling, and most drifts and crosscuts outside the vein require frequent retimbering. Drifts in the vein rarely require timbering, but walls in all stopes must be supported. A few narrow stopes on one vein are worked with stulls; but usually with sets 5 ft square and 7 ft 10 in high, of 8 and 10-in sq timber. As ore is removed, the sets are filled floor by floor with waste from development, and from waste raises run to surface. During the period covered by Table 12, ore was mined from about 60 stopes, some in pillars left in stopes already mined, and most of them were small extensions toward the walls, or out from ends of old stopes. Probably 40% of filling charges was for old stopes, insufficiently filled previously. The mines produce about 280 000 gal of strongly acid water per 24 hr, which, after neutralizing with 1 200 lb of lime, suffice for milling purposes.

Hoisting is done through 6 shafts, 300–1 400 ft. Transport is by rail from mines to mill, and no returns are made for cost of transport system. Operating costs, about 9¢ per ton for aver haul of 2.6 mile. Trammers on main levels handle about 32 ton per shift.

Table 8. Average Power Consumption per Day

Compressors	402 hp
Hoisting	170 "
Pumping	76 "
Machine shop, saws, lights on surface	77 "
Total mine power	725 "
Milling	1 755 "
Total power consumption	2 480 "

Diamond drilling was unsatisfactory, owing to its slow progress in the brecciated quartz in which the ore is found. Cost of diamond drilling averaged about $4.28 for following items: labor, $2.36; supplies, 58¢; carbons, 88¢; and power, estimated at 20 hp, 46¢ per ft (Table 8).

Elec power is used, costing $78.36 per hp per annum. Power is estimated at 90% of aver daily peaks exceeding one min in duration, and is probably in excess of actual hp which would be shown by meters.

Example 2. Goldfield Consolidated Mines Co (*Continued*)

Table 9. Employes in Mining Department, 1913

Note.—See Table 23 for general data on Aurora West United and the Meyer and Charlton.

Example 6. Transvaal Gold Mining Costs (*Continued*)

Table 23. General Data on the Aurora West United & Meyer & Charlton Mines

Data obtained Oct, 1913	Aurora West United Gold Mining Co	Meyer & Charlton Gold Mining Co
Average thickness of lode:		
Stoping width	42 in	25 in
Reef width	14 in	....
Amount of rock broken annually	216 000 tons	179 731 tons
Proportion of ore from stoping areas	180 000 milling tons	92.11%
Average distance broken ore is moved to tramming level (Note 1)	200 ft	115 ft
Average tramming distance to shaft	750 ft	700 ft
Average hoisting depth	1 079 ft	1 430 ft
Timber used per ton of ore extracted	cost 0.64¢	{ 0.12 ft poles 0.6 ft lagging
Development work performed during 1912:		
Shafts	251.5 ft	473 ft
Drifts	8 346 ft	2 713 ft
Raises and winzes	4 398.5 ft	1 674 ft
Tons of ore made available by development	194 605 milling tons	205 133
Diamond drilling	....	379 ft
Amount of water raised from mine in 24 hr	150 000 gal	65 000 gal
Depth from which water is pumped	1 000 ft	1 650 ft
Amount of power required:		
Pumping	70 h p	100 h p
Development headings	(See Note 2)	140 "
Stoping	"	560 "
Tramming	hand	hand
Hoisting	150 h p	425 h p
Crushing before delivery to mill	35 to 40 h p	55 "
Transport to mill	5 h p	10 "
Crushing at mill	300 "	280 "
Tube milling	....	80 "
Cyanide plant	100 h p	150 "
Lights	40 "	50 "
Men employed:		
White	140	128
Natives	1 345	920

Note 1.— Stopes run on an incline of about 30°; backs average 200 ft, with tramming levels directly below. Note 2.— Greater portion of stoping is done by manual labor, native hammer boys employed. It requires 750 hp to operate compressors used in driving machines in development faces and in stopes where machines are worked. General note. See Table 22 for other cost data for these mines.

Table 24. Summary of Operating Results, 1924 and 1925, at 9 Transvaal Mines

Name of mine	Modderfontein B Gold Mines, 1924	New Modderfontein Gold Mines, 1925	Rose Deep, 1924	Geldenhuis Deep, Ltd, 1924	Nourse Mines, 1925	City Deep Ltd, 1924	Village Deep, Ltd, 1924	Crown Mines, 1924	Randfontein, 1924

(a) These capital expenditures were financed by sale of additional capital shares, and working capital was placed in position to complete a comprehensive program of expansion of operations.
(b) Miscel expenses, net.
(c) Credit from return of unexpended balances previously appropriated.

Note. Exchange taken at $5.00 These mines produced approx 7 851 061 fine oz in 1937, or 68.6% of total output of Rand.

Table 32. Summary of Operations for 1937

Production from own mines:
- Tons ore....... 386 576
- Lead.......... 59 014 000 lb
- Zinc........... 36 246 000 " in concentrates
- Silver.......... 2 179 684 oz

Total production, including metals from custom ores purchased:
- Lead.......... 106 958 817 lb
- Zinc........... 36 246 000 " in concentrates
- Silver.......... 20 363 308 oz
- Gold........... 4 047 "

Copper, antimony, cadmium and bluestone, all in form of by-products, were also produced.

Gross metal sales..........................		$22 635 991
Direct operating costs...........	$20 726 854	
Depreciation and depletion......	513 486	
Taxes, federal, state and local....	390 783	
	21 631 123	
Less increase in metal inventories..	1 484 036	20 147 087
Operating profit..........................		2 488 904
Net other revenue.......................		101 557
Total profit.............................		2 590 461
Depletion charged.......................		366 193
Profit before depletion...................		$2 956 654

Note. If silver, gold, and all other metals produced, except lead and zinc, are credited to cost of producing lead and zinc, there was a profit before depletion of $62.07 per ton of lead and zinc. As the aver price received for these metals was about $122.20 per ton, the cost, after other metal credits, but before depletion, was about $60.13 per ton.

* Deficit. † Includes returns on sale of stored zinc concentrates produced in prior years.

Example 8. Sunshine Mining Company

Table 34. Summary of Operations for 1937

Tons milled	255 800
Metals recovered:	
Silver	12 146 853 oz
Gold	240 "
Lead	347 100 lb
Copper	2 784 000 "

After crediting all other metals produced to cost of producing silver, costs were as follows:

	Per ton	Per oz
Mining	$ 4.68	9.86¢
Development	.45	.95
Milling	.47	.98
Overhead and general	2.58	5.43
Taxes of all kinds	6.53	13.76
Total	$14.71	30.98¢
Net smelter receipts per oz silver	......	75.19
Profit after all charges, including deprec.		44.21¢

Example 9. Burma Corporation

Table 35. Summary of Operations for Year Ending June 30, 1937

Production: 478 806 long tons

Metals recovered:

Refined lead	74 885 long tons
Zinc concentrates	78 213 " "
Copper matte	8 250 " "
Nickel speiss	4 320 " "
Antimonial lead	1 090 " "
Silver	6 135 000 oz

After crediting all other metals sold to cost of producing lead and recoverable zinc in concentrates (39 000 ton approx), the profit from lead and zinc, including cost of treating zinc concentrate, was as follows, after deprec:

		£ = 4.95
Total profit	£1 236 794	$ 6 122 131
Estimated receipts from sale of lead and zinc	2 516 237	$12 455 374
Cost of producing lead and zinc	£1 279 431	$ 6 333 242

Cost of producing lead and zinc, per ton, £11–4–8, per lb, 2.47¢.

Example 10. Lead Mining Costs, Southeastern Missouri

Table 36. General Operating Results, 1925

(a)	Ore mined, wet tons	4 628 746
(b)	Ore milled, wet tons	4 630 036
(c)	Cone produced, dry tons	175 438
(d)	Flotation product, dry tons	71 668
(e)	Total of (c + d), dry tons	247 106
	Lead content of (e), tons	168 074
	Lead per ton ore, lb	72.6
		Cost per ton ore
(f)	Prospecting, $0.115; (g) Development, $0.195	$0.310
(h)	Mining, $0.969; (i) Mine suspense accts, $0.002	0.971
(j)	Milling	0.388
(k)	Shop, yard and stable expense	0.045
(l)	Indirect operating and local general expense	0.156
(m)	Other suspension expense	0.001
(n)	Local electric sub-station	0.009
(o)	Electric line loss and meter difference	0.017
(p)	Total operating cost at mine and mill (f to o)	$1.897
(q)	Mill product transportation	0.035
(r)	Smelting charges	0.498
	Total cost per ton ore, 90% of lead in concentrates being pig lead, f o b shipping point (p to r), excluding deprec, general expense and taxes	$2.430

Table 36a. Wage Scales

	Aug, 1913	May, 1926
Shift bosses	$3.10	$5.90–$5.95
Drillers	$2.15– 2.40	5.05
Blacksmiths	2.55	5.05– 6.60

Less receipts for Au and Ag	521 277	0.83	729 333	1 04	798 371	1 08
Cost after crediting Au and Ag	$6 794 953	10.77	$7 399 599	10.53	$7 436 299	10.10
Less other income:						
Dividends on investments	1 459 112	2.44	450 000	0.69	300 000	0.62
Other miscel income	82 808		35 338		153 119	
Net cost of copper on market	$5 253 033	8.33	$6 914 261	9.84	$6 983 180	9.48
Capital expenditure	620 714	0.98	1 394 622	1.99	619 394	0.85
Deprec charged	......	.....	$601 719	0.86	$671 450	0.91

Example 17. Union Minière du Haut Katanga, Africa

Income statement for 1924 shows a profit after all credits and charges, including depreciation, but before interest and depletion, of 93 994 010.40 francs, from a production of 188 370 798 lbs of copper, or 0.4459 franc per lb. With the franc at the value in March, 1926 of 3.91¢, this is equivalent to 1.743¢ per lb.

Table 51. Operating Results for 1925

Total ore mined (excluding fluxes)	1 383 453 metric tons
Copper produced	90 144 " "
Apparent yield, 6.49%, or, 129 8 lbs per short ton (2 000 lb)	129.8 lbs
Total profit after all credits and charges, including deprec, but before interest and depletion	130 521 117.59 francs
Profit as above per lb copper	0.6571 "
With the franc at 3.91 cents, this equals	2.569¢ per lb
Average *E & M Jour-Press* quotation, 1925	14.042¢ " "
Indicated cost per lb after credits and charges as above	11.473¢ " "

Table 52. Union Minière Operations for 1937

Total ore mined (excluding fluxes)	1 628 000 metric tons
Copper produced	150 588 " " or 332 037 139 lb
Apparent yield of copper	9.25%
Total profit after all credits and charges including deprec, but before interest and depletion	420 982 606 Belgian francs
Profit, as above, per lb of copper	1.271 " "
Profit with Belgian franc at 3.375¢ U S cur	4.29¢ per lb
Probable aver price realized (see Note 2 below Example 20)	12.441¢ " "
"Indicated cost"	8.151¢ " "

Example 18. Noranda Mines, Ltd, Hudson Bay Mining & Smelting Co

Table 53. Operations for 1937

Ore mined, tons			3 667 920
Metals recovered, lb:			
Copper	138 160 353	Tellurium	12 850
Zinc	68 972 224		
Cadmium	308 776	Gold, oz	410 220
Selenium	89 733	Silver, oz	2 326 814

Above figures do not include metals recovered from custom ores purchased.

Profits after all charges including deprec	$16 765 290
Applying these total profits to copper production gives	12.135¢ per lb of copper
Price received (see Note 2 below Example 20)	12.400¢ " "
"Indicated cost of copper"	0.265¢ " "

Note: These figures show the great advantage Canadian copper producers have over competitors, because of the by-product metals produced. International Nickel Co, showing similar results, is the largest copper producer in Canada, with Noranda and Hudson Bay second and third respectively in volume of production.

Example 19. Roan Antelope Copper Mines, Ltd, and Mufulira Copper Mines, Ltd, Rhodesia

Table 54. Operations for Year Ending June 30, 1938

Exchange £1 = $4.76	Mined, short ton, and costs	Milled, short ton, and costs	Total cost per ton	Blister copper produced	
				Short ton	Cost per ton
Roan Antelope	3 126 100 at 92.758¢	3 126 100 at 28.56¢	$1.213	84 280	$7.635
Mufulira	1 598 886 at $1.518	1 585 000 at 58.07¢	$2.099	58 101	$9.93

Net profit per lb copper, after all charges, including deprec: Roan Antelope, 4.448¢; Mufulira, 3.966¢.

Example 20. Anaconda Copper Mining Co, Kennecott Copper Corp and Phelps Dodge Corp, 1937

Copper production 2 074 974 125 lb. Net profit, after crediting all profits on other operations to electrolytic copper production: $93 951 029 = 4.528¢ per lb.

Summary of Copper Production, Costs and Profits in 1937

	Production, lb copper	Profit before depletion		"Indicated cost," cts
		Total	Cts per lb	
Canada	138 160 353	$ 16 765 290	12.135	0.265
United States and South America	2 074 974 125	93 951 029	4.528	7.913
Africa, Rhodesia	407 778 560	18 707 335	4 587	6.677
Africa, Belgian Congo	332,037 139	14 208 176	4.290	8.151
Totals and averages	2 952 950 177	$143 631 830	4.864	7.411

Note 1. In calendar year 1937 the above groups produced 58.86% of total World production.

Note 2. The large companies considered here have not reported, in recent years, the aver price received for copper. The aver *Eng & Min Jour* quotation in N Y for 1937 was 13.167¢ per lb. However, certain smaller companies, not considered here, do publish their figures and these indicate a substantially lower price, around 12.400¢ per lb. In arriving at the "indicated cost" by difference between price received and profits realised, this lower price has been taken, except in the case of the Rhodesian coppers, whose gross income represents their receipts from copper fairly closely, because receipts from other sources are insignificant. In the case of Rhokana, a small part of gross income came from sales of cobalt. This would tend to raise the stated aver price of copper and, therefore, the "indicated cost," by perhaps 1/4¢ per lb for that group.

Note 3. The above figures represent results for year ended Dec 31, 1937, with exception of the Rhodesian companies. In the latter case, the results are for the 12 months ending June 30, 1937.

Example 21. Iron Mining Costs

Efforts made to obtain representative current costs of producing iron ore have been without success, for the reasons given in the Introduction to this Section. In the absence of recent costs, it has been decided to retain the following Table. The prewar figures therein may be of some value, as they can be converted roughly into present-day costs by multiplying them by a factor of, say, 60 to 75%, as may seem appropriate in the judgment of the instructed reader.

It may be added that iron mining has become so largely a closely-controlled specialty, that mining engineers in general have less interest in the cost of producing iron than they have in the cost of the non-ferrous metals. Details of the technique of iron-mining methods, in deposits of different kinds are given in Sec 10.

Example 21. Iron Mining in Michigan

Table 55. A Five-year Summary from Records of All Iron Mines Operating in Michigan, 1906 to 1910, Inclusive, Showing Average Cost and Average Value of Ore per Ton, F O B, Cleveland, Ohio

Example 22. Coal Mining Costs

Examples of these costs are limited, few data being given out by the companies for publication. Tables 56 to 66 present some of the main facts.

Table 56. Data on Anthracite Coal Mining in 1913 (Philadelphia & Reading Coal and Iron Co)

Figures are from statements in annual reports, but do not represent all expenditures, as some relate to buying and selling of both anthracite and bituminous coal. Deducting receipts from the sales and amounts for purchase of bituminous coal, it appears that the profit was between 9¢ and 10¢ per long ton of anthracite during year ended June 30, 1913. Company apparently paid about $2.50 per ton for anthracite purchased.

Costs per ton 2 240 lb, year ended June 30

	1912	1913
Tons mined	8 671 013	11 089 742
Mining coal and repairs	$2.12	$2.09
Improvements at collieries, etc	0.097	0.11
Royalty of leased collieries	0.053	0.055
Improvements and repairs of houses	0.0038	0.013
Taxes on coal lands and improvements	0.0680	0.047
Damages on account of coal dirt	0.0007	0.0003
Fixed charges	0.0099	0.0085
Additional wages, account of sliding scale	....	0.0097
Total per ton of 2 240 lb	$2.3524	$2.3335
" " " " 2 000 "	2.10	2.08

During previous years, company has charged about 5¢ per long ton for depletion of coal lands.

Table 57. Bituminous Coal Mining (Pittsburgh Coal Co, from Sept 1, 1899 to Dec 31, 1913)

		Per ton, cts	
Tons of coal and coke produced (2 000 lb)	241 289 912

Wyoming	8	3.85	32.1	1.58

* Represents 60% of employes, 40% about equally divided between 9 and 10 hr.
† Average production per year per machine, 13 763 short tons.
‡ Includes Alaska.

Abstracts from Bull No 4, "Coal Mining Practice in Dist No 7," May, 1914, Illinois Coal Mining Investigation: District includes mines operating on bed No 6, west of Duquoin anticline, and covers Bond, Clinton, Fayette, Macoupin, Madison, Marion, Montgomery, Moultrie, Randolph, St Clair, Shelby, Washington, and a portion of Perry, Christian, and Sangamon Counties. Bed No 6 varies from 2.5 to 14 ft thick, average 7 ft. There are 6 slope and drift mines, but shafts are generally used, as bed lies at considerable depth; maximum 707 ft. General system of mining is unmodified double-entry room-and-pillar, but some are worked by panel system. Average recovery of coal, 55%. Output for year ended June 30, 1912, 22 454 672 short tons, or 39.1% of production of state. Mines operating, 196; shipping, 150; local, 46. Tons mined by machines, 13 558 530. Tons mined per 8-hr shift: 140 by chain, 71 by puncher machines. Average days operated by mines, 158. Days work performed, 4 399 826. Employes: surface, 2 354; underground, 25 493; total, 27 847. Aver number underground men for each surface man, 10.8. Tons mined per day per man, 5.1; per surface man, 60.5; per underground men, 5.6; per worker in shipping mines only, 7.3 tons. Tons mined for each man injured, 78 788. In one mine 1 keg powder breaks 30 tons coal in shooting from solid, and 90 tons after puncher undercutting. Tons broken per keg of powder, from 17 to 175, depending on method. Cost of powder, from 1¢ to 10.3¢ per ton coal. Total powder used during year, 426 353 kegs. Timber props range from 1.3 to 7.2 per 100 sq ft of roof, costing from 10.5¢ to 70.3¢ per 100 sq ft of roof, or 0.5¢ to 3¢ per ton of coal. Mines using locomotive haulage, 78; cable, 3; mules, 101; hand power, 14. At one mine a gasolene locomotive hauls to shaft bottom 1 300 tons of coal per shift (consuming 18 gal gasolene) at cost of 0.17¢ per ton. Another hauls 900 tons per shift (consuming 15 gal gasolene) at cost of 0.2¢ per ton; average trip, 25 loads of 4 000 lb each, including cars. Ton mileage in coal of all locomotives ranges from 311 to 2 203 per shift. Cost of keeping mules, from 75¢ to $1 per day. In one mine, on a 2% grade in favor of loads, 2 mules, weight 1 300 lb each, made 75 loaded trips of 700 ft, with 4 cars, capacity 3 500 lb, weighing 1 000 lb empty, the ton mileage for each mule being about 54.67.

Table 59. Cost of Hydraulic Filling at Collieries (prewar)

(U S Bureau of Mines, Bull No 60, to which reference is made for details)

Based on plants of at least 400 cu yd daily capac. Costs in ct per cu yd		Culm	Material used for filling: Culm mixed with crushed breaker and boiler refuse	Local hydraulic sand, loam, gravel, clay, etc	Local crushed sand, loam, gravel, clay, etc	Material brought from distance in returning empty cars

SECTION 22

WAGES AND WELFARE

BY

EDWARD K. JUDD

FORMERLY ASSISTANT PROFESSOR OF MINING, COLUMBIA SCHOOL OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

WAGES

1. "DAY'S PAY" OR "COMPANY" MEN

Day's pay system, an agreed amount of wages for a definite number of hours' work, is open to the objection that it may entail an undue expense for supervision, to avoid waste of time and supplies. But, for many classes of mine employees, as engineers, mechanics, foremen, office force, and miscellaneous laborers, the day's pay or salary system is the only practicable one. For underground work, day's wages are also preferable to contract or bonus arrangements in those mines in which the minerals are irregularly distributed, requiring discrimination in the separate handling of ore and waste, or in which the mining conditions are difficult, demanding slow and painstaking operation; both of these objects are likely to be defeated by any system which aims to promote speed. Day's pay system is preferred at several large open-pit copper mines (Sec 10, Art 96) where work can be standardized and readily supervised. Among 80 (mainly underground) American mines described (2) to 1932, 13 operated on day's pay exclusively, and 20 adopted day's pay except for mucking or development.

Day's wages compared. Data in Table 1 are useful mainly as a basis of comparison for estimates of mining cost, since labor is almost always the preponderating factor in cost of operation (60 to 65% in most American mines, and with no obvious relation to the mining method). Wages for the same class of labor are naturally higher in remote districts, where supply of workmen is limited, living conditions are unfavorable, and food is expensive.

Fair Labor Standards Act of 1938 (effective Oct 24, 1938) requires every employer (with certain exceptions not related to mining) to pay each employee engaged in commerce. or in production of goods for commerce the following MINIMUM WAGES: during first year (*i e*, to Oct 24, 1939) not less than 25¢ per hr: during next 6 yr, not less than 30¢ per hr; after 7 yr (from Oct 24, 1938) not less than 40¢ per hr, unless a lower rate (not less than 30¢) is ordered by the Administrator after examination and report by one of his appointed Industry Committees. During first 7 yr, the Administrator may similarly order a minimum rate not exceeding 40¢, but such order will expire Oct 24, 1945. Employers (with some exceptions not related to mining) are forbidden to work an employee, who is engaged in commerce or in the production of goods for commerce, longer than the following MAXIMUM HOURS: 44 hr per week during first year (from Oct 24, 1938), 42 hr per week during second yr, 40 hr per week after the second year, unless such employee receives compensation for weekly over-time at 50% increase above his normal rate. Regulation as to payment for over-time does not apply in cases where collective bargains certified by N L R B provide a max of 1 000 hr during 26 consecutive weeks or 2 000 hr during 52 consecutive weeks; in such cases, over-time at 50% increase in rate starts at 12 hr in any workday or at 56 hr in any week. An order of the Administrator can be reviewed in a U S circuit court of appeals within 60 days; findings of fact by Administrator, when supported by substantial evidence, are conclusive. Court will not review an order unless it has previously been argued with the Administrator. Initiation of court procedure does not stay Administrator's order unless so stipulated by the court, upon filing of bond by complainant to cover wages in dispute. Administrator and his representatives have free access to plants and employees; all employers subject to the Act must keep such records, and submit such reports, as Administrator may prescribe.

"Commerce" in the above Act "means trade, commerce, transportation, transmission, or communication . . . from any State (or U S possession) to any place outside thereof." The Act does not apply to the Philippine Islands. The Wage and Hour Division has declined to pass on application of the Act to gold mines. Where it is customary to pay wages partly in form of board and lodging, these items are to be figured at actual cost to employer. Piece-work, contracts, etc, are permitted so long as such earnings are equivalent to those stipulated by the Act. The "week" is 7 consecutive working days, but may begin at any hour of any day; loss (or excess) of time in one week can not be applied to a succeeding week in computing over-time; each week is a unit. Waiver of over-time pay by consent of employee does not excuse non-compliance with the Act. Time spent in attending meetings, lectures, etc, sponsored by employer, and related to employee's work (such as first-aid, mine rescue, etc) was once ruled to be working time; wholly voluntary attendance at such meetings, after usual working hours, was later (July 10, 1939) ruled to be not time worked. For current information, rulings, etc, on this Act, address U S Dept of Labor, Wage and Hour Div, Washington, D C. To late 1939, no Industry Committee on mining had been appointed.

State wages and hours regulations. To late 1939, no mining State had a statute fixing MINIMUM WAGES (except for females and minors). As to MAX HOURS (same and other excep-

(a) Plus a bonus. (b) 9-hr shift.

tions not related to mining), Ala, Calif, Ill, Ind, Md, N J, N M, Ohio, Penn, W Va, and Wis had no statute. In Ariz, Colo, Idaho, Mont, Nev, Okla, Ore, Utah, and Wash, 8 hr is legal working day, except in cases of emergency involving life or property; Ariz, Nev, and Wash permit a longer day for changing shifts every 2 weeks; Mo permits persons to contract for shorter or longer hours, and exempts those hired by the month from the 8-hr law. In Mich and Minn, legal working day is 10 hr; latter State permits over-time, on pay.

Federal unemployment compensation law (Title IX of Social Security Act, upheld by 5:4 decision of Supreme Court, May 24, 1937) requires an employer (with certain exceptions not related to mining) who has 8 or more persons in his employ for some portion of each of at least 20 days during the taxable year, each day being in a different calendar week (not necessarily consecutive), to pay a tax (since 1938) of 3% of their total annual wages. Credit up to 90% of this tax may be claimed as covering payments made to individual States under their unemployment compensation statutes (see below), provided such payments are made prior to the dates on which the Federal tax falls due. Employees pay no tax under the Federal law, and receive no benefits directly therefrom; compensation payments all come through State organizations, who requisition the necessary funds from the Federal treasury (where they have previously been deposited) upon conforming to requirements imposed by the Nat Soc Security Board.

State unemployment compensation laws. All 48 of the States, and Alaska and Hawaii, have enacted statutes acceptable to the Federal authorities, providing for collection of taxes and payment of compensation. Regulations vary (see Table 2) as to definition of a taxable employer, exemption of wages, rate of taxation, contributions by employees,

* With important omissions, impracticable to tabulate, relating to: due dates for information returns and tax payments; exemptions of certain employers and employees; partial exemptions of wages; benefits for partial unemployment; waiting periods; duration and calculation of benefits; eligibility and disqualifications for benefits. Full text of any statute can be secured from State Capitol. *P* = pooled. *Era* = Employer's reserve account. *mr* = Merit rating system. (a) Within each of 20 weeks per year. (b) On any day within each of 20 weeks per year. (c) Any employer who pays wages of $78 or more in any calendar quarter. (d) Any employer who pays wages of $225 or more in any calendar quarter. (e) Any employer who pays $450 or more in any quarter, or employs 2 or more in each of 13 weeks per year. (f) At any one time within current year. (g) Employer of 4 or more on any day within calendar quarter in which total payroll is $500 or more. (h) Any employing unit with wages of $140 or more per calendar quarter. (i) In each of 18 weeks. (j) And when payroll is $150 or more in a quarter. (k) Or 3/4 of weekly wages, if this is less than stated minimum. (l) Of quarterly wages.

manner of accounting for funds, eligibility for benefits, and their amounts. In all States (except Mich) the rate (1939) is 2.7% of the taxable payroll, whence the whole State tax may be claimed as credit against the 3% Federal tax. In Mich, the rate (1939) is 3% on only the first $3 000 of an employee's annual wages. Employees contribute (1%) only in Ala, Calif, and N J (in latter State, only on first $3 000).

Compensation funds may be treated in one of 3 ways: (a) POOLED FUND SYSTEM; contributions are consolidated and benefits are paid to those eligible regardless of their employers; no person has a preferred claim; there is no provision for adjustment of tax rates. In its simple form, this system is now in force in but few States; most of those with pooled funds also provide for separate employer's accounts for purpose of merit ratings (see below). (b) EMPLOYER RESERVE ACCOUNT; contributions from each employer are separately accounted and can be used only for payment of benefits to his own discharged employees. In the few States using this system, a partial pool or balancing account is usually set up, from which benefit payments can be maintained if an employer's reserve should be temporarily exhausted. (c) MERIT RATING SYSTEM has been adopted by many States (encouraged by Federal authorities) and nearly all of the others have it under consideration. By this plan, the tax rate of an individual employer is made proportional to his annual labor turnover, as an incentive towards stability of employment. The plan requires keeping a separate account for each employer; when experience (usually for 3 years) shows that his contributions substantially exceed benefits to his discharged employees, his tax rate may be considerably diminished or his tax even abolished. In such cases, the Federal law nevertheless allows credit up to the full 90% of its 3% tax. In most States, the merit rating plans do not go into effect until 1941 or 1942; their provisions, as also many other features of the unemployment compensation statutes, are too varied and complicated to permit abstracting here; the applicable laws of any particular State can be obtained from Unemployment Compensation Board (or analogous body) at the State Capitol.

2. SLIDING SCALES FOR WAGES

Sliding scales aim to establish parallelism between wages and price of product, where latter is variable, for mutual advantage of workman and operator.

Examples. TRI-STATE FIELD. Wages (varying slightly from mine to mine) are based on previous week's market price of zinc concentrate (60% Zn). In 1929–32, base was $40 per short ton, wages increasing by 25¢ per shift (contract mucking, by 1/2¢ per "can") with each $5 rise in price if maintained for 1 week; corresponding reduction with falling price to min of $40. COEUR D'ALENE DISTRICT, Idaho. Wages vary with preceding month's aver price of lead. In 1930, additions to base wages per shift at Hecla & Star mine (5) were: Pb @ 5.5–6¢, 25¢; 6–6.5¢, 50¢; 6.5–7¢, 75¢; 7–7.5¢, $1; 7.5–8¢, $1.25. WESTERN COPPER MINES. Wages at most of the large copper mines are graduated according to *E & M Jour* quotations on electrolytic copper delivered in Conn valley, and (in 1939) were increased in steps, usually of 5%, for each 1.5¢ rise in price. In most agreements, neither increases nor decreases become effective until expiration of 30 successive days from the date when copper price first enters the specified range, nor unless aver price during that period remains at or above lower limit (at or below upper limit) of the specified range. At mines where SILVER constitutes chief value, agreements with Mine, Mill, and Smelter Workers (Art 10) base miner's wages (around $4.50 per day) on Govt price of 70–89¢ per oz, and reduce them by 25¢ if price falls below 70¢; at prices above 89¢, wages are increased by 25¢ for each 10¢ rise in price. Same agreements provide that if price of GOLD varies by $1 per oz from that of Nov 1, 1937, both parties have guaranteed right to negotiate a new scale of wages.

3. CONTRACT, OR "PIECE-RATE" SYSTEM

Advantages rest on the psychological fact that most men work more efficiently for themselves than for an employer. The system in some form has been applied to almost every phase of mine operation. From standpoint of an operator, contract system tends to promote speed, reduce unit costs, and diminish expense of supervision; and a contractor generally obtains better returns with shorter working hours than a day laborer; adoption of contract system has almost invariably proved mutually beneficial. Operator can count with certainty on ultimate cost of a given undertaking, while contractor is free to reap reward of his energy and skill.

Drawbacks: (*a*) By creating a class of workmen whose interests do not exactly coincide with those of the company, difficulty arises in enforcing standards of workmanship, and rules for safety. (*b*) Discontent may be caused by misunderstanding terms of a contract, or by refusal of manager to renew a contract on terms which he feels are unduly lucrative to contractor. Disputes over accuracy in measurement of work performed are frequent. (*c*) The most expert foreman sometimes fails to foresee changes in character of rock or ore during term of contract. It has been proposed (47) to meet this by elaborate standardization of all operations affected by nature of ore. Cost of such standardization as thus proposed, or as practiced at North Butte mines (48), is too great for any small company.

Uncertainty is probably best avoided by short-term contracts; Anaconda Co's stoping contracts (49) are for 1 week and may be terminated after 1 day by foreman or contractor. (*d*) In stoping, incentive towards large production may reduce grade of output, unless checked by levying a fixed charge for hoisting or milling contractor's ore, or by refusing payment for volume broken outside of vein walls.

Applicability. For above reasons, contracting has been most successful in exploring and developing mineral deposits, as boring, sinking, tunneling, and driving drifts, winzes, and raises, and, in general, wherever size of opening is constant, rock fairly uniform, or character and amount of work readily measured and inspected. Many so-called "contracts" guarantee a basic rate for a day's work and hence are more correctly described (Art 4) as bonus systems. These, as well as straight contracts, have been increasingly adopted in recent years, and for a larger variety of operations, including stoping and tramming; among 80 American mines described (2) to 1932, 32 conducted almost their entire operations on some contract or bonus system. The following examples are confined to straight contracts, with no guarantee of earnings.

Examples. COAL is almost always mined on contract, payment based on short tons of run-of-mine coal delivered at tipple (Art 11); rates in the Appalachian area, 1937–39, were 98¢ per ton for pick mining, and 76¢ for loading; narrow work and room-turning is contracted per linear yard, to specified width, besides ton rates for the coal; "brushing" (taking up bottom or breaking down top slate to afford necessary head room) is contracted per lin yd per in of slate removed, for agreed width. MARQUETTE RANGE, Mich. At one mine (6) entire production of iron ore is on contract, at 75¢–$1.60 per 4-ton car. Company provides a scraper outfit for each gang; also drills and steel, air and electric power, and timber; miners pay for explosives, carbide, hand tools, and small accessories, and do their own blasting and timbering. For mining methods, see Sec 10, Art 71. TRI-STATE district. Hand loading of ore is usually on contract at prices varying with shoveling conditions; at Crestline, Kas (14) in 1929, price was 10.5¢ per can of 0.6 ton; at Barr mine (18) in 1929, hand loading into cars (unusual practice in district), price was 38–41.5¢ per 1.5-ton car. Aver duty of hand loader is about 25 tons per 8 hr. MASCOT MINE, Tenn (22), contracts nearly all of its underground work (Sec 10, Art 37). Mill-hole contractor breaks and delivers ore into cars at a fixed price per ton, supplying labor and explosives. Chute pullers sub-contract to draw their ore into cars at fixed price per ton. Contractor usually allows his men regular company wages (he may increase them); Company pays his men directly, charging their wages to him. Company settles with contractor every week, holding back 30% of his earnings until a definite amount has accumulated, payable at termination of contract. EL POTOSÍ MINE, Chihuahua, Mex (24), employing about 500 men underground in 1934, lets nearly all of its underground work to contractors. Payments for stoping are based on number of car- or skip-loads; for development, on advance or volume excavated. Unit prices are adjusted to location and size of opening, character of formation, tramming method (hand or motor), accessibility, and other variable conditions. Contracts are measured twice a month. Company pays contractor's men legal wages, charging them to him, along with explosives and carbide. Contractor bosses his own crews and thereby saves the company considerable supervision. For mining method, see Sec 10, Art 37.

Contract prices, for similar work, vary as widely as actual costs; hence not instructive to enumerate them here. For costs, see sections relating to the several operations; in general, a contractor should be allowed a profit of at least 20% above actual cost, this being offset by benefits accruing to company by reason of greater speed. Contractor should usually be required to furnish his own blasting and other supplies; arrangements as to supply of powder, use of machines, tramming facilities, sharpening of drills, bits, repairs, etc, are settled by individual preference.

4. BONUS, OR PREMIUM, SYSTEM

Nature of bonus system. From operator's standpoint, two chief drawbacks of ordinary contract system are: difficulty in maintaining standards of mining, and the fact that contractor reaps practically the whole benefit of reduced cost of operation. Bonus system consists in setting a minimum daily or monthly task (or a minimum wages rate based on aver performance); work performed (or wages earned) in excess of the minimum is then paid for at an additional rate, so computed that the employer shares the saving in operating cost, besides profiting from more rapid work. For comparison of several bonus systems, see Bibliog (3). Following examples include several inaccurately described as "contracts."

S E Missouri in 1929. At one mine (25) HAND-LOADING was paid on "contract" at: $5 for 21 tons, $5.55 for 22 tons, 28¢ for each additional ton. Same, on company work: $5 for 18 tons, $4.50 for anything less than 18 tons provided shift-boss certified valid reason. POWER-SHOVEL OPERATOR: 8¢ per ton, but if his earnings exceeded $60 per week, he received only half of the excess. STOPE CONTRACTOR was guaranteed $5.05 per shift, but usually earned more on a tonnage basis graduated to height of stope: 8 ft high or less, 14¢ per ton broken; 8–20 ft high, 13¢ per ton; over 20 ft high, 10.5¢ per ton; prices were reduced by 1¢ per ton if ore was loaded by machine instead of

by hand; if contractor's earnings exceeded $60 per week, he received 1/2 of excess. At another mine (26) day's wages were guaranteed. Payment for STOPING was on basis of tons broken, measured by number of 2.5-ton cars loaded, and varied with height of stope: low ore, 16-18¢ per ton; medium-high ore, 12-14¢; high ore, 8¢ per ton. Contractors furnished only labor and explosives (sold them by company at less than cost) and carried their own steel. HAND-SHOVELERS ordinarily loaded 20 tons for a day's pay, with bonus for each additional ton; task might be reduced to 14-16 tons for a long tram or scattered ore. For mining method, see Sec 10, Art 31.

Magma mine (43). In 1928, 60-75% of all underground work was on "contract," with day's wages guaranteed; prices set by foreman and approved by supt and gen mgr. Prices per ft for DEVELOPMENT by drifts and crosscuts varied with size and other features of opening; price for raises increased with each 50 ft above level; uniform price per set for drift timbers. Payment for STOPING, on basis of volume excavated, varied with mining method (Sec 10, Art 37). Measurements were made twice a month; earnings computed by supt and auditor. Contractor received allowance above wages for his supervising. Excess earnings on a "contract" were divided among all engaged, on basis (only) of shifts worked.

Champion mine (52). STOPING at this mine involves careful sorting (Sec 10, Art 63) which the bonus system is designed to encourage. A miner and 1 or 2 pickers do whole work in a stope, and distribute their bonus in proportion to shifts worked. Monthly measurements give total volume broken, and car count gives tonnage of sorted ore hoisted from each stope. Bonus BASE is subject to 3 variations: (*a*) it is higher for wider stopes; (*b*) lower for a larger proportion of waste rock handled; (*c*) allowance of free explosive increases with width of stope.

Alaska Juneau (53). In 1928, about 75% of all underground labor was on "contract" with base wages assured. ESSENTIAL FEATURES of system, developed by experience: (*a*) division of bonus among all workers concerned in a given contract on basis (only) of shifts worked; (*b*) close supervision and prompt adjustment of prices to changed conditions; (*c*) judicious selection of contractors; (*d*) withholding small part of contractor's earnings, to be forfeited for poor work or drawn upon to maintain standard day's wages if earnings diminish; (*e*) furnishing good equipment and ample supply of steel and comp air; (*f*) fixed price for explosives, regardless of market; (*g*) combining 2 or more working places under same contract, to promote efficiency. Written DEVELOPMENT CONTRACT was let to successful bidder at set price per ft depending mainly on size of opening; rock conditions were usually known in advance and no timbering was necessary. Contractor paid for direct labor (including liability insurance @ 3% of total wages, including his own) and for explosives; these 2 items usually amounted to about 60% of total cost to company. Contractor's earnings were maintained at minimum of $6 per day by advances (when necessary) from future earnings; when his earnings exceeded $11 per day, surplus was divided among his men and himself in proportion (only) to shifts worked. Contract rates for BULLDOZING, LOADING, and HAULING were adjusted at short intervals with reference to season, weather, character of ore (chunky or slabby), condition of the stope (Sec 10, Art 68) or other factors affecting the handling of ore. At end of every month, contract was credited at set price (aver 14¢ in 1928) per ton trammed out; explosives and direct labor, including contractor and timberman (at company base rates), were deducted; balance, if any, was "divided among contractor's entire crew, in proportion to a certain maximum bonus rate per shift." Any further surplus was divided equally, per shift, among all in the mine, including company men, provided a man had worked 26 shifts in the month. If incapacitated by accident, he received a share of bonus proportional to the time he did work. A man quitting within the month was paid at company's base rate only. TRAMMING was a sub-contract, charged to the stope contractor; trainmen received a bonus of 50¢ per shift (above their base rate) whenever the stope contractor earned a bonus.

Britannia Mining & Smelting Co (54) in 1935 employed a true bonus system based on fixed standards of work; rates for excess work were so adjusted that workers and company shared equally in savings of cost. Standards, and any alterations due to changed conditions, were posted in advance; a considerable staff of bonus engineers was required. System proved disappointing when applied to caving into branched raises or to large shrinkage stopes, because the bonus had to be divided among so large a group that each man's share gave little incentive for increased effort. Method was satisfactory for: (*a*) all development work, on basis of standard footage; such work was sometimes let on straight contract; (*b*) square-set stoping, on basis of tonnage broken, as measured by count of new sets; (*c*) cut-and-filled rill stopes, on basis of surveys; (*d*) narrow shrinkage stopes, based on area of new footwall exposed, regardless of width so long as the whole vein could be broken by the same number of holes; (*e*) back-filling, based on measured volume. Provided the standards were correctly set, there was not much difference in cost (to the company) of a given work on bonus or on straight contract; latter system was preferred where speed was essential, since a contractor's profit may increase more rapidly than the earnings of a bonus worker.

Matahambre, Cuba (55). In 1929, all underground work (Sec 10, Art 62) was on "contract," with day's wages guaranteed. STOPE contractors (usually 2 in a stope, on opposite shifts) were paid a fixed price for all work done, itemized separately under cars of ore drawn from chute, sorting, spreading fill, timbering and lagging, and were charged for explosives, carbide, and time of their men, who were paid at fixed rates directly by the company; also for company men's time setting chutes. Contractor's men trammed timbers and all other materials from shaft stations. A contractor was allowed a small increase in day's pay for his supervising, but his earnings above that rate were divided among his men on basis (only) of shifts worked.

Mascot mine, Tenn (22) in 1930 applied a bonus system to men employed in TRANSPORT (for contract stoping, see Art 3). Motor- and car-men, skip tenders and helpers, shared a bonus based on weekly tonnage; day-shift foremen shared a monthly bonus on production of zinc concentrate; bonus for night-shift foremen (occupied mainly with chute-pulling and shoveling) was based on total tonnage hoisted.

Morenci, Ariz (56). In 1928, 72% of all underground work was on "contract" or bonus, standard day's wages being guaranteed in both cases. "CONTRACT" system, at standardised prices, was applied mainly to development, but included drift timbering, track laying, ditching, undercutting and shrinking in stopes (Sec 10, Art 80), and salvaging of materials. Rates were seldom changed, and then only (on authority of supt) before a contract was let. Work was measured twice a month and earnings were computed by engineers. Earnings might be divided in 4 ways, at discretion of foreman: (*a*) equally to all workmen concerned in contract; (*b*) respective day's wages to all concerned, plus equal share of surplus; (*c*) respective day's wages, plus a share of surplus proportional to day's rate; (*e*) straight payment to each man for his individual work, depending upon its nature. BONUS system was applied to workers in stopes and on transport. "Base cost per ton" was aver day's earnings (based on past records) for each type of work, divided by aver tonnage handled per day. Base for each working place was subject to adjustment at beginning of a pay period. Bonus was half of excess earnings above the base. Shift-bosses did not share in production bonus, but were rewarded for 1 000 man-shifts without accident.

United Verde underground mine (57) in 1931 employed "contract" and bonus systems almost identical with those at Morenci, requiring a staff of 8 engineers and a clerk to set standards and compute earnings.

5. COOPERATIVE SYSTEMS

Division of profits is sometimes arranged by permitting employees to buy shares in the company, their employer; additional incentive to participate in such system may be offered in form of a discount from market price of shares, a guaranteed annual bonus, or an installment plan of purchase. U S STEEL CORPORATION, in 1903, instituted a plan by which common shares were offered to all employees upon easy terms, with benefits beyond those enjoyed by ordinary stockholders. Price of stock was the market price, or usually a little less. This plan was discontinued in 1929, at the precipitous fall in stock prices. For details of its provisions, see Edn 2, p 1530.

On the Comstock Lode, in 1908, certain companies divided 10% of the net value of ore produced each month, in excess of $50 000, among all employ es, in proportion to their wages. Another company made similar division of all its net proceeds (7).

At an Indiana coal mine, a legal corporation of miners was organized, to which the owner leased his property for a test period of 1 yr under restrictions aiming to maintain safety of mine. Owner's royalty, 5¢ per ton, and 0.25 of net profits. The arrangement resulted in increased earnings by miners, and steadier output during dull season (8).

6. LEASING, OR TRIBUTE, SYSTEM

Mining lease, as term is used in U S, is a simple contract by which the LESSOR (mine owner) grants to LESSEE ("leaser," or "tributer"), under certain conditions, the exclusive right to do a certain piece of work, for which the lessee agrees to accept payment in form of a proportion of net returns. Unlike an ordinary contractor, lessee thus shares risk as well as profit (R. W. Raymond, *Trans* A I M E, Vol 21, p 916). A clause called BOND AND LEASE is sometimes included, by which owner promises to sell his mine and deliver a valid deed therefor to lessee for a stipulated price at any time before termination of lease.

Leases may be granted for exploring and developing newly discovered ore deposits, as at Goldfield (9); to reopen a seemingly exhausted mine, as at Aspen and Eureka (10); or during the height of a mine's prosperity, as at Leadville, Cripple Creek, and other Colorado camps (11). In latter case, advantages of leasing are most pronounced when the deposit exists in form of stringers or pockets of high-grade ore. Many such mines return large profits under leasing system, while unable to operate profitably on their own account, for reasons stated below.

Advantages of leasing system, from OWNER'S point of view, are: (*A*) Development accomplished at small cost, since lessees are usually willing to take a risk in performing dead work which a cautious mine manager might shun. (*B*) When developed, ore is produced with small working capital. (*C*) Profits to owner are absolutely net, since lessee usually pays for power, pumping, and hoisting, besides his own working expenses. (*D*) Less ore is lost during mining, tramming, and sorting, whether by carelessness or by stealing. (*E*) Mine is not liable for lien. (*F*) Lessee is responsible for damage to mine and for accidents to workmen. (*G*) Slight supervision required. From viewpoint of LESSEE, advantages are: (*a*) He frequently has keener perception of ore occurrence in the particular deposit than even a skilful foreman can acquire (company miners sometimes deliberately conceal information leading to discovery of new pockets). (*b*) No heavy initial outlay required for machinery or expensive development. (*c*) No expense for office force, interest, insurance (of property), and other customary fixed charges. (*d*) By more careful personal supervision, loss of time and waste of explosives and supplies are reduced, hence affording cheaper mining than an owner can usually attain on his own account. (*e*) Even under adverse conditions, a leaser's returns are usually larger than ordinary day's wages

(as is right and proper considering his extra diligence and skill); excessive dead work is sometimes compensated by an allowance for "footage" (say, $2 per ft), or by stipulation of a smaller royalty.

Royalty rate is usually based on a sliding scale which varies with gross value of ore, while its amount is computed on net returns from smelter or reduction works, after deducting haulage, freight, and treatment charges (sometimes also sampling and assaying fees). Shipments are ordinarily made in name of mine owner, who first deducts his royalty, then his charges (if any) against lessee for supplies or services rendered; balance going to lessee.

At Goldfield, during first stages, royalty rate was 25% on ore over $50 per ton, and 20% on less valuable ore. At one Colo mine (12) rate was numerically equal to 1/3 value of ore; $51 ore, 17%; $150 ore, 50%; special provisions for $300 ore. At a mine in Gilpin county, Colo (13), royalty was 33 to 75%, if drift had already been run under leased block; 25 to 33%, if drift had to be run by lessee At Leadville: under $10, 10%; $10 to $15, 15%; $15 to $20, 20%; over $20, 25%. Table 3 gives royalties in recent leases at Cripple Creek, Colo, and Oatman, Ariz. For mathematical discussion of a rational basis for levying royalties, see (15).

Table 3. Examples of Lease Royalty

Cripple Creek, Colo 1935 (58)		Tom Reed, Oatman, Ariz 1934 (59)		Pioneer, Oatman, Ariz 1935 (59)	
Ore Value	Royalty, %	Ore Value	Royalty, %	Ore Value	Royalty, %
To $15	10	To $10	5	To $15	10
$15–20	15	$10–12	6	$15–25	15
20–30	20	12–15	9	25–40	20
30–50	25	15–20	15	40–50	25
50–100	30	20–25	20	50–60	30
$100 +	35	25–30	25	60–70	35
......	..	30–35	30	70–80	40
......	..	35–40	35	80–90	45
......	..	40–45	40	$90 +	50
......	..	45–50	45		
..	.	$50 +	50		

Other covenants of a mining lease. A lessee can void his contract at any time without penalty, while a lessor has no means of ousting a lessee if the latter fulfils the letter of the contract. For this reason, and because most lessees are not financially strong, it is particularly important that mining leases be carefully drawn, and clearly understood.

Two covenants most likely to cause trouble are: (*a*) What constitutes ABANDONMENT and FORFEITURE? Usual stipulation is for a minimum number of days' work (200 man-shifts per 90 days, at Cripple Creek; 60 shifts per mo, at Goldfield), or a minimum amount of new development (300 ft per yr, at Leadville). Forfeiture results from violation of any covenant of contract (not attributable to casualties, strikes, or litigation) and owner may thereupon resume possession without formality of a lawsuit. (*b*) Ownership of PLANT erected by lessee and disposal of ORE-DUMPS remaining on property at expiration or forfeiture of lease. At Goldfield, all improvements underground, and all broken ore not hoisted before expiration of lease, become sole property of mine owner. At Cripple Creek, all structures and dumps remain property of mine owner, but lessee must remove his machinery within 60 days. It is advisable to include a definite stipulation as to the length of time, after termination of lease, within which owner must market ore on dumps, or beyond which the lessee's equity in that ore shall cease; neglect of this provision has been a fruitful source of lawsuits. Additional stipulations, not already mentioned, relate to: (*c*) Exact boundaries of leased block. (*d*) Date of expiration of lease. (*e*) Work to be done "mine-fashion" to yield maximum output with due regard to development of orebody and safety of both miners and workings. (*f*) Adequate timbering to be placed and maintained. (*g*) Minimum dimensions of openings: shafts commonly 4 by 8 ft, and drifts 3.5 by 6.5 ft clear. (*h*) No underhand stoping; no stoping within 10 ft of shaft; no levels within 50 ft of one another. (*i*) Workings to be kept clear of ore, rock, rubbish, and water. (*j*) Owner or his agents to be admitted to mine at any time for any purpose. (*k*) Bills incurred by lessee to be settled promptly, and vouchers to be shown to lessor on demand. (*l*) No sub-leasing without owner's consent. For verbiage of typical Colo leases, see (16).

Leasing at Cripple Creek (58). In 1935, probably 75% of all mining in the district was being done by leasers. Success of the practice requires continuous and strict supervision by owner; where this has been relaxed, results have often been highly unsatisfactory. On straight leases, royalties have been fairly uniform at the rates shown in Table 3. The larger mines, with managers and superintendents on the ground, frequently adopt the SPLIT-CHECK system. At the CRESSON MINE, such leases run for 1 yr, but are terminable at option of management. Owner retains full authority over safety and sanitation of mine, removal of pillars, etc. Leaser must work minimum of 50 man-shifts per month.

Lease blocks are usually 200 ft square and 1 level (usually 100 ft) high. Owner supplies equipment (except drills), comp air, explosives and all other supplies, and provides hoisting service, but charges 10¢ per ton for transport of shipping ore via aerial tram and loading into RR cars. Leaser supplies labor of miners, trammers, and sorters, and pays their compensation insurance. Net returns, after freight and treatment, are divided equally, but leaser contributes 1% of gross value of shipment as his share of taxes. Owner of a large property sometimes lets a straight royalty lease (at rates usually lower than those in Table 3) to a leasing company, which may then sub-lease to individuals on the split-check system.

7. METHODS OF PAYING WAGES

Interval between pay-days. MONTHLY pay-days reduce amount of clerical labor in preparation of payroll, but often work hardship on individual miners; this arrangement is commonest at mines which are remote from head office, and from banking facilities. BI-MONTHLY pay-days are the rule in anthracite district, and are common elsewhere; involve more clerical labor, but are generally considered more equitable by the miners. WEEKLY pay-days are feasible only with companies having large clerical force, and where there are ample banking facilities. Pay-day intervals are fixed by statute (with penalty for violation) in all mining States except Idaho, Wash, and in the Philippines (60); legality has often been disputed, but generally upheld though for varying reasons. Law in Ala applies only to public-service, and that of S Dak and W Va only to RR employees. Semi-monthly pay-days prevail in most mining States; N J prescribes 2 weeks; Minn, 15 days for public-service and transitory labor (no other regulation). Weekly payment is required in Puerto Rico, and (if requested) in Ind. Alaska and Ore permit monthly pay-days; also Utah, to employees on annual salary (semi-monthly to others). Wyo and Nev allow departure from semi-monthly rule in contracts. Legal lapse between end of pay period and pay-day varies from 5 days in Mont to 10 days in Ind, N M, and Utah, 12 days in N J, 15 days in Md, Mich, Nev, Ohio, and 18 days in Ill. Mo requires 30-day notice of any proposed reduction in wages.

Wages are paid: (*a*) By check. This is often preferred by operators, as it avoids necessity for filling out individual receipts; objection of miners is that cashing checks requires opening of a bank account or visit to store or saloon, sometimes involving a discount; method not recommended for remote districts, and is specifically prohibited by laws of Ariz, Cal, Colo, Ill, Ind, Md, Nev, N J, N M, Okla, Ore, Utah, Wash, unless checks are payable in cash, at sight, without discount. Nev prohibits payment of wages in saloons. (*b*) In currency. This is preferred by miners, and the only serious disadvantage to operator is the risk of theft of cash during transit from office or bank. (*c*) In orders on company store. In an isolated locality, able to support only one store, and when this belongs to mining company, payment of part of wages in this form may not be objectionable; elsewhere, the plan is liable to abuse by company, and may lead to serious discontent among miners; it has been abandoned in the anthracite field, after long protest from the organized workers. Company scrip is debarred by law in Ariz and Colo; permitted (at option of employee) in Ill, Mich, N J, N M, Ohio, and W Va, provided it is redeemable at sight in cash at face value; Wis places no restrictions on methods of paying wages. Compulsory buying at Company stores is prohibited in Ariz, Idaho, N M, and W Va.

Time-books, payrolls, etc. Where day's wages are in force, each foreman has a TIME-BOOK, in which to record the number of hours worked per day by each man under his charge. Some time-book systems are so arranged that the foreman can distribute time of each workman according to nature of his employment, for purposes of cost accounting, but it is unwise to demand too much clerical work from mine foremen. Every day, or once a week, entries are transferred to a time-book in office, where a distribution to different working accounts can be made. At required periods, PAYROLL is compiled from office time-book, setting opposite each name the total hours (shifts, or days) worked, rate per hr (which may be different for different kinds of work by same individual), and total wages earned. In contract work, amounts due are computed from returns of surveyors, foremen, weighmen, etc. DEDUCTIONS, comprising all charges of company against each man, such as store supplies, rent, board, cash advanced, contribution to hospital and doctor's or benefit funds, wages of check-weighman, and Union dues (in some cases), are compiled from the appropriate sources and entered. A copy of this payroll, showing total amount in cash needed for following pay-day, as well as amounts credited to the several accounts, to balance deductions, is sent to main office, which then sends required amount to mine office. Meantime, at best organized mines, an individual "DUE-BILL" is delivered to each man, showing amount earned, itemized deductions, and net wages coming to him. These statements are preferably distributed a few days before pay-day, to give opportunity for rectifying mistakes and for dividing proceeds between partners, in case of a contract. For details of an elaborate payroll system at Britannia Beach, B C, making extensive use of mechanical office devices, see Bib (61): for accounting of payrolls in general, Bib (17).

Anthracite agreements (Art 11) require a contractor to notify company as to the amount due to each of his laborers, so that they can obtain their wages direct from paymaster. If wages are paid in cash, it is convenient to have a coupon at bottom of statement, which can be signed and delivered to paymaster, as receipt for wages.

8. ACCIDENT COMPENSATION AND INSURANCE

Development and purpose. Under the COMMON LAW, an employer, when sued for damages by an employee injured in his service, was allowed to plead the defenses of contributory negligence, negligence of fellow-servant, and assumption of risk by employee. EMPLOYERS' LIABILITY LAWS abolished or modified the defenses of fellow-servant and assumption of risk, but an injured employee was still under burden of proving personal negligence on part of someone as proximate cause of his injury. An injured employee was thus under necessity of incurring both expense of law-suit and enmity of his employer; an employer, on other hand, was liable to be held for excessive damages, based on mere conjecture of a sympathetic jury, or must insure his liability at a high premium, the rate of which was commonly based upon the worst rather than on the best or the average conditions surrounding the employer's particular line of industry. COMPENSATION LAWS seek to diminish injustice to both parties by: (*a*) making obligation to pay damages independent of fault (except criminal or wilful negligence of injured employee); (*b*) making measure of compensation automatic and predetermined (based on aver weekly earnings); (*c*) permitting employer to insure his compensation liability at more equitable rates. Such laws are in force in all mining States, usually under jurisdiction of a special Compensation Board; in Ala, Alaska, N M, Tenn, and Wyo, law is administered by county or State courts. Decisions of a Board are usually final as to facts, but may be appealed to courts on questions of law.

General character of compensation laws. DIRECT, or simple, compensation law places obligation for indemnity immediately upon person in whose employment an injury occurs. INDIRECT, or State insurance, law requires employer to pay an annual tax graded according to nature of his business and proportional to his payroll; an injured workman is then indemnified out of this fund by State officials. COMPULSORY compensation law places absolute obligation on employer, either to pay direct indemnity or to contribute to State fund. ELECTIVE law permits employer to choose whether to abide by State compensation provisions, or to operate under a liability statute which deprives him of all three common-law defenses; employees are similarly required to state their choice; except in Mich, Mont, Nev, and W Va, election is presumed (as to both employer and employee) in absence of positive rejection. Purpose of elective system is to circumvent the usual constitutional provision against the deprivation of property without due process of law, which the N Y Court of Appeals has held to be an inherent defect in any compulsory compensation statute.

Nature of injuries. Existing compensation statutes have adopted practically a uniform wording: "all personal injuries from accidents arising out of and in course of employment, unless due to intoxication or to wilful or intentional misconduct." Necessity of proving responsibility for accident, and degree of fault, is thereby eliminated, except in case of intoxication and wilful misconduct, different forms of latter sometimes being expressly indicated by statute.

Amount of compensation. There is wide diversity in statutory provisions on this subject; common aim is to make amount of compensation, in any case, mathematically determinable. In almost all States, payments are calculated on a variable percentage (66²/₃% is frequent upper limit) of previous aver weekly wages, payable over a limited period of weeks; max (frequently \$16–\$20) and minimum (commonly \$5–\$8, or actual wages if below stated minimum) weekly rates are usually stipulated. MAXIMUM TOTAL PAYMENTS under 4 conditions are given in Table 4; details impracticable to tabulate can be secured from appropriate State authorities.

Insurance of compensation liability. In all mining States except Alaska, employers are required to insure their liability, and in all but Nev, Ore, Puerto Rico, Wash, and Wyo, they are permitted to choose method of insurance. In the most liberal statutes 4 methods are allowed: (*a*) Self-insurance, on satisfactory proof of solvency. (*b*) Mutual companies. (*c*) Regularly organized stock liability-insurance concerns. (*d*) Organization administered by State. In any case, an injured employee usually has direct claim against insurer, for an amount which in no case may be less than that stipulated in compensation act. An indirect benefit of scientifically applied insurance is the influence that it exerts in promoting safety of workmen, since an employer's premium will properly be in direct proportion to accident rate at his works.

Status as of July 1, 1938 (62). Among numerous recent changes, most frequent has been provision of compensation for occupational diseases, now compensable in 27 States (18 on Jan 1, 1936); some statutes enumerate specific diseases; others provide for disability resulting from occupational disease; a few States make "injury" from occupational disease synonymous with "accident" and hence compensable. Many compensation statutes include safety regulations and provide for their enforcement; most of the important mining States accomplish this purpose through other channels.

Table 4. Workmen's Compensation in Mining States (*Monthly Labor Rev*, Sep, 1938, p 566)

State	Compensation is—	Ins req'd in: State fund	Ins req'd in: Private Co or Self	Exemptions (a)	Occupational diseases compensable	Com-law defenses	Waiting time, days	Retroactive, weeks (b)	Max Total Payment (c): Death	Max Total Payment (c): Perm total disab	Max Total Payment (c): Temp partial disab	Max Total Payment (c): Temp total disab	Limits on medical care

(a) Employer of fewer than stated number is exempt. (b) If disability lasts for stated number of weeks, compensation is retroactive to date of accident. (c) These payments are *maxima* allowable; for graduated scales, consult compensation board of particular State (or county courts in Ala, Alaska, La, N M, Tenn, Wyo). (d) Employer forfeits common-law defenses on neglect or lapse of insurance. (e) Election presumed (as to both employer and employee) in absence of positive rejection. (f) No suits permitted after employer and employee have accepted comp act. (g) As to employers. (h) No security required, but if a beneficiary files notice of death claim, employer may deposit $9 000 with court or give bond for that amount; in other cases, claimant is entitled to writ of attachment, unless employer files undertaking for double the amt sued for. (i) As to public employees and hazardous occupations only (j) Compulsory as to public employees and coal mining. (k) $18.46 per wk during widowhood, or specified minority age of children. (l) $30 per mo for widow, plus $8 per mo for each dependent child, during widowhood or specified

In most States, both self-insurance and insurance in private companies are permitted; only Nev, Ore, Puerto Rico, Wash, and Wyo compel insurance exclusively in a State fund; Ohio and W Va maintain such exclusive funds, but permit self-insurance in certain cases. Some States maintain insurance funds competing with private companies, and permit employers to choose. Data on these and other provisions in the compensation statutes of (only) the important mining States are compiled in Table 4. About 2/3 of the States allow compensation for accidents occurring outside of the State, provided the employee was hired within it, or is a resident of it, or his employer's place of business is within the State; courts of other States have often ruled similarly, in absence of statutory provisions. Utah affords same protection to an employee (of a Co in Utah) even though hired elsewhere. Where both parties have accepted an elective compensation act, suits for damages are usually forbidden. If his employer has accepted, an employee who has rejected may bring suit, but employer retains his common-law defenses. In a large majority of the States, an employer who fails to secure his liability, to provide insurance, or to pay premium when due, may be sued for damages and forfeits his common-law defenses.

Total amount of compensation in a given case depends upon: (*a*) the weekly rate, usually a percentage of normal wages; (*b*) period over which payments are made; (*c*) in most States, a fixed max weekly or total payment (minimum rates are also usually stipulated). These factors are variable, according to nature of the injury: (1) death; (2) permanent total; (3) permanent partial; (4) temporary total; (5) temporary partial disability. "Permanent partial disability" is variously interpreted: sometimes by specific description, sometimes by reference to lost earning power. In general, permanent total disability is treated as a more serious loss than death. No State (except Ore) pays compensation for the first few (most commonly 7) days after a disabling accident, but if disability lasts longer than a specified time, payments in many States become retroactive to date of accident. "SECOND INJURY" compensation receives special provision in all mining States (except Alaska, Philippines, and Puerto Rico). When an employee, already partially disabled and receiving appropriate compensation, is injured a second time and becomes eligible for increased compensation, his then employer is responsible only for the increment, the difference being paid out of "second-injury" fund, which is maintained (among the mining States) in Idaho, Ill, Minn, N J, N C, Ohio, Penn, Utah, Wis; a convenient source of such funds is the compensations awarded in fatal cases where no one proves legally entitled to receive them. All States require MEDICAL AID to be furnished an injured employee, free in nearly all States; in Alaska, an employer may deduct \$2.50 per mo from wages, for medical fund; in Ariz and Nev, 1/2 the cost (but not over \$1 per mo) may be deducted; in Wash, workman pays 1/2 cost. In 16 States, there is no limit on time or amount of medical care, 12 States limit amount but not time, 12 limit time but not amount, and 13 limit both (Table 4). In many States with statutory limits, courts or Compensation Boards have discretionary powers to extend them.

No compensation act discriminates between U S citizens and resident aliens, but 38 out of 53 such acts do now (more than formerly) restrict to some extent the benefits to non-resident alien dependents. Commonest restrictions are: (*a*) reduced benefits; (*b*) limitations on beneficiaries; (*c*) commutation of weekly benefit to a lump sum figured at a lower rate. Among mining States, only Minn, Ohio, Tenn put non-resident alien dependents definitely on same footing as those of citizens; Ind, Mo, N J, and Philippines make no special provision. Several States exempt Canadian dependents from such restrictions.

Compensation statutes of Ariz, Colo, Mich, Mo, Mont, Nev, N M, Ohio, Okla, Ore, Penn, Puerto Rico, S Dak, Utah, Va, Wash, Wyo, demand REPORTS on all industrial accidents; Cal, Idaho, Philippines, on those causing disability of 1 day; Ind, Iowa, Kans, Ky, more than 1 day; Md, N C more than 3 days; Ill, more than 1 week; Ala, more than 2 weeks. In N J, insured employers must report all accidents; uninsured, those causing permanent total disability, or disability of more than 1 week. Minn requires reports on all accidents causing death or serious injury, and on others causing disability for more than 1 day. In W Va and Wis, Compensation Board has discretion as to reports. Alaska's compensation law demands no reports, but accidents in coal mines are required to be reported under a separate enactment.

---

minority age of children. (*m*) \$18 per wk for 500 wk, and thereafter until remarriage. (*n*) \$55 per mo to widow with 2 children, plus \$5 for each other child, during widowhood or specified minority age of children. (*o*) \$30 per mo to widow, plus \$5 for each child, during widowhood or specified minority age of children. (*p*) 65% of wages, for life. (*q*) Plus 40% of wages thereafter, for life. (*r*) 50% of wages, for life. (*s*) Plus \$8 per week thereafter. (*t*) 50–65% of wages for 416 weeks, plus life pension of 8–12% of previous payments. (*u*) Plus 25% of wages thereafter, for life. (*v*) 60% of wages, for life. (*w*) 66 2/3% of wages, for life. (*x*) \$8.08 per week, plus \$8 per mo for each dependent child, during period of disability. (*y*) \$18 per wk for 500 weeks, plus \$30 per mo thereafter, for life. (*z*) 60% of wages for 260 weeks, plus 45% of wages thereafter, for life; increased 5% for each dependent child to max of 5. (*aa*) \$60 per mo during period of disability. (*bb*) \$16 per week, for life. (*cc*) \$21 per week, for life. (*dd*) 55% of wages for 260 weeks. (*ee*) In addn to allowance for temporary total disability, at same rates. (*ff*) Plus \$10 per mo for dependents. (*gg*) In addn to payments for total disability for period up to 64 weeks. (*hh*) In addn to payments for total disability. (*ii*) 65% of wages for 433 weeks. (*kk*) No limits. (*ll*) No limit on amount. (*mm*) No limit on time. (*nn*) Both amount and time limited.

9. PENSIONS AND BENEFIT FUNDS
(See also Art 8, "Compensation")

Federal old-age and survivors' benefits. Social Security Act (Titles II and VIII, as amended Aug, 1939) levies an income tax on employees within the U S (with certain exceptions not related to mining) who are under age of 65 yr; also an equivalent excise tax on all employers of such persons, regardless of their number. Excess of an employee's wages above $3 000 per yr is exempt from both taxes, which began to accrue Jan 1, 1937. Rates: 1937–42, 1%; 1943–45, 2%; 1946–48, 2.5%; 1949 and thereafter, 3%. Employer must withhold employee's tax from his wages (giving a receipt therefor) and remit it quarterly, together with his own tax, to collector of internal revenue. Returns are required from each separate employer; consolidated returns of parent and subsidiary organisations not permitted; sundry information returns are also required. Employees are identified by numbers assigned by local branches of the Security Board.

Retired employee is ELIGIBLE FOR MONTHLY BENEFITS if he: (*a*) is 65 yr old; (*b*) is fully insured; (*c*) files a claim. A worker is FULLY INSURED for life when he has received (*a*) as much as $50 for taxable employment in each of 40 calendar quarters; or (*b*) $50 in each of a number of calendar quarters equal to one-half of those elapsed between Dec 31, 1936 (or his 21st birthday, if later) and the quarter in which he reaches age of 65 (or dies), but in not fewer than 6 quarters. MONTHLY BENEFIT (beginning Jan 1, 1940): 40% of first $50, plus 10% of next $200 of aver monthly wages, plus 1% of above total for each year in which worker earned $200 or more in taxable employment. Minimum benefit, $10; max under any conditions, $85. Benefit is forfeited for any month in which worker earns $15 or more in taxable employment. AVER MONTHLY WAGES in above formula is total accumulated wages (excluding amount above $3 000 received in any 1 yr), divided by number of months claimant could have worked between Dec 31, 1936 (or his 22nd birthday, if later) and the quarter in which he becomes eligible for benefits, or dies. SUPPLEMENTARY BENEFITS for dependents: 50% of claimant's personal benefit for (*a*) wife 65 yr or older; (*b*) each unmarried dependent child under 16 yr, or under 18 yr if regularly attending school. SURVIVORS' MONTHLY BENEFITS of a fully insured worker: 75% of worker's benefit for a widow over 65 yr, or for any widow with dependent children; 50% for each unmarried dependent child under 18 yr, or for each dependent parent if there is no widow or dependent child. Amended Act makes provision for widows and minor children surviving a worker, not fully insured, if he has received as much as $50 in each of at least 6 quarters during preceding 3 yr. If no survivor is eligible for monthly benefit, a lump sum equal to 6 times the worker's monthly benefit may be paid to nearest relatives or (up to that amount) to anyone who defrays funeral expenses.

Note that the above is exclusively a Federal affair, as to both taxation and disbursements; no credit against the tax can be claimed on account of payments under any State statute.

Pensions are granted by many of the most progressive companies, and paid from a fund to which employees may or may not be asked to contribute. BENEFIT FUNDS are more frequently maintained by the employees alone, with occasional assistance from company's accounting and clerical force; in some cases, the company also contributes financially.

Homestake Mining Co began in 1917 to pension old employees retiring voluntarily or at suggestion of foremen (21). Annual pension, 25% of last full yr's pay, plus $10 per yr of service; total not exceeding $600. To mid-1931, 163 employees had been pensioned, of whom 52 were then receiving benefits. Co also pensions widows of employees killed by accidents before State compensation law became effective; monthly rate, $30 plus $5 per child under 16 yr. HOMESTAKE AID FUND, organised 1910, with Co supt as treas, chief clerk as secty, and 5 elected directors. Employees each contribute $1 per mo, and up to adoption of State compensation laws the Co contributed $1 000 per mo; fund formerly paid benefits for both sickness and accidents; now only for sickness, since Co must pay accident compensation. If sickness lasts over 3 mo, fund pays $1.50 per day for 9 mo; $800 for death or $200 for suicide or insanity. Co still pays $1 per day lost by accident, up to 10th day, when State compensation begins.

Copper Queen Employees' Benefit Assoc (consisting of Phelps Dodge employees at Bisbee and Douglas, Ariz) provides benefits for death and disabling accidents even though occurring while not on duty (in which case State compensation would not apply); also for sickness, not compensable by State. Admission to membership is limited to employees under age of 60 yr, but benefits for death due to sickness are limited to $200 for an employee admitted at age above 45 yr, against a maximum of $1 500 for those admitted at earlier age. A member contributes, in advance, 2.2% of his pay, to max of $3.30 per mo; contributions are waived during a period of disability. Company contributes $18 000 annually, provided Assoc numbers 50% of total employees (excl Mexicans) at the plants mentioned. Benefits at 50% of a member's wages, but not exceeding $2 per day, are paid during sickness or for accidents occurring off-duty, excepting the first 5 days in either case. For a dis-

abling accident while on duty; (*a*) no benefit unless disability exceeds 5 days; (*b*) if disability lasts between 5 and 14 days, benefit is paid for only 2 days; (*c*) no benefit for disability exceeding 13 days. (If disability from an accident on duty continues for 2 weeks, Ariz State compensation is payable from date of accident). Death benefit of a member is equivalent to his daily wages times the number of calendar days in last previous year, but not to exceed $1 500 (see above); Assoc may advance $200 out of benefit for funeral or other urgent expenses. Accidental total disablement while off-duty receives same benefit as death. Lump-sum settlement at option of member is permitted in case of off-duty injury or chronic sickness.

"Keg funds" are often maintained at collieries. Miners collect and bring up their empty powder cans; company provides storage for them, and periodically sells them to powder companies for about 8¢ each, the money being used for sick benefits and funeral expenses of employees. D L & W company pays out, from this source, about $1 700 monthly.

For additional data, see Bibliog (23).

10. LABOR RELATIONS IN GENERAL

Recent years have yielded a flood of legislation controlling employer-employee relationships. Federal law ("Wagner Act") rests on the Interstate Commerce clause of the Constitution. Among the mining States, only Mich, Minn, Penn, Utah, and Wis (to late 1939) have enacted such laws for regulating their own industries, usually patterned after the Wagner Act, but (in every case, except Utah) with addition of clauses defining "unfair labor practice" by employees, the most criticized omission from the Wagner Act. Mont and Ore permit their State Labor Boards to cooperate with National Board. Statutes of all mining States (except Calif and N M) provide channels for ARBITRATION of labor disputes; for examples, see Art 11. "YELLOW DOG" CONTRACTS (stipulating membership or non-membership in a labor union as a condition of employment) are specifically prohibited in Ariz, Calif, Colo, Idaho, Mich, Minn, Nev, N J, Ore, Penn, Utah, and Wis. Blacklisting is unlawful in Mont, N M, Okla, and Wash. Financial or other material contributions to COMPANY UNIONS are prohibited to employers by Federal law and by State law in Mich, Penn, Utah, and Wis. This last prohibition relates only to collective bargaining functions of such organizations; it does not outlaw an employer's support or encouragement of local organizations purely for social, educational, or benevolent activities. Decisions by two Fed Circuit Courts of Appeal (late 1939) upheld individual plant unions as legitimate collective bargaining units, provided evidence fails to show that such union is "tied to the management."

National Labor Relations ("Wagner") Act, approved July 5, 1935.

Sec 2: Term "employee" includes all employees, and any individual whose work has ceased as a consequence of, or in connection with, any current labor dispute or because of unfair labor practice, and who has not obtained other regular and substantially equivalent employment. Term "labor organization" means any organization, or any agency or employee representation committee or plan, which exists for the purpose of dealing with employers concerning grievances, labor disputes, wages, rates of pay, hours of employment, or conditions of work. Term "commerce" means trade, traffic, transport, or communication among the several States, or any Territory of the U S, or between any foreign country and any State, or between points in the same State, but through any other State, or any foreign country. Term "affecting commerce" means in commerce, or burdening or obstructing commerce, or having led or tending to lead to a labor dispute burdening or obstructing commerce.

Sec 7: Employees have the right to self-organization, to form, join, or assist labor organization, to bargain collectively through their own representatives, and to engage in concerted activities, for collective bargaining or other mutual aid or protection.

Sec 8: It is unfair labor practice for an employer: (1) to restrain, or coerce employees in the exercise of rights guaranteed in Sec 7; (2) to dominate or interfere with the formation or administration of any labor organization or contribute financial or other support to it; provided, that subject to rules by the Board (N L R B) an employer is not prohibited from permitting employees to confer with him during working hours without loss of time or pay; (3) by discrimination in regard to employment or any term or condition of employment to encourage or discourage membership in any labor organization; provided, that nothing in this Act, or in any other U S statute, precludes an employer from making an agreement with a labor organization (not established, maintained, or assisted by unfair labor practice) to require as a condition of employment membership therein; (4) to discourage or otherwise discriminate against an employee because he has filed charges or given testimony under this Act; (5) to refuse to bargain collectively with the representatives of his employees.

Sec 10 (*a*): The N L R B is empowered to prevent any person from engaging in unfair labor practice affecting commerce. This power shall be exclusive, and is not affected by any other means of adjustment or prevention that may be established by agreement, law, or otherwise.

Sec 13: Nothing in this Act shall be construed to interfere with the right to strike.

Applicability of Wagner Act to an employer appears to be measured by the extent to which either his raw materials or his product enter interstate commerce. "The question is necessarily one of degree" (U S Supreme Court). N L R B has taken an expanded view of its jurisdiction, but has been upheld by Federal courts in several cases within mining industry where the employer's dependence upon interstate commerce was fairly obvious (Jones & Laughlin, Eagle-Picher, Alaska Juneau); also in a few cases where as little as 25% of employer's product went outside of his State. In the Idaho-Maryland case (Calif) the Fed court vacated a cease-and-desist order from N L R B, on showing that the company's entire operations, including purchase of supplies, were confined to Calif, its bullion being sold to San Francisco mint and its concentrates shipped to Selby. The fact that some of its supplies and equipment (though purchased in Calif) were manufactured elsewhere was held immaterial to the case. On lapse of legal period for filing an appeal, this decision is now binding in the 9th Fed circuit, including Calif, Oreg, Wash, Ariz, Idaho, Mont, and Nev, and would also carry weight in other circuits dealing with similar cases.

Unfair labor practices by employees. Federal law is silent on this subject. Four of the 5 mining States which (to late 1939) have enacted "little Wagner Acts" have added provisions defining unfair practice by employees as well as by employers. PENN (as amended and approved June 9, 1939) makes it unfair practice for a labor organization: (*a*) to intimidate or coerce any employee with intent to compel him to join or refrain from joining any labor organization, or to influence his choice of bargaining representatives; (*b*) to join a sit-down strike, or to seize or damage an employer's plant with intent to compel him to accede to terms of employment, including a demand for collective bargaining; (*c*) to intimidate or coerce any employer by threats of bodily force or violence with intent to compel him to accede to demands. MICH LABOR RELATION ACT (June 8, 1939) makes it punishable as a misdemeanor: (*a*) to take or withhold possession of property against the will of its owner or rightful occupant; (*b*) by intimidation, to force any person to become or remain a member of a labor organization, or to refrain from engaging in employment. MINN LABOR RELATIONS ACT (Apl 22, 1939) includes in its definition of unfair labor practice both of the misdemeanors recognized by Mich, and adds: (1) to institute a strike in violation of a valid collective agreement with which the employer is complying, or without serving the prescribed 10-days' notice upon employer and State Conciliator; (2) for any person to picket a place of employment of which he is not an employee, unless a majority of persons picketing are employees at the place. WIS EMPLOYMENT PEACE ACT (May 3, 1939) makes it an unfair labor practice for an employee individually or in concert with others (or for any other person): (*a*) to intimidate an employee in enjoyment of his legal rights (including those granted by other sections of the same Act); (*b*) to intimidate an employer into interfering with those rights; (*c*) to violate terms of a collective bargaining agreement (including an agreement to accept an arbitration award); (*e*) to refuse or fail to accept the final determination of any tribunal having competent jurisdiction; (*e*) to engage in picketing or boycotting unless, by secret ballot, a majority of the collective bargaining unit has voted to strike; (*f*) to hinder or prevent by force or coercion the pursuit of any lawful work; (*g*) to engage in secondary boycotts; (*h*) to take unauthorised possession of employer's property, or engage in concerted effort to interfere with production, except by peaceably leaving the premises.

Internat Union of Mine, Mill, and Smelter Workers, an outgrowth of the old Western Federation of Miners and now affiliated with Congress of Industrial Organization, with over 50 000 members (Sep, 1938), is predominant labor organization in U S metal mining districts; in 1937, it signed 97 agreements with employers. Following data (63) refer to MINING AGREEMENTS; smelter and refinery agreements are similar in principle, but differ in some details. CLOSED UNION SHOP is usually stipulated; Co is usually required to furnish the Union with a complete list of its employees within 1 week after the end of each month, and to notify any employee whose good standing is questioned; such employee, if still delinquent after 10 days, is not permitted to work. Check-off collection of Union dues is not usually required (1 such case in 1937). Several Mont mines agree to employ only local men, so long as they are satisfactory to Co. WAGES are usually on a sliding scale with metal prices (Art 2). Over-time draws 1.5 times regular rate; double-time on holidays; 8-hr day is standard, including 30 min for lunch. In some mines, 50¢ extra is paid for wet work. Work between regular shifts is usually paid on guarantee of 4 hr at regular rate. At some mines, engineers and pumpmen are permitted to work 7 days a week, with privilege of arranging for annual vacation.

Some agreements limit night-shift work to 2 weeks at a stretch. Nearly all require provision of change-houses, baths, and first-aid equipment. Some agreements forbid a miner to work alone at actual mining underground; in 1 case, use of machines is required when practicable. Seniority is the usual rule governing employment. All agreements arrange for SETTLEMENT OF GRIEVANCES. A dispute which can not be settled with the foreman may be referred to mine manager or higher official. On disagreement as to facts, a Union committee may make an examination jointly with a Co representative. Men who have been discharged without cause are guaranteed back pay. LOCKOUTS AND STRIKES are prohibited before all means of settlement have been exhausted. It is usually agreed that a strike shall not affect pumpmen and other maintenance men so long as Co makes no attempt to resume production; Union usually reserves right to call out such men if negotiations are not completed within 15 days. At each plant of ANACONDA COPPER MINING Co, there is a local industrial-relations committee, with 5 representatives of each party; if 7 members can not agree, the dispute is referred to an executive industrial-relations committee composed of 1 representative from each party from the Butte, Anaconda, and Great Falls plants; agreement by 4 members of this body is final.

Cons Mining & Smelting Co of Canada (64) offers a notable example of harmonious relations maintained since 1918 under auspices of a cooperative committee composed entirely of employees; earlier complete affiliation with Western Federation of Miners has since been almost wholly abandoned, though membership in outside unions is not restrained.

Committee members, 1 representative from each department, or each shift in a large department, are elected by secret ballot every 6 mos for term of 1 yr (to allow overlapping). Committee elects its chairman, vice-chairman, and secretary; chairman appoints 5 standing sub-committees and others when necessary. Out of aver 5 000 employees, over 300 had served on committee to 1935. No rigorous by-laws have ever been adopted. Committee meets twice a month, about 1/2 on its own and 1/2 on company time; no representative of Co management attends meetings, unless invited. Committee assists management in adjustment of nearly all grievances, and, in case of a complaint deemed not well founded, assumes responsibility for adverse decision. It also co-operates with, but does not control, the employment department. Applications for EMPLOYMENT are received only at Trail (to ensure uniform consideration); Canadians, and sons or relatives of present employees receive preference; applications are not accepted when opportunity to work is likely to be unduly delayed. Applicants must read English, and pass medical examination. Except skilled tradesmen, all new employees enter a general "yard" department, from which other departments draw when necessary; "yard" also absorbs those temporarily not needed elsewhere. Foreman may discharge a man for a serious offense, but must file statement of case with employment manager; latter may uphold foreman or alter the discharge to an "open transfer." Foreman also may issue an OPEN TRANSFER to an unsatisfactory employee, who may then be re-employed by another department; a third transfer within 2 yr from the first means automatic discharge; such discharges amount to less than 2% of the annual turnover. Minimum WAGES are set in relation to local costs of living, subject to bonus for better than aver work; bonus also is on sliding scale with metal prices. In all wage agreements, Co reserves right to increase the rate of a workman above his group scale. For promotion, ability is first consideration; of 2 equally capable men, senior in service receives preference. Every employee, at end of 3-yr service, receives a share of company's stock; free, if he is married, or for $12.50 (1/2 par) if single. HEALTH INSURANCE covers hospital and doctor's care for men and their families; employee pays $2.50 and Co contributes about 90c per man per mo. For LIFE INSURANCE, including total and permanent disability, Co pays for a group policy of $1 500 per man; employee may pay for additional $1 000 at group rate. BENEVOLENT SOCIETY is conducted exclusively by employees; dues of $1 per mo draw benefit of $1.50 per day for max of 6 mos in any one year. Co maintains a revolving fund of $750 000 for HOUSING LOANS on 5% mortgages, principal and interest deducted from monthly pay. Applicant deposits 10% of combined value of house and land, and gets clear title in 8–10 yr. About 1 000 houses have been financed thus; applicant has free choice of plans, under advice from Co's building inspector. PENSIONS, administered by 2 Co officials and chairman of co-op comm, are payable at age of 55 yr after 25-yr service, or at 60 yr after 15-yr service; rate, 1% of aver earnings during preceding 10 yr for each year of service; minimum pension, $240 per yr. APPRENTICESHIP system, primarily for sons of employees, starts with pay at 25% of base rate, increases every 6 mos, and reaches full scale in about 4 1/2 yr.

11. ARBITRATION AND CONCILIATION BOARDS

Conciliation Service of the Federal Department of Labor, established Mch 4, 1913, and still functioning as a separate Bureau, authorizes the Secretary of Labor to act as mediator in labor disputes, and to appoint conciliators. It attempts to adjust disputes in industries over which the Federal gov't has no mandatory jurisdiction; its jurisdiction is not exclusive. It intervenes only on request of either party to a dispute or of State authorities, and is confined to mediation and offering suggestions as to proper settlement. It is not a board of arbitration and can not force either party to confer with its agent.

State-sponsored arbitration. Channels for arbitration and settlement of labor disputes are provided by statute in all mining States except Calif and N M. Powers assigned to

authorized conciliation or mediation officers show considerable variation; arbitration is nowhere compulsory (though practically so in Minn), but an agreement to arbitrate is enforceable in Nev, N J, Utah, and Wis. In nearly all States, the designated mediatory officials have court-supported authority to make complete examinations, compel attendance of witnesses, and take sworn testimony. In Colo, Ill, Md, Mo, Wis, decisions of an arbitration tribunal are binding if parties previously agree thereto: in Penn, only upon agreement after the award. In Ill and Mont, an arbitrated decision is binding for only 6 mos or until revoked on 60 days' notice; in Nev, a decision binds for 3 mos, subject to 30 days' notice of withdrawal. Strikes, lockouts, or changes in working conditions subject to dispute, are expressly forbidden in Ala, Colo, Mich, Minn, Mont, and Nev, so long as arbitration is proceeding or about to begin; Ore does not recognize a jurisdictional quarrel between rival unions as a labor dispute subject to its Board of Conciliation. Following examples illustrate procedure in important mining States (65).

Colorado. (1935 stat, ch 97, sec 29–33). "Industrial Commission shall promote the voluntary arbitration and conciliation of labor disputes, and may appoint temporary arbitration boards, prescribe their rules, conduct hearings, and publish reports The Commission may subpoena witnesses and administer oaths. Its jurisdiction shall extend to all disputes between employer and employee and shall continue until entry of final award. Neither party to the dispute shall alter the conditions of employment until after final determination by the Commission. Findings of the Commission shall bind the parties only when they have, in writing, so agreed" (sec 133): "The Commission shall inquire into labor disputes and, if agreement is not reached, shall attempt to have the parties consent to arbitration by 3 arbitrators selected, 1 by employer, 1 by employees, and the third by these two or by the Industrial Commissioner. Findings by the arbitrators shall be final."

Montana. (Revised code of 1935, secs 3055–58). "The state board of arbitration and conciliation shall, on application of the employer, employing 20 or more, or the majority of the employees in the department in which the controversy arises, visit the dispute, hear all interested persons, advise the parties as to adjustment, and make a written decision which must be made public at once. The parties to the application must agree to continue in business without any strike or lockout until the decision of the board, if made within 4 weeks of the filing of the application. Any decision of the board shall be binding on the parties for 6 months, or until either party has given the other written notice of his intention not to be bound at the expiration of 60 days therefrom".

Nevada. (Compiled laws of 1929, secs 2763–69). "Whenever a labor dispute arises between an employer and his employees, threatening to interrupt the employer's business, the governor shall, on request of either party, attempt to settle the dispute by mediation and conciliation. If unsuccessful, he shall attempt to bring about an arbitration. If the parties consent thereto, an arbitration board of 3 members shall be selected, 1 by the employer, 1 by the labor organization of the employees, and the third by these two or the governor. The submission to arbitration shall contain a stipulation that the award shall be filed within 30 days from the appointment of the third arbitrator, during which time there shall be no change in the status of the parties, and the award shall be final, unless set aside for error of law. Employees dissatisfied with the award shall not withdraw therefrom before 3 months from the making thereof, without 30 days' written notice; nor shall employees be dismissed due to the employer's dissatisfaction before 3 months from the making of the award, without 30 days' written notice. The award shall be in force for 1 year." (Sec 510): "Written agreements to submit any controversy existing at the time of the contract to arbitration are valid and enforceable, and may not be revoked without consent of the other party to the agreement, except upon grounds existing in law or equity for the revocation of any contract."

Pennsylvania (1931 stat, title 43, ch 13, secs 691–701), provides that judges of the courts of common pleas shall, upon petition of 50 or more persons employed as workmen by 5 or more separate firms or persons, or at least by 5 employers, each employing at least 10, or by the representatives of a firm employing at least 75, authorize a tribunal for settlement of disputes between employers and employees in the iron, steel, glass, textile, and coal trades. If a suspension of work has occurred, or is probable, the judge shall hear testimony as to the representative character of the petitioners and may deny the authorization if it appears that the petitioners do not represent at least one-half of each party. Tribunal exists for 1 year. An umpire shall be chosen by the 2 employer and 2 employee representatives on the tribunal, and shall act only after 3 disagreements; his award shall be final as to matters submitted in writing and signed by the tribunal or by the parties, and on questions affecting the prices of labor. Award of the umpire shall only bind employers or employees as they agree after the award. Tribunal may administer oaths and sign subpoenas, and attorneys-at-law shall not appear before it. Award shall be made within 10 days of submission of dispute. Labor Mediation Act (No 177, of 1937) permits the Department of Labor and Industry to offer its services for conciliation of disputes, but failure or refusal of either party to submit to arbitration is not a violation of the Act, nor can it be used as basis for other action in law or equity.

Michigan. Public Act 176 (effective June 8, 1939) creates a labor mediation board of 3 members appointed by the governor, selected without regard to political affiliations, for term of 3 years; 2 members constitute a quorum, but all official orders require concurrence of a majority of the board. Sec 8: "It shall be lawful for employees to . . . form, join or assist in labor organization, to engage in lawful concerted activities for the purpose of collective negotiation . . . or to negotiate . . . collectively with their employers through representatives of their own free choice." Sec 9: "If a dispute arises, which the parties thereto are unable to settle, no strike or lockout shall be put

into effect, unless either party shall serve a notice upon the board of such dispute, with a statement of the issues involved. Sec 9a: "For a period of not less than 5 days after the above notice is served, or until the board undertakes the adjustment and settlement of the dispute (if within 5 days) it shall be the duty of both employees and employers to use their best efforts to avoid a cessation of employment or a change in the normal operation of the business, and during said period the parties shall undertake a mediation thereof. Violation of this section shall be a misdemeanor and punishable as such." Sec 10: "After the board has received the above notice, or upon its own motion, in an existing, imminent, or threatened labor dispute, the board may, and upon the direction of the governor, the board must take such steps as it may deem expedient to effect a voluntary, amicable and expeditious adjustment. To this end, it shall be the duty of the board: (*a*) to arrange for, hold, adjourn or reconvene a conference between the disputants; (*b*) to invite the disputants to attend such conference and submit the grievances; (*c*) to discuss such grievances; (*d*) to assist in negotiating and drafting agreements for the adjustment of such grievances and for termination or avoidance of the labor dispute. The board may designate one of its members to act in its behalf, with all the powers hereby conferred upon the board." Sec 11: "The board and each member (or designee) shall have power to subpoena witnesses and compel their attendance, administer oaths, and receive evidence. Subpoenas may be issued only after the mediation of a dispute shall have been actually undertaken. In case of contumacy or refusal to obey a subpoena, the circuit court of any county within the jurisdiction of which the inquiry is carried on, upon application of the board or commission, shall have jurisdiction to issue an order requiring such person to appear before the board or commission, to produce evidence or to give testimony. Failure to obey such order may be punished by the court as a contempt." Sec 12: No member or officer of the board having financial interest or membership in or affiliation with any labor organization in a trade in which a labor dispute exists, or is threatened, and of which the board has taken cognizance, shall be qualified to participate in the acts of the board in connection with settlement or avoidance thereof." Sec 15 declares sit-down strikes, however accomplished, to be misdemeanors punishable as such. Sec 17: It shall be unlawful (punishable as a misdemeanor) for any employee or other person to attempt to force any person to become or remain a member of a labor organisation, or to refrain from engaging in employment.

Minnesota. The Labor Relation Act (laws of 1939, chap 440) closely parallels that of Mich, except that, instead of a board of 3 members, the governor appoints a permanent labor conciliator, and may appoint other conciliators, all with powers like those in Mich; also, the period following the service of notice, during which strikes or lockouts are unlawful, is 10 instead of 5 days. Powers of the conciliators are upheld by district courts. Labor organizations, as well as employers, must file sworn statements giving names and addresses of their responsible officers.

Anthracite strike commission was appointed by President Theodore Roosevelt in Oct, 1902, when a strike in the anthracite districts, already in its fifth month, threatened to cause hardship to consumers during the winter. Operations were thereupon resumed, pending investigation by the commission, whose report (1), Mar 21, 1903, still retains historical interest as underlying many current labor practices in the anthracite field.

Anthracite conferences. Since expiration, in 1906, of Strike Commission's 3-yr award, wages and other details affecting labor have been adjusted at successive conferences between operators' committees and officials of the United Mine Workers, always the preponderating and now the exclusive bargaining agent of the workers. For accounts of the proceedings and their outcomes, see Bib (27, 28, 50, 75), also Edn 2 of this book, Art 11.

Conferences have been held at irregular intervals of 2–5 yr, and were often accompanied by suspensions of mining, sometimes lasting several months; no interruption occurred in 1936. WAGES of contract miners and their laborers were increased 10% by the 1903 award, another 10% in 1912, and an additional 7% in 1916. Successive increases during the World War increased the 1920 rate up to 65% above that of 1916; a further increase of 10% in 1923 fixed a rate since maintained by agreements in 1926, 1931, 1932, 1936, and June, 1939 (the latter to expire in 1941). No code for anthracite wages was adopted (minimum of $4.62 was proposed) during the life of N I R A. WORKING HOURS were reduced from 10 to 9 by 1903 award. to 8 hr in 1916, and to 7 hr in 1937. CHECK-OFF became obligatory (previously general) in 1936 agreement. SLIDING SCALE for wages (based on N Y price of white-ash coal), established by the 1903 award, was abolished in 1912.

Anthracite board of conciliation, created by fourth award of the 1902 strike commission, and still functioning, consists of 6 members, 3 being appointed by mine operators and 3 by any "organization representing a majority of the mine workers" in the 3 anthracite districts (Wyoming, Lehigh, Schuylkill). Full membership of the board is to be maintained, and either operators or workmen may change their representation on the board at any time when a controversy is not pending. Parties to a controversy may be represented by other persons at all hearings before the board. A decision by a majority of the board is final; if a majority is unable to agree, the board requests a U S circuit judge of the third circuit to appoint an umpire, whose decision is final. Suspension of work by strike or lockout, pending a decision by the board, is forbidden.

Board of conciliation, organized at Wilkes-Barre, June 25, 1903 (29), adopted following RULES OF PROCEDURE: (*a*) Aggrieved workman must first attempt to adjust dispute with mine foreman. (*b*) If unsuccessful, he must request interview with company's supt or mgr, for purpose of adjust-

ment. (*c*) If not satisfied with solution offered, workman may then submit his case to the 2 representatives of the conciliation board in that district, accompanied by proof that effort had been made to settle dispute with supt or mgr. (*d*) If supt or mgr has refused an interview within 10 days, the board or its two representatives in the district, will endeavor to secure an interview for aggrieved workman. (*e*) If dispute still remains unsettled, it comes formally before the full board, which then calls upon the operator to give his reasons for not offering an adjustment. Board may then request presence of both parties for a full hearing. (*f*) Grievance of operators against workmen can be submitted at once to board, through its representatives, the board then calling for explanation from the workmen, or requesting presence of both sides for a hearing. (*g*) Board will not consider a grievance of workmen unless they remain at work, with the understanding that awards by the board will be retroactive, dating from time dispute is first opened.

Grievance committee. In the 1912 anthracite agreement, it was stipulated that a committee of 3 employees might be elected by the workmen of each mine, with power to consider complaints which individual workmen had not been able to settle with mine foreman. It was made allowable for the miners' district representative on the conciliation board to confer with this committee. In case of failure of negotiations between committee and mine officials, complaints were then to follow prescribed course before full conciliation board (see above). It was supposed that the committee might add weight to the grievance of an individual workman, thereby increasing probability of a satisfactory interview with mine officials and diminishing the number of complaints to be carried before the full board, which was felt to be too remote and deliberate a body.

Bituminous interstate joint conference, for adjustment of wages and working conditions, was in sustained operation in the central competitive bituminous territory (Ohio, Ind, Ill, and Western Pa) from 1898 until Apr 1, 1927; after lapse of 6 yr, its functions were resumed, Sep 22, 1933, under protection of the N L R A, by a similar conference representing the Appalachian area, extending from central Pa to Ala (29, 75). The following conditions have become firmly established: (*a*) Privilege of workmen to organize and authority of union (U M W) to negotiate agreements on behalf of mine workers are recognized by employers. (*b*) Basing point is designated in each state, thus compensating operators in one state for natural advantages (distance to market, character of coal seams, etc) enjoyed by those in a more favored state. For example, the basic minimum rates for 8-hr work established in 1933 were (75): Northeast, \$4.60 (increased, 1937–39, to \$6 for 7 hr); south, \$4.20; midwest, \$4.575–\$5; southwest, \$3.75; northwest, \$4–\$5.63; deep south, \$3.40–\$3.84. (*c*) Ton of 2 000 lb is standard. (*d*) Run-of-mine basis of payment, formerly optional in some cases, has universally displaced the screened-coal basis since 1913. (*e*) Differentials are established between machine and pick mining, and between thick and thin coal seams. (*f*) Uniform working day of 8 hr, prevailing 1898–1933, was reduced in 1934 to 7 hr for all classes of mine employees.

Conferences are held in Mch every 2 years, at a previously selected city, and are attended by delegates from miners' unions (usually national and state officials of U M W) and by representatives of coal mine operators selected in any desired manner. Committee on credentials, rules, etc, comprise 2 members of each side from each state; scale committee includes an equal number of members from each side, but numbers vary for different districts; unanimous vote is required to adopt an agreement. Miners' demands, having usually been formulated at a shortly preceding annual convention of U M W, are presented in form of resolution, which customarily fails of unanimous acceptance. Resolution then goes to scale committee, where it is discussed seriatim; agreement is seldom reached on any clause, and being reopened in full conference, resolution is further debated and generally fails to pass. It is then referred to a sub-scale committee, the meetings of which are strictly secret. At this point, a counter-proposition is usually offered by the operators, and argument then ensues until a compromise is effected. Report of sub-scale committee is then approved by scale committee, and is finally adopted by the convention; it is then signed by 2 representatives of each side from each state.

Consistent TREND OF MINERS' DEMANDS has been towards: (*a*) Uniform scale of payment for coal in all states within a competitive territory. (*b*) Adoption of run-of-mine basis alone (finally effected in 1914). (*c*) Decrease of premium for pick-mining over machine mining. (*d*) Uniform wages for outside employees.

Bituminous state agreements (29) are in force in all states represented in the interstate conferences, and also in many others, nearly 100% of the coal-mining territory of the U S being governed, as to wages and working conditions, by formal contracts between operators and organized employees. State conventions follow the interstate conferences and are usually held prior to Apr 1; they are attended by officials of U M W and by delegates from the operators.

In those states in which a basing point has been designated by interstate conference, principal work of convention consists in establishing a system of COAL MINING RATES, ranging both above and below the basic rate, and so adjusted that miners in a given district (those who break down or produce coal) shall receive as nearly as practicable the same returns for a day's work. Factors involved in adjustment of rates are: (*A*) Pick *vs* machine mining; bonus in favor of former is intended to compensate for slower and more laborious nature of operation, but miners constantly

advocate raising the machine-mining rate, for 2 reasons: (a) To discourage use of machines and thereby add to number of miners employed. (b) Chain undercutters produce less slack coal than pick mining and thereby add to operator's profits, to a share of which the miners consider themselves entitled. (B) Thickness of seam; higher rate per ton for thin seams, to compensate for smaller tonnage per unit area undercut. OTHER SETTLEMENTS effected by state conventions relate to: (a) Prices for narrow work and room turning. (b) Wages of inside workmen other than miners; these wages are practically fixed on a uniform minimum basis by the interstate conference, and are accepted, usually unchanged, by state convention in that territory. (c) Wages of outside workmen. (d) Frequency of pay-days, and details as to issuing of wages, statements, etc. (e) Hours of labor; a 7-hr day is generally considered to mean 7 hr spent at working place, exclusive of lunch and traveling time. (f) Provisions for timbering working places, disposal of mine refuse, removal of waste from loaded coal, etc. (g) Loading and firing of shots; generally stipulated that practice must follow legal requirements of the state. (h) Disciplining of miners for sending out inferior coal, for ignoring or disobeying rules, for absenting themselves on working days, etc; in this connection, the Union usually promises its support and cooperation in enforcement of discipline. (i) Procedure for settlement of disputes; this is closely analogous to the present practice in the anthracite fields (see Conciliation Board, and Grievance Committee, above), except that final resort is to a conference between officials of the company and state officials of the U M W. (j) "Check-off" system, withholding Union dues or fines from a workman's wages, is generally accepted by the operators in states where agreements are in force. (k) Prices and quality of powder, oil, tool sharpening, etc.

WELFARE

12. WASH AND CHANGE HOUSES

Change houses, usually provided with bathing facilities, have become a recognized necessity at all mines employing more than a few men. Some companies have hesitated to incur expense of such building, through apprehension that its privileges would be abused or unappreciated; statistics covering several thousand miners provided with such facilities indicate that 85% use the wash house regularly. Use of change and wash house is commonly offered gratis, but one company found that the levying of a small charge, 50¢ per mo, induced better appreciation of the benefits afforded.

Structural and operating details (30, 66). In designing a composite change and wash house, following points deserve consideration: (a) Should be situated as closely as convenient to mine opening; in a cold climate, a tunnel or covered passageway from top of shaft is advisable. (b) Structure must be fireproof, commonly of brick, tile, concrete, or sheet steel on wood frame. (c) Floor space, of changing room only, should be 15 to 20 sq ft per man to be accommodated. (d) Floor and inside walls free from obstructions, the former preferably of concrete sloping 0.25 in per ft towards drain, so that entire interior can be washed with hose. (e) If lockers are used, they should be not less than 12 by 16 in by 3 to 5 ft high, of open metal construction and provided with combination instead of key locks; tops should slope steeply, for ease of cleaning, and to prevent piling rubbish on them. (f) Drying racks standing on floor, or hooks and lines suspended from pulleys spaced 30 in apart in ceiling, are recommended for hanging mine clothes, but should not be used for street clothes; if lockers are used for mine clothes, advisable to give every man 2 lockers. At Noranda, Quebec (66), wire-netted lockers for mine clothes are partly depressed below dressing floor, their hinged and locked wooden-covered tops serving as seats between rows of street-clothes lockers; forced ventilation passes down through these lockers into ducts on lower floor. (g) Ample heat must be provided for drying mine clothes; usually in steam coils running underneath lockers or drying racks. (h) Adequate ventilation is essential because odors and dust are abnormally oppressive; natural ventilation through cupolas is usually sufficient, but artificial and automatically controlled ventilation has been installed in some modern dry-houses; in latter case, it is advisable to admit warm air at ceiling and exhaust through floor, to avoid raising of dust. In the Eureka change house (Fig 1) 8 000 cu ft of fresh air per min displaces entire volume of "dirty" side in 3 min. (i) Desirable for wash room to be separated from change room, preferably by a short passageway having spring door at each end. Some recent change houses are divided by a longit wall into "clean" and "dirty" sides (Fig 1), communicating only through shower rooms; men in mine clothes not permitted on the "clean" side (19). (j) Shower baths most advantageous, but wash basins should also be provided; tubs and swimming pools are unhygienic in this connection; 1 shower booth, 4 by 5 ft, for every 20 lockers is considered adequate if men do not all use wash house at same time. Where a large number of men come off shift at once, as at McIntyre Porcupine mine, Ont, congestion can be avoided by installing continuous sprays in a long, narrow passageway, starting with warm water at one end and finishing with a cold dash at the other; before entering here, men have

opportunity for soaping and scrubbing in a larger space, also supplied with warm water (20). (*k*) About 40 gal water per bath should be provided, but can be reduced by careful supervision; if hot and cold water are separately brought to the booths, pipes should be of ample size to avoid fluctuation in temp when an adjoining bath is opened or closed; mixers for

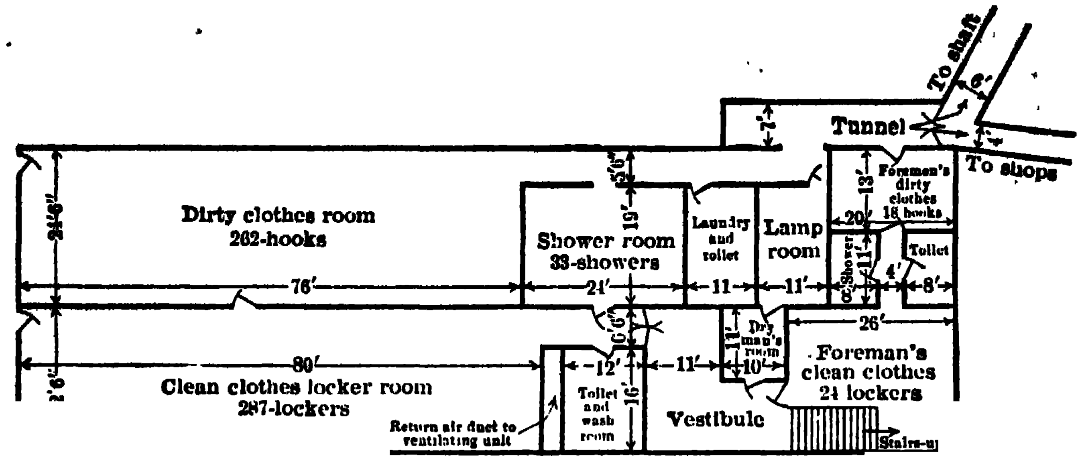

Fig 1. Plan of Eureka Mine Change House, Ramsay, Mich (not to scale)

hot and cold water should be carefully designed; Fig 2 shows one such installation. (*l*) A capable attendant, constantly on duty, will readily justify his wages. TOILETS, specifications for, see Art 15.

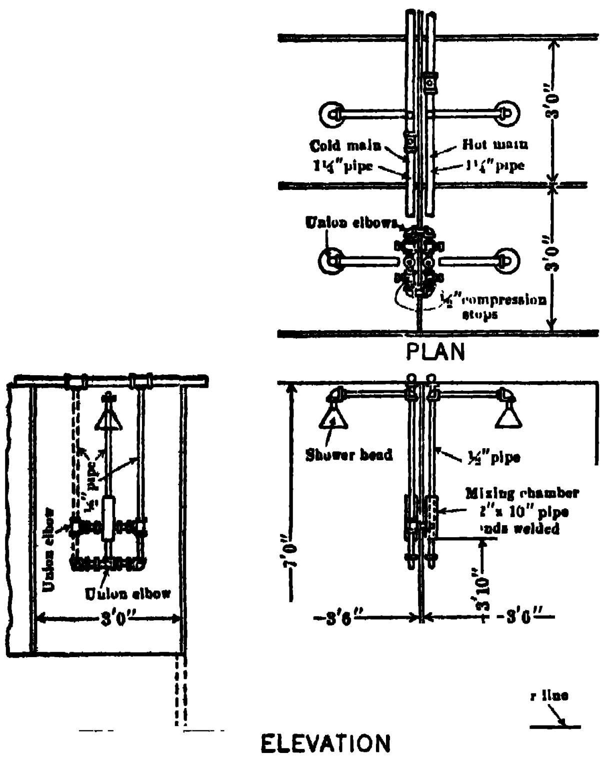

Fig 2. Fittings for Shower Bath, Tenn C, I & RR Co

Detection of "high-grading." Stealing of rich ore by miners has been a notorious source of loss at Bendigo, Kalgoorlie, Kimberley, Cripple Creek, Cobalt, Goldfield, and elsewhere; rich ore is brought out, a few lb at a time, in clothing and dinner pails, among other schemes, and is sold to illegitimate assayers or to prospectors who may operate a small worthless mine simply as a blind. Courts and statutes have proved incapable of stopping this practice. Only practicable method is to require all miners to change clothes as they come off duty, preferably keeping mine clothes in one room and street clothes in another. This procedure has been strenuously opposed by organised labor, and led to a strike at GOLDFIELD in 1907. A compromise was there effected on following basis: Each miner was allotted 2 adjoining lockers; coming from mine, working clothes were removed and placed in one locker; other locker was then opened and street clothes put on; company's time-keeper and other designated watchers allowed to be present, but no strangers. At McIntyre Porcupine mine, Ont, a miner coming off-shift puts his lunch box on a belt conveyer passing through inspection room, and recovers it on leaving the change house (20).

13. MINE COMMUNITIES AND MINERS' DWELLINGS

Advantage of judicious planning of a mining community, to promote healthfulness, cheerfulness, and convenience, is as important from the financial as from the sociologic point of view; a healthy and contented population is both more efficient and less transient. TOWN SITUATED NEAR MINE OPENING has following advantages (31). Shorter distance to walk, entailing less loss of energy in going to work, a serious factor in many mountain dis-

tricts, and less exposure in wet clothes after work, in absence of change house. Having homes, stores, and pay-office nearby is convenient for housekeepers. Responsible officials are within easier reach at all times. Where mining company owns the townsite, proximity to mine plant permits some economies in cost of haulage, lighting, heating, and fire protection. TOWNSITE AT DISTANCE FROM MINE can usually be selected with better regard to economy in construction as well as desirability of situation. Wider spacing of houses pro-

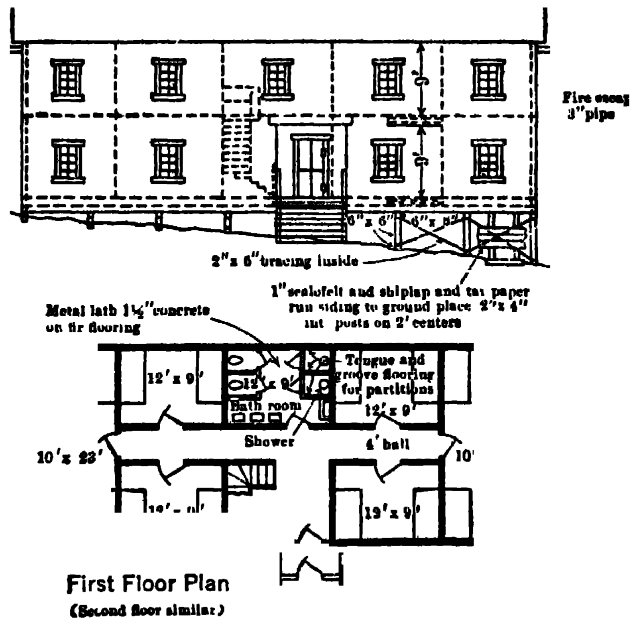

Fig 3. Two-story Bunk House, Flin Flon, Manitoba (67)

motes health and reduces fire risk. Gentle slopes reduce cost of grading streets and erecting houses. Absence of noise, smoke, and dirt is genuine asset. Permissible distance from mine depends upon facilities for conveyance; electric cars in many districts have greatly enlarged the radius of daily travel; some mines operate work trains, and some steam railroads run special cars at reduced fare for mine workmen.

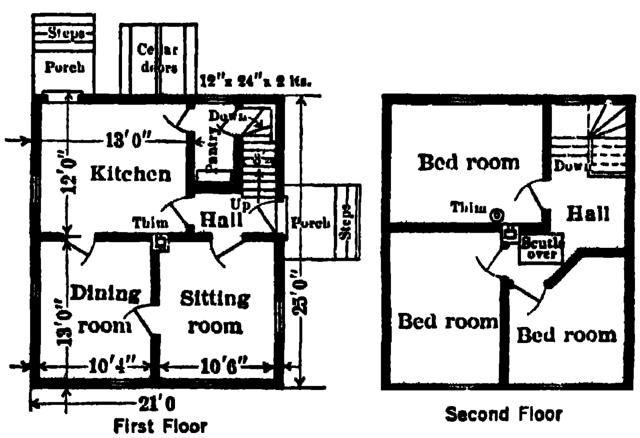

Fig 4. Six-room House, Trimountain Mine, Mich

In locating a new townsite, the following features deserve attention, though all may not be practicable. (*a*) Accurate contour map is indispensable for efficient planning. (*b*) Principal thoroughfares should be approx parallel to contours, involving less expense for grading, bridging, sewers, and surface drainage. (*c*) Narrow but well surfaced street, with gutters and sidewalks, is more suitable for requirements of an ordinary mine town than wide street in poor condition. (*d*) Trapezoidal house lots, fronting on a diagonal street, afford better air and light to each house than rectangular lots with houses all at same distance from street. (*e*) Deep, narrow lot involves less expense for street improvements and permits better utilization of land than a wide shallow lot of same area. (*f*) On closely spaced, deep lots, houses should not all be at same distance from

street; 2-story houses should be farther back than single-story. It is desirable to alternate single and 2-story houses. (g) Houses on both sides of a narrow street should not be directly opposite one another. (h) Along a contour street on a hillside, 2-story houses should be placed on down-hill side and should be as narrow, from front to back, as convenient. Lots on down-hill side may be graded up to level of street, by setting retaining wall under front of house instead of at front of lot. (i) Houses on steeply sloping lots are always expensive and usually inconvenient. Steps and verandas of hillside houses should be at ends rather than at front or back.

Principles of design. A company should have a number of different house plans for: variety of appearance, better utilization of land, diversity in rental. Number of houses of each size can be estimated by investigating size of families in neighborhood. Most work-

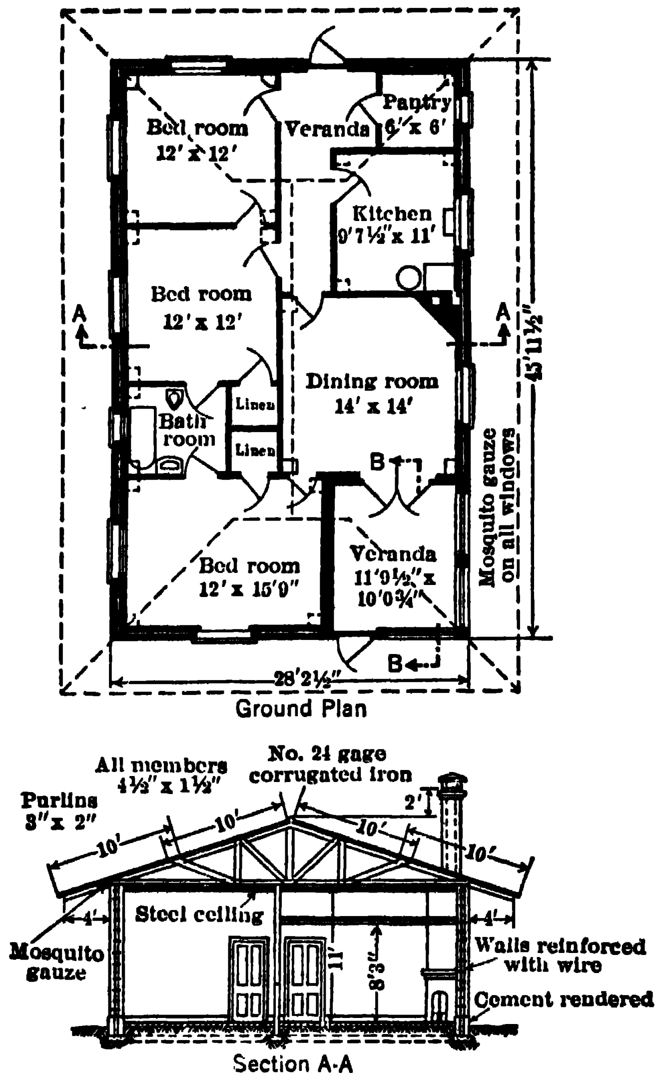

Fig 5. Five-room Brick House, Roan Antelope Mine, Luanshya, Nor Rhodesia (67)

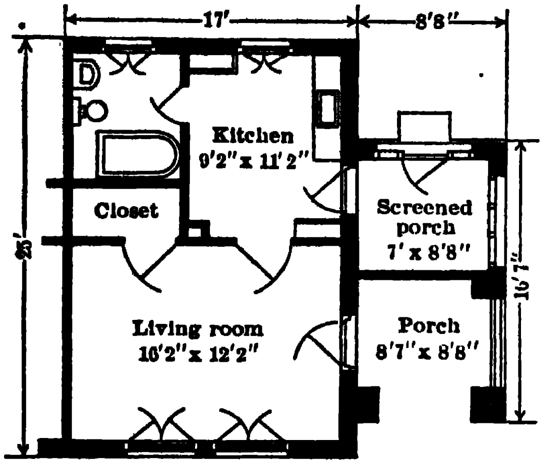
men's houses are too small; probably 40% of foreign workmen in U S use all but 2 rooms of house for sleeping. Kitchen, being most important room in workman's home, should be larger than commonly accepted, and situated on pleasantest (south or east) side of house. Houses of more than 4 or 5 rooms should be of 2 stories, to reduce area of roof and foundation and permit better lighting.

Materials of construction. WOODEN FRAME houses have following advantages: (a) variety in design more easily attained; (b) more readily enlarged; (c) more cheaply constructed; (d) better decorative effects. Certain lumber firms specialize in lumber ready out for erection according to standard patterns, economizing in carpentry and waste. POURED CONCRETE, now widely used (notable examples, Gary, Indiana, and "Concrete City," at Truesdale mine, near Nanticoke, Pa), has advantages of being durable, fireproof, weatherproof and relatively vermin proof. Unless precaution is taken to leave air space in walls, they are likely to condense moisture. MOULDED CONCRETE BLOCKS can often be made cheaply from mill tailings. Variety of appearance attained

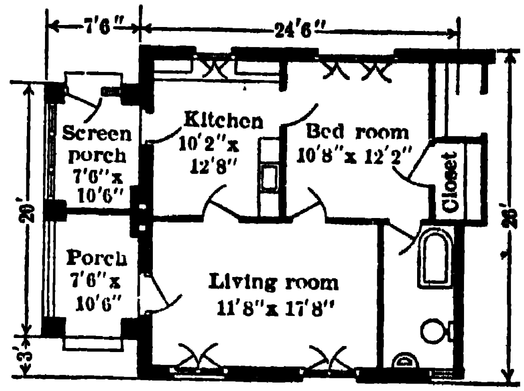
by facing mould with tailings of different coarseness. BRICK AND HOLLOW TILE are excellent for better class of houses, if cheaply obtainable.

Owing to great variety of equally desirable plans, it is not practicable to include here details of either design or construction; see Bib (32, 67, 69).

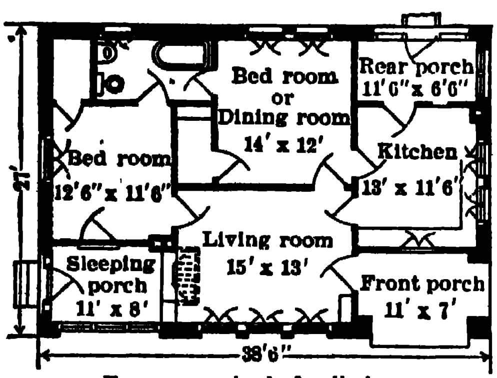
Cost of erection. Table 5; for more complete specifications on these examples, and on several others for which costs are not given, see Bib (67).



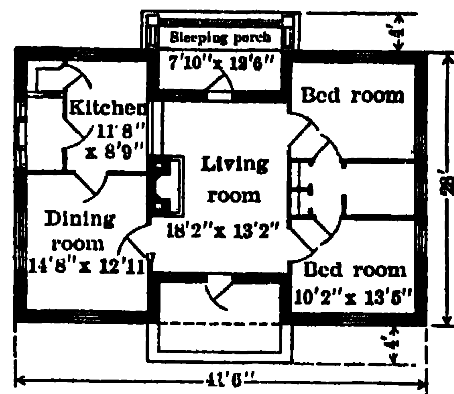
Half of double house having two two-room apartments



Half of double house having two three-room apartments



Four-room single-family house



Five-room one-family house

Fig 6. One-floor Houses, Phelps Dodge Corp, Tyrone, N M (67)

Keast and Jackson (68) give data in Table 6 on preliminary CAMP STRUCTURES erected in Feb and Mar, 1930, to accommodate 60 men developing the Central Patricia claims in northern Ontario; lumber was sawn on the property but all other supplies were hauled 100 miles by tractor and sleds; all buildings framed with 2" × 4" studs, sills, and joists, and covered with a good grade of roofing.

Housing in cold climates. Following observations by Clement and Govan (69) are based on experience in northern Ontario. Benefits anticipated from wall and roof insulation may be largely nullified by poor, leaky construction around doors and windows. As defined here, thermal "resistance" is the time, hr, required for 1 btu to pass through 1 sq ft of wall area when temps on opposite sides differ by 1° F. Resistance of good commercial insulators is 2.5–4 hr per in of thickness, or 10–12 hr for customary 3 to 4-in thickness. Resistances of some common, uninsulated walls (Am Soc Heating and Ventil Engrs) are as in Table 7. Addition of 1 layer of thin-board insulation to such walls decreases heat losses by 20–25%; but, as, in such houses, fuel consumed to supply heat losses through walls and roof is about 60% of total consumption, actual saving by such insulation is only 12–15% in fuel. By more suitable and readily available insulators, properly applied, savings of 50–70% in heat losses are economically possible, reducing fuel consumption by 30–40% or more. As fire retarders, the loose varieties of mineral insulator are worthless.

Table 5. Cost of Erecting Mine Dwellings. Data from A. H. Hubbell (67)

Locality and date	Ground area, ft	Rooms (a)	Cost: Per sq ft	Cost: Per cu ft	Specifications
Luanshya, No Rhodesia	46 × 28	5	$3.40	......	No cellar; walls local brick; floors concrete; inside walls plastered brick; ceilings pressed steel; Oregon pine joists; roof corrug galv iron.
Achotla, Guer, Mex	45 × 28	4	1.60	......	No cellar; stone foundations; adobe walls; concrete floor; tile roof.
Monterrey, Mex	43 1/2 × 31	5	1.60 (b)	......	No cellar; stone foundation; outside walls slag-brick; inside, hollow brick; double wood floors; ceiling beaver board; roof 3-ply asphalt.
Matahambre, Cuba	28 × 30	4	3.57	......	Hardwood posts and sills; pine studs and floor; sides 24-gage iron; partitions battened boards.
	29 × 44	10 (2 fam)	1.20	......	
	80 1/2 × 38	20 (bunkh)	0.73	......	
Pecos, NM (c) 1925–1926	26 × 12	2	1.66	......	Mud sills; double wood floors; 2″ × 4″ studs; walls sheathed and covered with Slate Cote roofing; partitions wallboard on 2×4 studs; ceilings same on 3 × 4 joists; brick chimney single thick; elec wiring; all screened.
	34 1/2 × 14	3	2.13	......	
do	96 × 56	5	0.80	......	
do	48 1/2 × 22 1/2	8 (bunkh)	1.56	......	
Tyrone, N M, 1915–16 For Americans	34 × 25	4 (2 fam)	3.15	......	Small cellar; concrete foundations; walls 8-in hollow tile stuccoed outside; wood studding, metal lath and plaster inside; flat roof with 3-ply asbestos; plumbing and elec fixtures; porches screened.
	49 × 26	6 (2 fam)	2.86	......	
	41 1/2 × 28	5	2.90	......	
	38 1/2 × 27	4	2.45	......	
Tyrone For Mexicans	27 × 24	3	1.76	......	About same, except no cellar; floors wood or cement
	31 × 24	4 (2 fam)	1.84	......	
FlinFlon, Manit	58 × 24 (2 stories)	12 (bunkh)	5.75	$0.32	No cellars; framed with BC fir; walls shiplap outside 2″ × 4″ studs, roofing material inside, and space filled with Insulex; roof asbestos on BC fir boards over Celotex; plumbing and elec fixtures.
do	28 × 23	3	5.75	0.64	
do	36 × 28	5	5.15	0.57	
Chuquicamata, Chile, 1925	112 × 35	18 (bunkh)	2.84	0.28	No cellars; concrete foundations; frame Douglas fir; outside wall metal lath and cement stucco; inside walls and ceilings sheet iron; roofs corrug iron; water and elec fixtures in all but the 3-room apts.
	433 sq ft	3 (d)	2.35	0.24	
do	26 1/2 × 23	4 (e)	4.46	0.44	
do	125 × 32	20	5.00	0.56	
do	43 1/2 × 30	7	5.30	0.49	
Copperton, Utah 1926–30	46 1/2 × 30	5	4.00	0.63	Full basements; walls brick, or stucco on hollow tile; metal work copper or brass; Flintkote copper-clad shingles; hot-air furnaces; water and elec fixtures .
	35 1/2 × 28	4	5.10	0.64	
do 1929	48 × 24	8 (bunkh)	3.00	0.39	
Ruth, Nev, 1924	96 × 29	12 (bunkh)	1.22	......	Frame; 2″ × 4″ studs, 2″ × 6″ joists; inside walls compo board; wood floors; water, elec, and steam heat.
1929	33 × 27	4	2.80	......	
Conda, Idaho, About 1927	32 × 20	4	2.81	......	Concrete foundations; frame Douglas fir; roof and siding pine or cedar; shingles copper-clad compo; inside walls gypsum board or plaster; water, elec, sewage fixtures.
Arvida, Quebec, 1926	26 × 20	6 (f)	9.00	0.37	Full concrete basements; frame BC fir; cedar siding; asbestos or aluminum shingles; floors fir or birch; inside walls plaster board and plaster, painted; water, and elec fixtures; roof and outside walls thoroughly insulated. Variations in cost due principally to inside trim and heating equipment.
do	26 × 26	6 (f)	8.58	0.31	
do	25 × 20	6 (f)	10.00	0.42	
do	36 × 30 1/2	9 (g)	12.75	0.48	
do	26 × 24	6 (f)	16.00	0.49	

(a) Excl bathrooms, closets, and porches. (b) At 1 [illegible] 50¢. (c) Inexpensive construction for expected short life. (d) In blocks of 9 apartments, one of which has 4 rooms. (e) In blocks of 6 apartments. (f) On 2 floors. (g) On 3 floors.

Table 6. Camp Buildings at Central Patricia, Ont.

	Floor area, ft	Cost Total	Cost Per sq ft		Floor area, ft	Cost Total	Cost Per sq ft
Bunkhouse 1	18 × 20	$218	$0.60	Residence	24 × 24	766	1.33

Hollow-concrete block, 1/2-in plaster on furred wood lath	5.0 "
Brick veneer on wood frame, wood lath and plaster	4.6 "

Type of small house most economical to build and maintain in cold climates has 1 1/2 stories, without dormers or other breaks in roof; objection to stairs can be largely overcome by putting bathroom on first floor. Cost of such houses in northern Canada (1928), complete with plumbing and electric fixtures, was: for 4 rooms and bath, $1 600–2 200; 4–6 rooms and bath, better finished, $2 600–3 200. Largest saving in cost is by omitting cellars or making them less than full size; foundations may be concrete piers or creosoted cedar posts, latter surrounded, within their pits, by broken rock or coarse cinders. Floor, well insulated, is high enough above ground to permit free access beneath; wooden side walls are carried to ground. For interior partitions, Clement and Govan prefer 3/8-in mineral wall-board to lath and plaster, because of its superior rigidity; the interior bracing afforded by such partitions may permit omission of outside sheathing. For wall and roof insulation, same authorities recommend a gypsum product, containing ingredients which, when wetted, evolve bubbles; the mixture is poured wet, solidifies in about 30 min to a porous mass weighing (when dry) about 8 lb per cu ft, but requires 3–4 mos for thorough drying. Successful use of this poured insulator may involve slight modifications in design of wall-plates, door and window frames, to insure complete filling between studs or joists. With any form of insulation, it is specially important to avoid air pockets on the cold side, where moisture may condense.

Above ideas governed erection of bunkhouse and cottages at a mine 475 miles north of Toronto. In both designs, 2″ × 3″ studs replaced usual 2 × 4's, and 2″ × 4″ joists replaced 2 × 6's. Inside walls and partitions of 3/8-in gypsum board; outside walls ship-lapped only (no sheathing). Wet-poured Insulex was 2.75 in thick in outer walls of cottages and partitions of bunkhouse; 3.75 in thick in outer walls and 4 in under flat roof of bunkhouse. COTTAGES, 1 1/2 story, with 6 rooms, storage room, and bathroom, cost $3 000 (wages of carpenters and electricians, 72¢ per hr; other labor, 53¢ per hr; lumber, $36–44 per M). A single stove or heater in living room kept whole house (9 100 cu ft) comfortable (outside temp sometimes −42° F), with 1/3 to 1/2 the fuel consumed in neighboring non-insulated houses of same size. Two-story BUNKHOUSE, 103.5 × 27.25 ft, with 8-ft ceilings, accommodating 50 men in 32 bedrooms, 2 common rooms, and 2 bathrooms, cost $12 000. All heat for bedrooms came through doors or transoms from longit central halls (1 on each floor) having combined radiator area of 660 sq ft. For plans and some structural details, see Bib (69).

14. PURIFICATION OF DOMESTIC WATER SUPPLY

Impurities in domestic water (33) are not all equally objectionable; probably many supplies which are physiologically wholesome, or could easily be made so, are rejected for purely æsthetic reasons. Most objectionable features are turbidity, color, taste, odor, and pathogenic bacteria; ordinary hardness is objectionable for laundry and boiler supply, but not hygienically. TURBIDITY, most noticeable in river water, can be removed by storage, coagulation, or filtration. COLOR is characteristic on water-sheds comprising swamp areas; produced also by decomposition of vegetable matter in bed of reservoir and by growth of algæ on water surface; seldom deleterious, but may become obnoxious at time of spring and autumn "overturn," when bottom layer of water, highly charged with organic extracts, mixes with whole body of water in reservoir. Color may be partly corrected by filtration, and entirely eliminated by chemical means. TASTE results from same causes as color and also from presence of iron in excess of 1 part per million; iron can be removed by aeration followed by filtration. ODORS arise from same causes as color, and from presence of sewage and industrial wastes; they can be corrected by storage, aeration,

or chemical methods; except for its offensiveness, water having tastes and odors may produce only negligible physiological effects. HARDNESS is known as "temporary," calcium or magnesium carbonate held in solution by presence of CO_2, and precipitated when latter is eliminated by boiling or by addition of quick-lime; and "permanent," mainly sulphates and chlorides of calcium and magnesium, requiring more elaborate chemical processes for their removal.

Contamination by sewage, from hygienic standpoint, is not necessarily objectionable of itself, but possibility is always present that domestic sewage may contain pathogenic germs, notably those of typhoid fever and cholera. These germs, when carried by water, are less tenacious of vitality than BACILLUS COLI, which is always present in enormous quantities in human intestines and in those of some animals; hence, substantial absence of bac coli is considered a sure indication that no pathogenic germs are present. Presence of CHLORINE, beyond that normally contained in domestic water near seashore or salt-bearing springs or strata, is strong presumptive evidence of contamination by sewage. NITROGEN in various compounds may result from vegetable decomposition, but is generally considered proof of sewage pollution, and the nature of its combination indicates the probable length of time elapsing since introduction of sewage; the probable virulence of pathogenic germs can then be deduced. Stages in decomposition of organic matter are: albuminoid ammonia, free ammonia, nitrites, nitrates. Hence, a high proportion of albuminoid ammonia in a colorless water indicates recent pollution; high nitrites, free ammonia, and chlorine occurring together are strong evidence of continuous pollution by sewage. Following figures, in parts per 100 000 (Mass State Board of Health, 1913) show difference between pure and polluted water:

Potable and Polluted Waters of Massachusetts

	Ammonia		Nitrogen as		Chlorine
	Album	Free	Nitrite	Nitrate	
Boston, surface origin	0.0145	0.0015	0.0000	0.0062	0.35
Springfield, surface, filtered	0.0080	0.0009	0.0000	0.0039	0.15
Lowell, tubular wells	0.0064	0.0377	0.0001	0.0162	0.38
Blackstone river, at Worcester	0.1286	0.9320	0.0084	0.0158	4.49
Hoosic river, below North Adams	0.0489	0.0638	0.0024	0.0053	0.88
Merrimac river, above Lawrence	0.0224	0.0245	0.0007	0.0167	0.57

Interpretation of nitrogen determinations should be made by a sanitary chemist, and cover a considerable length of time; remember that principal purpose of these determinations is to indicate probability of presence of pathogenic germs.

Total number of BACTERIA is determined by microscopic count in 1-cc sample, careful note being made of the number of times bac coli is observed in a series of such samples. Bac coli may appear in 1 cc as often as once in 20 times (Cincinnati, 1912) without arousing apprehension of typhoid, but the possibility of typhoid and cholera germs in polluted water must always be considered. In 1912, N Y water supply showed bac coli once in every ten samples (1 cc) but death rate from typhoid was 10 per 100 000; at Baltimore, same year, bac coli was found once in every 100 samples, typhoid death rate being 22. Bacteria, both pathogenic and harmless, can be nearly eliminated by storage and filtration, and completely devitalized by ozone or hypochlorites.

Storage serves 2 purposes: (*a*) equalization of supply; (*b*) purification. For discussion of storage requirements under different conditions of rainfall, run-off, and consumption, see Sec 38; also Bib (34).

Opinions differ as to necessity for stripping all vegetable mould from bed of a reservoir under construction, but this precaution probably diminishes opportunity for color and odor. Reservoir should preferably be narrow and deep, rather than wide and shallow, so that fluctuation in water level between spring and autumn will expose less area for growth of weeds. Supply from reservoir should be drawn from just below surface; if excess water can be wasted, it should be from bottom.

Purification by simple storage is effected by: (*a*) giving sediment (either natural or produced by coagulant) an opportunity to settle, taking majority of bacteria with it; (*b*) diminishing bacterial life by action of sunlight and air (bacteria can be almost completely devitalized by storage in open reservoirs for 48 hr); (*c*) expelling odors by action of wind, and color by action of sunlight.

Growth of ALGÆ is a drawback to extended storage, although its effect is limited to non-deleterious production of color and odor; algæ can be prevented by treatment with $CuSO_4$ (1 part in 4 to 10 million parts of water), or, in case of small reservoirs, by covering with light-proof roof. For recognition of the varieties of microscopic organisms causing tastes or odors, the proportions of $CuSO_4$ required to suppress them, and methods for applying it, see Bib (70). Simple but effective method for reservoirs is to tow from a boat a burlap bag containing $CuSO_4$ crystals.

Aeration, accomplished by fountains, cascades, or flowing over dam, is useful for expelling odors; also, when followed by filtration, for removing iron.

Coagulation is a valuable help for curing turbidity and diminishing bacteria, when followed by storage or filtration. Coagulant commonly used is alum, 1 gr per gal, added to stream of water entering first storage reservoir. Coagulating reaction of alum requires presence of lime, which must be added if not originally present in the water.

Temporary hardness (35) can be reduced by addition of slaked lime in quantity sufficient to neutralize the CO_2, which holds $CaCO_3$ and $MgCO_3$ in solution (say 1 lb per 1 000 gal water of 10 B hardness). Water which is both turbid and hard, requiring an excessive amount of alum, can be more cheaply clarified and softened by lime.

Filtering (36), when properly conducted, will remove all turbidity, practically all bacteria, but less than one-half of color. Two general methods are: (*a*) slow sand filtration; (*b*) pressure or mechanical filtration.

Sand filters. Construction: a shallow reservoir, with water-tight sides and bottom, is made of clay, or more advantageously of concrete, sloping towards one corner. Area may vary from 10 000 to 40 000 sq ft; small bed requires more frequent cleaning, but can be more cheaply protected against freezing; advisable to build at least 2 beds, for alternate cleaning. Radiating system of tiles with open joints is laid down, leading to discharge point. Tiles are next covered by 6-in layer of coarsely broken stone; 5 successive 2-in layers of crushed and screened stone or gravel, of diminishing coarseness, are then placed, surmounted by a layer 30 to 40 in deep of sand. Best sand for upper layer is of clean, sharp quartz, 0.3 to 0.4 mm diam, and of nearly uniform size. Water to be filtered is allowed to fill reservoir to depth necessary to cause percolation at the desired rate of flow, say, 4 in per hr descending velocity; the slower the percolation, the more complete the removal of bacteria. When upper layer of sand becomes clogged, its surface is scraped and removed to depth of 1 or 2 in; when thickness of sand remaining is reduced to 12 or 16 in, fresh sand may be added or the removed portions may be washed hydraulically and returned to bed. Clogging of sand filter increases in proportion to amount of turbidity to be removed and with excess of algæ; in extreme cases, it is desirable to apply preliminary sedimentation, coarse filtration, or coagulation.

Mechanical filters are more commonly used after preliminary treatment just mentioned. By admitting water under pressure up to 10 to 12 lb per sq in, percolation is much more rapid, up to 150 in descending veloc per hr, and, if properly controlled, is no less efficient. Installation of mechanical filters should be supervised by specialist in hydraulic engineering, and their operation must be continuously under careful control.

Disinfection (37) is most advantageously applied to water which has previously been clarified by sedimentation, coagulation, or filtration, for purpose of additional security against pathogenic bacteria.

Liquefied chlorine has almost completely replaced other means for chlorination of public water supplies in U S (51) at about 6 000 plants treating water supplied to 70% of the country's population, at cost estimated at 1¢ per capita per year.

Liquefied chlorine costs (1939) 5.25¢ per lb, or 7¢–21¢ per million gal treated. Annual cost for repairs and maintenance of chlorinating equipment in 36 large cities (1924) was 3.6% of investment; at 71 smaller units, 7.6%. A small public-works chlorination plant costs about $1 000, and still smaller and cheaper units for domestic or transient use are on the market. Most waters, even after aeration and filtering, contain organic or mineral matter the oxidation of which consumes chlorine, the reaction being 90% complete within 10 min at 20° C; this "chlorine absorbed" or "chlorine demand" must first be satisfied before bacteria can be effectively attacked, but the additional quantity of chlorine required for the latter purpose is relatively small. Chlorine is usually added in such amount that rarely more than 0.2 part per million of water is present 10 min after the application. Odors and tastes in disinfected water are probably due to chlorinated organic compounds, and can be avoided by increasing the dose of chlorine to, say, 0.3 part per million of water, tested after 10 min.

Other chlorination methods (51). ELECTROLYTIC CHLORINE, obtained by electrolysis of sodium chloride, has displaced liquefied chlorine in some localities favored by cheap salt and low power costs. CHLORIDE OF LIME (bleaching powder), averaging 30% available chlorine, is now mainly confined to small and isolated plants. The powder is first emulsified in water, kept in agitation, and fed automatically into the stream of water to be treated. Chlorine supplied in this manner is just as effective as liquefied chlorine, but the unavoidable addition of lime may sometimes be objectionable. CHLORAMINE is prepared by mixing ammonia water with bleaching-powder solution, in proportion of 1 lb free NH_3 to 3–4 lb free Cl; or NH_3 and Cl_2, both in gaseous form, may be injected separately (NH_3 first) into water headers. Addition of NH_3 permits more effective application of chlorine, with less danger of producing tastes and odors resulting from chlorination of organic compounds. SODIUM HYPOCHLORITE is convenient for sterilizing water on a small scale, as in camps, fresh-water steamboats, etc.

For domestic and camp service, a useful device (38) is a water-tight canvas bag, 20 in diam by 28 in deep, having loops at top for suspension and one or more nickeled faucets at bottom. Chloride of lime is put up in sealed glass tubes holding 14 to 16 gr each (30 to 32% free chlorine). One tube will kill all pathogenic germs in 300 lb of water in 30 min, and water is safe to drink in 10 to 15 min.

Desirable to filter water through a cloth before treatment. A neutral or slightly acid water is more rapidly and completely sterilized by chlorine than an alkaline water.

Activated carbon (71) is an efficient adsorber of impurities giving rise to tastes and odors. It is most often applied in powdered form, either wet or dry, requiring special equipment due to lightness of the carbon and its resistance to wetting. When applied to an open reservoir, preferably within a day following a $CuSO_4$ treatment, service should be interrupted for 24–48 hr while the carbon is settling. When used in connection with filters, carbon may be added: (a) after coagulation; best where required treatment is slight or of infrequent occurrence; (b) before coagulation, giving the carbon more time to operate; desirable where raw water is high in organic matter, and occurrence of taste or odor is frequent or continuous. Proportion of carbon consumed varies widely; aver about 2 parts per million, or 16 lb per million gal. Granular carbon, supported on sand and gravel within a pressure filter, is convenient at small water systems for removing last traces of taste and odor from previously filtered water.

Boiling is last resort to insure sterility of drinking water. All pathogenic germs are killed by boiling 5 min; some sporiferous vegetable germs require higher temp, but it is not certain that they are dangerous. Taste of boiled water is improved by aeration.

Distilled water, though safe pathogenically, is physiologically unwholesome for continuous use. A still can readily be improvised by a tinsmith from copper pipes and pans, preferably tinned on surfaces which come in contact with water (39). Evaporator can be heated by live steam.

15. SANITATION

Wastes requiring disposal are: garbage and domestic refuse, excreta, wash water. Under favorable conditions, such as: porous gravelly soil, sloping topography, small opportunity for stagnation of water, not too dense population, cool, dry climate, and water supply obtained under reasonable precautions against contamination, no serious difficulty is likely to arise from following well known and archaic methods. In absence of any of these conditions, disposal demands attention, and may become an engineering problem of importance.

Garbage should be placed in covered and water-tight pails, and collected at least once a week in covered wagons. It may then be buried in trenches, burned on surface, at distance from town, or incinerated. Usually, enough inflammable waste is available to provide fuel for latter purpose. Descent of garbage into hearth of incinerator must be retarded by baffle rods, giving it a chance to dry partly. Bib (66) shows a well designed incinerator.

Excreta. Only 2 methods of disposal should be tolerated in a settled community: dry closets, or a system of sewerage, individual or communal. Latter system is expensive to install but cheap in operation. In many mining camps a communal sewerage system is impracticable, because: (a) water supply may be inadequate for flushing; (b) extra liability of ground to settle makes difficult the maintenance of both water mains and sewers; (c) ignorance of many classes of workmen induces expensive repairs.

Dry-closet, an improved form of privy, may be the only available means of disposal in many mining towns. Where water supply must come from shallow wells, as at Mineville, N Y (40), the old form of earth vault must be abandoned. Essential details of construction: (a) Receptacle, galvanized iron, preferably cylindrical for ease of cleaning, must be water-tight. (b) Seat should be only slightly higher than top of receptacle. (c) Lid of seat so designed as not to permit it to stay open, to admit flies. (e) Receptacles removed through door in back, so designed as to fall tightly shut. (e) Adequate ventilation through screened aperture. (f) Door and window screened. Cost of erection at Mineville, N Y, $15 for structure, $3 for receptacle. OPERATION: Once a week in warm weather, twice a month in winter, full can is removed, covered with tight-fitting lid, and a cleaned, empty can is returned to place. Full cans are then loaded on low wagon passing along alley in rear of houses, and taken to disposal grounds for burial, septic treatment, or incineration. Cans are emptied, washed, and dried on a rack. At Mineville, incinerator for disposing of excreta from 238 families cost $500 to build; total cost of disposal averaged $1 per family per mo. Same plan has been adopted at Docena, Ala (Tenn C, I & RR Co) and elsewhere (41).

Sewage disposal (42). Where water supply is adequate for flushing and cost of laying sewers is not prohibitive, a system of sewerage is most desirable. Sewage can be disposed of by dilution, irrigation, septic treatment, or activated sludge process.

Dilution. If mixed with sufficient volume of water, organic matter in sewage decomposes into solids and gases, under combined action of sunlight and of oxygen absorbed from atmosphere. If flow of a stream exceeds 6 cu ft per sec per 1 000 persons discharging sewage, objectionable conditions are unlikely to result; this refers only to creation of a nuisance and does not mean that a stream so polluted would be safe for water supply. If flow is variable between seasons, or if its water has opportunities to stagnate, objectionable conditions may arise. Roughly speaking, a stream will purify 0.02 of its volume of sewage, but not 0.05.

Irrigation with crude sewage has been practiced for centuries in Europe, and has proved successful in many parts of western U S. Prime requisite is a porous, sandy soil, nearly level in topography; less porous soil requires preliminary removal of solid matter in sewage, by sedimentation or septic treatment (see below).

Sewage farm must be underdrained, preferably by tile pipes, 3 to 4 ft deep and 30 to 50 ft apart. In aver soil, 1 acre will absorb raw sewage from 300 persons, or 30 000 gal per day. Land must be so arranged as to take sewage in rotation; it commonly flows for 4 to 10 days, followed by at least an equal period for drying. Berries or salads, eaten uncooked, should not be raised on sewage farms.

Septic treatment involves 2 steps: (*a*) putrefaction, in absence of oxygen, whereby suspended solids are disintegrated and reduced in volume, and most of the organic matter is decomposed into NH_4OH, CH_4, and CO_2; (*b*) oxidation, or "nitrification," in presence of air, whereby NH_4OH is converted into HNO_3, which immediately combines with alkalies, normally present in sewage, to form nitrites and nitrates.

Both processes depend upon bacteria, and considerable delay may occur before their operation becomes well established. Putrefaction is stimulated by temp of 55° to 75° F, and absence of acidity; nitrification proceeds best under following conditions: abundance of air, best afforded by intermittent flow through porous bed; free ammonia not exceeding 0.05%; presence of alkaline base, preferably lime and magnesia, but not in excess; rapid drainage of final products; temperature, the warmer the better. Putrefaction and sedimentation are conducted in "septic tank," the effluent of which is led away for nitrification on natural soil, or in artificial filter or contact beds.

Septic tank for a small system is shown in Fig 7. Capac of sedimentation chamber should be equal to a minimum of 6-8 hr flow of sewage, while more than 24-hr capac is undesirable, because bacterial activity is retarded by accumulation of decomposition products. Flow should enter and leave this chamber with minimum disturbance of sludge and "mat." If sewage contains much mineral matter, as pavement washings, a preliminary "grit" chamber is advisable, and if grease is likely to be abundant, as from a camp cook-house, a grease trap should be placed ahead of the septic tank. Univ of Kansas Eng'g Sta (74) recommends the dimensions in Table 8; those for the siphon compartment or "dosing tank," discharging at a depth of 17-23 in of liquid, refer to a tank from which the effluent is distributed by a line of open tile (see below); for a sand filter (recommended for more than 20 persons) discharge capac of dosing tank should be such as to cover the filter to a depth of 2 in at each discharge, at intervals of 4-6 hr.

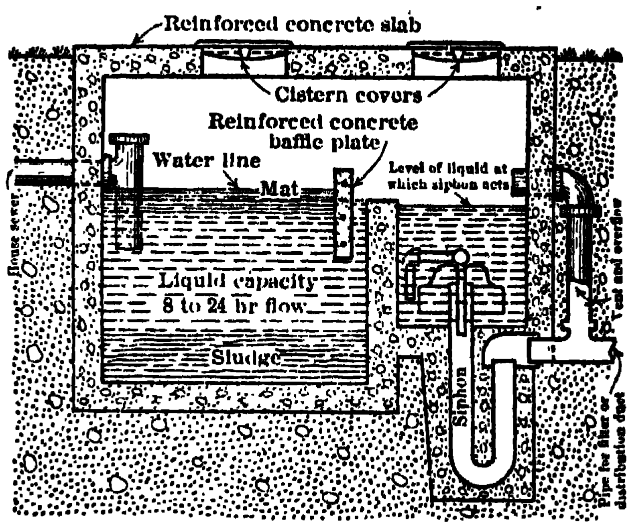

Fig 7. Septic Tank and Siphon Pit

26-30	1 360	4-6	4-6	9-0	3-6	550	680
31-40	1 700	5-0	4-9	9-9	3-6	680	850
41-50	2 000	5-0	5-0	11-0	3-6	800	1 000

(*a*) Total depth should allow 12 to 18-in air space above liquid.

Sludge constitutes at most only 30 to 40% of organic solid material entering with sewage, averaging (in U S) 15 to 20 tons (carrying 90 to 95% water) per million gal sewage. It is removed

at long intervals, by bailing (or through blowout, in larger installations), and disposed of by drying, burying, or burning. Its fertilizing value is small.

Nitrification. Effluent from septic tank may be well used for irrigation, on porous sandy soil. SAND FILTER BEDS, where natural soil is suitable, are made by trenching (4 to 6 ft deep, 50 ft apart) and tiling an area of about 1.5 acre per 1 000 persons contributing sewage. Surface requires occasional raking, to give uniform distribution of effluent over whole area. Where soil is not suitable, artificial sand filter, resembling water filter (Art 14) can be made, preferably with concrete walls and bottom, with radiating open-joint tiles for discharging filtered sewage. Tiles are covered with 12 in coarse gravel, 12 in fine gravel, 12 in coarse sand. Area computed on basis of 1 acre per 400 000 gal per day or 0.5 sq ft per gal per day. Aver cost of maintenance (Mass), $7.50 per million gal sewage treated. With sand filters, intermittent treatment is essential, to permit bacteria to obtain their necessary oxygen. In cold climates, filters must be covered with boards and earth, and have ventilators. Removal of sewage bacteria by sand filtering will be over 99% complete, under ordinary care. CONTACT BED is a concrete pit filled with coarse stone, pebbles, coke, etc, with tile drains on bottom, leading to discharge. Septic effluent admitted from open-joint tiles in upper layer. During treatment, organic matter is decomposed by bacteria adhering to a gelatinous film surrounding stones. Best depth is 3 to 4 ft; volume 1 to 1.5 times daily flow. To maintain

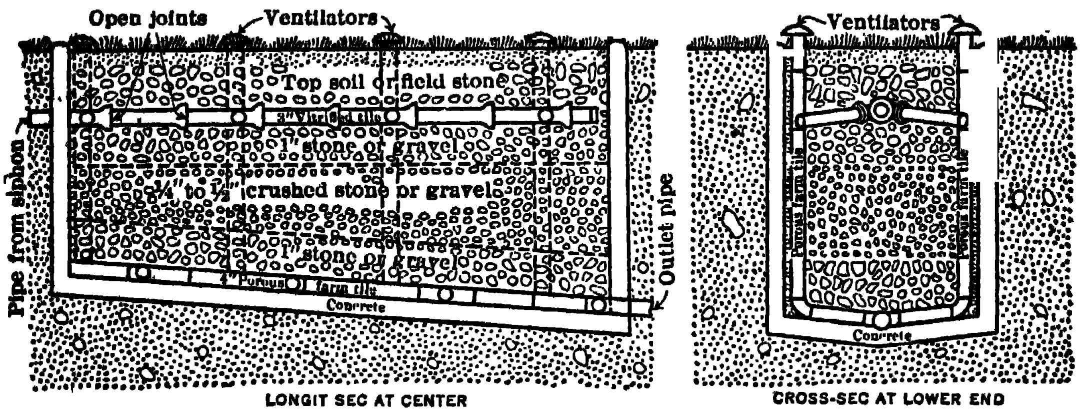

Fig 8. Percolating Nitrification Bed

bacteria in best condition, bed is allowed to fill for 1 hr, stand full for 2 hr, drain for 1 hr, and stand empty for 4 hr, making 3 cycles per day. PERCOLATING BED is similar in construction to contact bed, but flow of septic effluent is continuous; in small installations it enters through open-joint tiles (Fig 8); in larger ones through variety of sprays and nozzles. Filling is 1.5 to 4-in broken slag, coal, or cinders; depth 4 to 5 ft. Percolating bed is cheaper to operate than contact bed, and will dispose of over twice as much effluent per unit area; sand filter is more efficient than other types in removal of bacteria. Where soil is porous, and no wells are closely adjacent, concrete walls and bottom (Fig 8) may be omitted, and bed made in form of a long trench. Such a trench may be 2 ft wide and 26 in deep, and, on sloping ground, should approx follow a contour so that tiles may be laid on grade of not over 2–3 in per 100 ft. Bottom should be filled about 6 in deep with coarse stone on which 3 or 4-in tiles in 1-ft lengths are laid with $^1/_8$-in spaces; tiles are then covered with a few in of coarse stone and the trench finally back-filled. Recommended lengths of trench are given in Table 8. Close approach to trees should be avoided to prevent clogging by roots; if unavoidable, tight-jointed CI pipe should be substituted at that place.

Activated sludge process (73) reverses the septic-tank procedure in that nitrification by ærobic bacteria comes first; system has been widely adopted for large and medium-sized communities, but exceptional circumstances, as in examples below, may justify the cost for plant and its operation on a smaller scale. Raw sewage, from which all solids coarser than about $^1/_{16}$ in have been extracted, and to which has been returned a portion of the sludge recovered by the next subsequent step, is vigorously ærated in a tank or a continuous channel, either mechanically or by diffusion of comp air through a porous medium; air required is 1–2 cu ft per gal of sewage; power, 20–40 hp to compress air to treat 1 000 000 gal per day.

Some mechanical aerators operate with less power, but diffusion gives faster reaction (73). After aeration for 4–6 hr, depending on strength of sewage, mode of agitation, and proportion of sludge returned (the more of the latter, the shorter the time), colloidal constituents become flocculated and, upon settling, collect suspended fine solids, together forming a sludge strongly enriched with aerobic bacteria. Overflow from settlers is innocuous water. Of the sludge here abstracted, 10–20% is returned to the raw sewage entering the plant, either directly, or after receiving added aeration to increase its bacterial activity. Remainder of the sludge, containing up to 99% water, may be spread out to dry, in case of a small installation, but is best transferred to a digestion tank, holding 3–4 months' output, where anaerobic decomposition occurs, stimulated by seeding with partially decomposed sludge or introduction of especially active types of bacteria. Sludge thus decomposed is greatly diminished in vol, dries readily when spread on sand beds, and is good

fertilizer. Gases evolved during digestion of sludge are rich in CH_4; at some large English installations, this gas supplies the whole operating power.

Examples (72). NORANDA, Quebec, is on a lake which affords the only practicable source of domestic water and also the only natural outlet for sewage; extreme precautions are therefore necessary. Water is treated, at 1 000 000 gal per day, by coagulation, gravity filtration, and chlorination. Sewage, 750 000 gal per day, is treated by activated sludge system. A bar screen with 1.5-in spaces catches about 1 cu ft of coarse refuse per million gal, which is removed by hand and buried. A 3 by 3-ft self-cleaning drum screen (Dorrco) with 1/16 by 2-in slots removes about 4 cu ft per million gal, or max of 40 cu ft per day of finer refuse; also buried. Liquid sewage is then aerated and nitrified in activated sludge channels, supplied with comp air through porous tiles in bottom, taking 6 hr for treatment; it is then settled in a 30 by 16-ft clarifier, the overflow running into the lake. Of the sludge, 20% is returned as seed to the nitrifiers; remainder, after digestion in another clarifier, is spread on sand beds to dry, and then goes to dump. FLIN FLON, Manitoba, has 2 lakes, drawing water from one, and applying activated sludge treatment before discharging sewage into the other. Initial plant, treating 150 000 gal of sewage per day (pop, 2 500), was similar to that at Noranda, but sludge was dried on sand beds without further digestion. Latter step was to be included in a proposed larger plant; gases from digestion, carrying 70% CH_4 and with fuel value of 650 btu per cu ft, were to be utilized for warming sewage to best temperature for nitrification.

Toilets. Following standard specifications for use in connection with sewerage systems have been adopted by the U S Steel Corporation's committee on sanitation:

(*a*) Closets should be located as close as possible to the work. (*b*) There should be a number of small closets rather than a few large ones. (*c*) Each toilet room must open to outside light and air. Minimum window space for a toilet room containing one fixture must be 4 sq ft, and for each additional fixture 2 sq ft. Windows must be designed to open. Each toilet room to have not less than 10 sq ft floor space and not less than 100 cu ft air space for each fixture. (*d*) Closets should be separated from lockers and wash rooms. (*e*) Unless wash rooms are nearby, each closet should be supplied with at least one wash basin. (*f*) Adequate urinals should be provided in each closet. (*g*) Number of seats, one to every 15 persons, based upon max number of employees in a shift in departments using the unit. (*h*) Closets should be of bowl type, of porcelain or china, not enameled iron. (*i*) Every bowl should be separately vented and trapped. (*j*) The seat of closet should be of wood or other non-heat absorbing material and varnished or painted. Seats should never be ironware or porcelain. (*k*) Opening should be at least 7 in wide and 11 in long. (*l*) There should be partitions between seats, 6 ft high and 12 in off the floor. (*m*) Distance between partitions should be not less than 30 in, and from front of seat to door not less than 30 in. (*n*) Partitions and bowls should be so arranged that all spaces can be easily cleaned. (*o*) Toilets should be heated in cold weather. (*p*) Floors should be of glazed tile or concrete, with smooth surface and cove corners. (*q*) Regular cleaning is necessary; disinfectant not to be relied upon. (*r*) Toilet paper should be furnished. For underground toilets, see Sec 23.

16. DISEASES ENCOUNTERED IN MINING

Ankylostomiasis, an intestinal disease, is transmitted by germs contained in excreta; germs will survive for long periods in mud and water underground. PRECAUTIONS: (*a*) prohibit indiscriminate pollution of mine workings; (*b*) wash hands in clean water before eating. Symptoms and treatment, see Sec 23.

Silicosis, a laceration of the lungs induced by breathing fine siliceous dust, is now believed to be due to solubility of silica in fluids present in the lungs. Dusts of coal, shales, and practically all rocks not having a vitreous quartz nature, have less direct harmful effect, but serious danger arises through increased liability to contract other pulmonary diseases, even where acute silicosis may be absent. PRECAUTIONS: (*a*) adopt wet drilling methods, or (*b*) require workmen to wear respirators. Symptoms and treatment, see Sec 23.

Malaria (44) prevalent in tropics is transmitted by sting of a few varieties of mosquito (genus anopheles). These mosquitoes breed most freely in clean, running water open to sunlight, less so in stagnant or marshy water, and practically not at all in muddy water, as in dredge or tailings ponds. The most virulent anopheles swarms just before dark and for 2 or 3 hr thereafter, is notoriously persistent in search for an opening in screens or nets. It can be distinguished from other mosquitoes by its attitude of " standing on its head " while feeding. According to Watson (44) it rarely travels more than 1/2 mile (unless carried by a breeze).

Malady is slow and cumulative, and a sufferer usually has sufficient warning to enable him to escape to more healthful climate. Regularity in recurrence of chills is not so characteristic of tropical malaria as of other types. Recognized preventive is quinine, which should be taken regularly on going into a malarial district; sulphate of quinine is more insoluble and therefore less effective than bisulphate or hydrochloride.

Prevention: 3 gr quinine before each meal; avoid constipation, by fruit diet or laxatives, if necessary. Build houses on highest ground available, remove foliage in immediate vicinity, screen carefully, and drain mosquito-breeding pools if possible. SYMPTOMS: fever or chill, sometimes accompanied by violent vomiting; in former case, induce active perspiration with hot lemonade, acetanilid or other antipyretic; in latter case, empty the stomach with 30 gr ipecac and much tepid water, followed by 5 gr soda bicarb. TREATMENT: 15 to 20 gr quinine 3 times a day; more quinine than sufficient to induce dizziness is not necessary. Promote movement of bowels by 10 gr calomel mixed with equal weight sodium bicarb, taking 0.25 of mixture every 20 min. Six hours after calomel, take 1 oz magnesium citrate in water, followed 2 hr later by 20 gr quinine. Patients should remain in bed at least 1 week, taking 30 to 35 gr quinine per day, in 2 or 3 installments, and continued until 25 days pass without return of fever.

Typhoid (45), an intestinal disease, is transmitted by a bacillus in food and drink, but (unlike typhus) probably not by contact.

Precautions: Doubtful water should be boiled, or distilled, and milk sterilized on least suspicion. All refuse should be incinerated, especially excreta from a typhoid patient, all of whose clothing, bedding and utensils must be disinfected. General and individual cleanliness, particularly in connection with preparation and eating of food, is important. SYMPTOMS: headache (frontal), chilliness, languor, increasing in severity; followed by dry hot skin and great thirst; tongue dry, with brown or dark yellow coating; pulse weak and rapid; later, pale red isolated spots, like flea-bites, appear on chest or abdomen; fever 102° to 104° F, usually entailing coma or delirium. SPECIFIC TREATMENT unknown. Liquid diet, principally milk, followed by meat broth after middle of second week; stimulants if necessary. Cold water or tea may be taken in large quantities. Cool baths or sponging with alcohol, or wrapping in wet sheet, helpful for reducing fever, except in case of complications or weakness.

Yellow fever (45), usually an epidemic, is a mosquito-borne disease (carried by Stegomyia fasciata) particularly likely to attack newcomers into countries where it occurs. Promoted by high temp, low barometer, lack of cleanliness, and impure water. One attack generally brings immunity.

Symptoms: invasion usually sudden, denoted by chills or convulsions with severe headache, pain in back, constipation, and vomiting. Urine scanty. These symptoms last 2 to 6 days, when convalescence may begin, or the disease proceed to third stage marked by vomiting of disorganized blood (black vomit). Blood appears in stools and urine and may exude from mouth and nose. Stupor becomes marked and skin yellow. Recovery from third stage is rare. TREATMENT: quarantine and thorough disinfection are necessary. At beginning, complete rest and hot mustard foot-baths advisable. For fever, cold sponging and application of ice. Liquid food in small quantities at frequent intervals. Black vomit is restrained by entire rest for stomach, counter-irritation of abdomen and fixing muscles by broad pad.

Cholera (45) is an epidemic caused by bacillus infesting intestines, which enter only with food or drink. Contributing causes: gastric derangements, excessive heat, and lack of cleanliness.

Symptoms: invasion is always sudden, consisting of painful griping and spasms of muscles of abdomen and calves of legs, with coldness of surface and extreme collapse. Diarrhœa is pronounced, becoming more frequent and consisting of whitish or brownish fluid. Temp sub-normal, pulse weak and rapid, drawn appearance of face. Urine partially or wholly suppressed. Duration of disease may be as short as 2 hours, but in fatal cases death usually ensures on second or third day. TREATMENT: in first stage, enemas of opium and tannin, with stimulants; wrap in hot blankets, bathe several times daily in disinfectant solution. Diet, thin porridge exclusively. During convalescence, careful nursing necessary. Isolation and disinfection of dejecta essential and persons in infected area should use extreme care about cleanliness and moderation in food and stimulants.

Scurvy (45) is a derangement of the blood, most commonly encountered in arctic explorations, supposed to be caused by lack of fruit and vegetable acids and potash salts. Indicated by blood clots under skin, ulcerations on skin or mouth, tongue and gums swollen and ulcerated. Hemorrahages frequent, fever usually absent. Symptoms can be modified by increasing ration of fresh vegetables or fruit; onions and lime or lemon juice are particularly beneficial.

Tropical complaints, in general, may be alleviated by observance of following suggestions (46): (*a*) Before making a first visit to tropics, consult physician; those afflicted with chronic weakness of stomach or liver are most liable to diseases. (*b*) On arriving in a malarial district, begin taking quinine (see "Malaria") for its tonic and prophylactic effects; (Warburg's Tincture, liquid or in capsules, is excellent). (*c*) Build houses on highest available spot; raise a few feet from ground; cut grass and underbrush from immediate vicinity, and screen houses against all insects. Around a permanent camp, drain pools and other breeding places of mosquitoes. (*d*) Diet should be light, and composed largely of fruit and vegetables, fresh if possible; meat may be reduced to small amount, and fresh killed meat should be secured at any reasonable cost; small refrigerating plant is a justifiable expense where practicable. Variety of food and reasonable supply of table luxuries

are important, because appetite is likely to be weak. (*e*) Water should be boiled or distilled. (*f*) Omit liquors entirely; this is particularly important, because alcohol retards normal prophylactic action of the blood. (*g*) Protect top of head and back of neck from direct heat of sun; arrange working hours to permit siesta during middle of day. (*h*) Provide enough light-weight clothing to permit frequent changing, and do not allow wet clothing to dry on the body. (*i*) In short, the care of one's health, under conditions which are known to be unsalubrious, and where failure of an entire undertaking may result from incapacity of one individual, deserves more serious attention than it usually receives in the temperate zone.

Snake bites. Tie ligature as quickly as possible around limb above the bite. Cut deeply enough to start flow of venous blood from the bitten spot, aided by sucking, if possible, which may be done safely unless mouth has an open sore. Apply strong solution of potassium permanganate or bichromate. Purpose of alcoholic liquor, usually recommended, is to stimulate heart action and counteract narcotic effect of the poison.

SECTION 23

MINE AIR, GASES, DUSTS, HYGIENE, EXPLOSIONS, AND ACCIDENTS

BY

GEORGE S. RICE

FORMERLY CHIEF MINING ENGINEER, U S BUREAU OF MINES

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

MINE AIR, GASES, DUSTS, HYGIENE, EXPLOSIONS, AND ACCIDENTS

1. ATMOSPHERIC AIR

Table 1. Composition of Pure, Dry, Normal Atmospheric Air

	Symbol	By volume	By weight	
Oxygen	O_2	20.93	23.024	Percentages of these constituents are lower when water vapor is present, as is always the case under normal conditions
Carbon dioxide	CO_2	0.03†	0.040	
Nitrogen *	N_2	78.10	75.499	
Argon	A	0.94‡	1.437	
		100.00	100.00	

* Includes small amounts of rare gases behaving, as does argon, like N; hence, ordinarily grouped under N.

† Haldane (*Jour of Hygiene*, Vol 2, p 241) states percentage of CO_2 at about 3 ft above the ground, as varying from 0.025 by day to 0.035 by night; mean about 0.030%. In large towns there is more CO_2. In a London fog Russell found 0.14% CO_2.

‡ According to Sir William Ramsay.

Weight of dry air. At sea-level press (14.7 lb per sq in), 1 atmosphere = 760 mm or approx 30 in mercury barom; wt of 1 cu ft, 0.086354 lb at 0° F, and 0.070914 lb at 100° F (Sec 39, Art 9). Dry air is subject to the general laws of gases. At constant temp its density increases directly as the press.

Humidity. Aqueous vapor is always present in the atmosphere, the quantity depending on climatic and local weather conditions. The percentage of saturation, except in arid districts, is rarely less than 35%, ranging to 100%.

Presence of moisture in a given space is independent of presence or absence of air in that space. Therefore it is not technically correct to say that air is moist, or dry, but this is the common mode of expression, and in mining practice it is convenient to say the ventilating current or the mine air has a certain relative humidity, or carries a certain wt of water vapor per 100 000 cu ft of air in the current (1, 64*a*). Quantity of moisture present is chiefly dependent on temp; press and, other things being equal, the higher the temp the greater the quantity of water vapor, if water is present to furnish vapor.

Absolute humidity is the quantity or wt of aqueous vapor present in a unit of space. Aqueous vapor is saturated when, at the vapor press, the space contains the maximum quantity. If vapor is partly saturated, the percentage of saturation is termed RELATIVE HUMIDITY, which is the ratio of the wt of vapor present to that necessary for saturation. It may be measured by hygrometers (psychrometers) which have 2 thermometers, one termed "dry bulb," the other "wet bulb"; latter has tight thin muslin cover over bulb, kept wet. Evaporation by air current or by whirling cools and "depresses" "wet bulb" thermometer in geometric proportion to decrease of relative humidity of atmosphere.

Mine air, beside normal atmospheric constituents, contains moisture, gaseous impurities and dust (Art 2).

Relative humidity varies widely in different mines and different parts of a mine, and is important in connection with ventilation (Sec 14). Relative humidity of intake air varies with changes in humidity of the outside atmosphere. When intake air is colder than the mine walls, it becomes warmed and its humidity decreases; when warmer than the walls, as in summer, it is cooled and its humidity increases, usually above the saturation or dew-point, in which case moisture is deposited. This effect may extend far from the mine entrance.

In some coal mines water sprays are used in warm weather to cool and thus condense moisture in the intake air; and in some deep, hot metal mines, as at Butte, Morro Velho, Brazil and in South Africa, intake air is dehumidified to improve working conditions (Sec 14). As the temp of mine walls generally varies but little from summer to winter, the relative humidity changes in different parts of a mine with dryness or wetness, and the extent to which spraying is applied.

Dew-point is the temp at which drops of visible moisture form from saturated vapor.

Psychrometric formula, employed by the U S Weather Bureau for determining relative humidity, and the temp of dew-points, is:

$$e = e' - 0.000367\,P\,(t - t')\left(1 + \frac{t' - 32}{1571}\right)$$

where t and t' are the temps of the dry and wet-bulb thermometers; P is the corrected barom press, in; e' is the max or saturation press of aqueous vapor at temp t' of the wet bulb; and e is the press of aqueous vapor corresponding to observed temps t and t'. Weather Bureau tables (3) are too extensive for insertion here. Fig 1 shows curves of equal wts of water vapor per cu ft and curves of equal depressions of the wet bulb for varying temp and relative humidities.

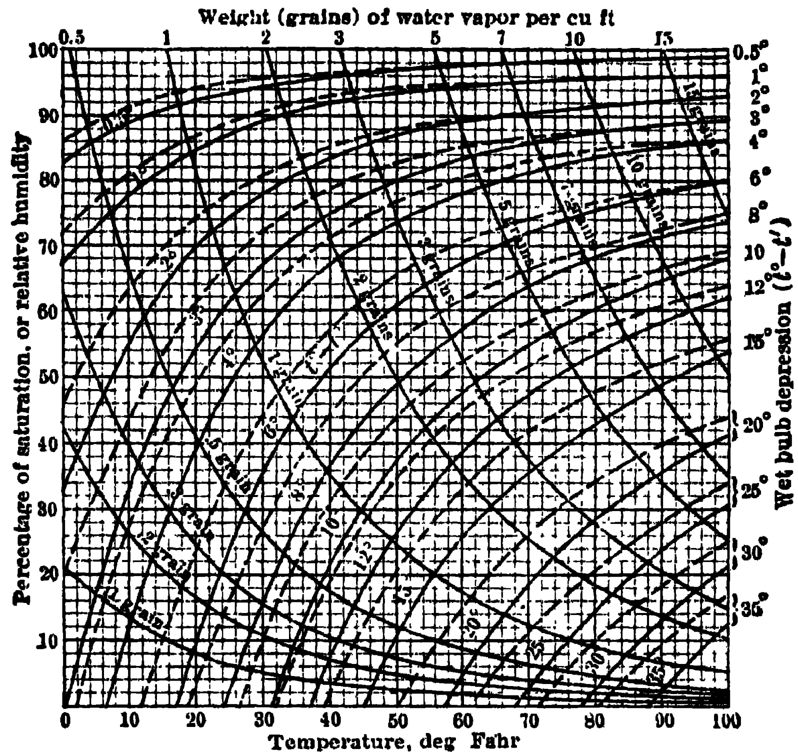

Fig 1. Psychrometric Chart. (Full lines for 30-in; broken lines for 23-in barom)

Example of use of chart. Required relative local humidity and wt of aqueous vapor at barom press of 30 in. Take temp readings of dry bulb t and wet bulb t' (if sling psychrometer is used, readings are made after whirling). If $t = 58°$ and $t' = 50°$, $t - t' = 8° =$ wet-bulb depression. Follow the full-line wet-bulb depression curve of 8° from the right until it intersects vertical temp line 58; then, relative humidity, 56%, is read in left-hand margin opposite point of intersection. Wt of vapor per cu ft is found by noting the curve (or interpolated curve of equal wt) which passes through point of intersection; in this case, 3 grains. At a high altitude, where barom press is, say, 23 in, temp 58°, and wet-bulb depression 8°, the broken line curve of 8° is followed until it intersects temp curve 58°. Relative humidity in this case is 61%; weight of vapor, 3.2 grains. For other barom pressures it is necessary to interpolate, or refer to complete psychrometric tables (2). Barom readings for different altitudes are given in Sec 37. For wt of dry air and water vapor, see Sec 39, Art 9, 10; for wt of mixtures of gases, see Sec 14.

Psychrometer. To determine the difference $t - t'$, between wet- and dry-bulb temp, the sling, or whirled psychrometer, is the most accurate instrument. It is swung to give the wet bulb a veloc of not less than 15 ft per sec. It is easily used, but is fragile, and therefore less suitable for mines than those having protective frames. A form designed by Bur of Mines (Fig 2) has thermometers attached to an aluminum frame. It has a leather case, with aluminum liner and shoulder strap. In whirling the psychrometer, observer stands sideways to air current, and if in open air should shade instrument from sunshine. Tests are repeated several times to insure lowest reading of wet bulb. When temp is below freezing, whirling must be continued for a time after wet muslin cover of the wet bulb freezes, as vapor from ice is given off slowly. STATIONARY PSYCHROMETERS (hygrometers), while not so dependable as the whirling type, are useful; those having a wet bulb are fairly accurate in a strong current of constant veloc. **Recording hygrometers:** one type utilizes changes in length of a hair corresponding to changes in humidity, another

employs differential expansion of large metal bulbs, wet and dry, to operate a scribing pen. Stationary hygrometers, if checked by whirling psychrometer and adjusted periodically, are useful to determine hygrometric condition of an artificially humidified ventilating current.

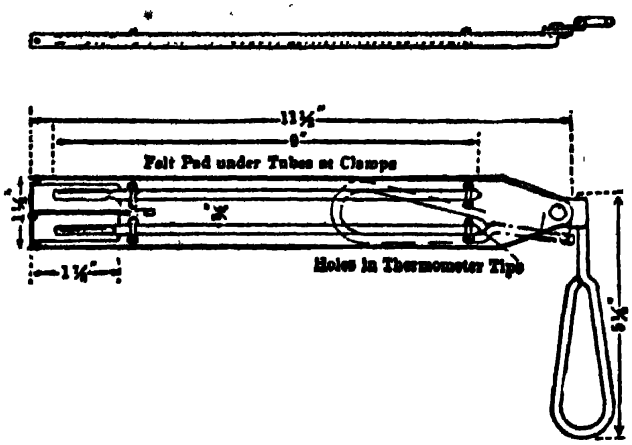

Fig 2. Bureau of Mines Psychrometer

Kata thermometer, for measuring cooling power of the atmosphere, gives a better index of physiological conditions of atmosphere than the wet- and dry-bulb thermometer.

It is a large-bulbed spirit thermometer, graduated between 100° and 95° F. The bulb is heated in hot water (thermos flask may be used), then dried, suspended, and time of cooling from 100° to 95° taken with a stop watch. The number of seconds divided into a factor number (approx 500, and determined for each instrument) gives the cooling power for convection and radiation on the surface of the Kata. Operation is repeated with a muslin fingerstall on the bulb, thus obtaining the wet Kata cooling power due to evaporation, radiation and convection. The difference is the EVAPORATIVE COOLING POWER (3). The Kata is widely used in Great Britain and its colonies, but in the U S is not preferred to the wet- and dry-bulb thermometer, with record of air veloc.

2. CONSTITUENTS OF MINE AIR

Mine air differs from normal atmospheric air in the extent to which it is contaminated by mine gases, or normal percentage of O is depleted. O is absorbed by breathing, rapid and slow combustion or decay, and by the mine walls. Impurities come from exhalations of men and animals, blasting, fires, or explosions, bacteriological action, and gases from strata.

Quality of mine air may vary widely in different parts of same mine. In a mine not artificially ventilated, variations in temp, and influx of gases and water from the walls, cause air currents. Ordinarily the composition of mine air is largely controllable by systematic ventilation (Sec 14). Recent laws in Great Britain and elsewhere require a certain minimum percentage of O, and limit the maximum of deleterious gases in the air (Art 6), as opposed to the older coal mine regulations, which specify certain quantities of fresh air per min to be circulated.

Normal mine air is air considered not injurious to breathe, and which does not contain dangerous proportions of inflammable gases (Art 6). Its composition varies but little from that of the open atmosphere (Art 1).

Oxygen (O) is vitally important for animal life; it forms about 20.93% of the atmos (dry basis) and is slightly heavier than air. One liter of O at 0° C and 760 mm weighs 1.429 gm. At −118° C it may be liquefied at 50 atmos (735 lb) per sq in. Liquid O boils at −183° C, at 760 mm. O has strong affinity for most elements. Slow combination is called oxidation; rapid oxidation due to flame or heat is termed combustion. Self-generation of flame by rapid oxidation is called spontaneous combustion. When air is mixed in certain proportions with carbonaceous or other inflammable dusts or gases, and a spark, glowing piece of metal, or a flame is introduced, an explosion will probably take place. O has neither color, taste, nor odor, and can not be distinguished by the senses as different from air. In well-ventilated mines O rarely falls below 19%. In some collieries, oxidation of coal and roof shale may be so rapid that spontaneous fires result. Pyrite, generally present in coals that fire spontaneously, may assist, but spontaneous combustion may occur in its absence. Coal and carbonaceous shale absorb O without formation of a molecular equivalent proportion of CO_2. This action is more rapid with coal and shales in mines especially subject to "gob fires." In these, if the ventilating current is slow, the O content often falls to 18%. For physiological effect of O and of O deficiency, see Art 4.

Nitrogen (N) in volume forms nearly $^4/_5$ of the earth's atmos. It is colorless, odorless, and tasteless; has little chemical affinity for other elements. At ordinary temp it is inert, and will not support life; acts as a diluent of other gases. An important feature is its faculty of promoting the growth of certain bacteria, thus enriching soils. It boils at −195° C, whereas O boils at −183° C; hence, when liquid air is exposed to the atmos, the first portions that evaporate are richer in N than in O. This fact is taken into account in using liquid-air rescue apparatus (Art 19).

Argon forms 0.94% of the atmos. It is heavier than N (sp gr = 1.38), and behaves essentially like N, being grouped with it in ordinary analysis.

Table 2. Components of Normal and of Impure Mine Air

(b = molecular wt, when O = 16; d = sp gr with air as unity, at 0° C (32° F) and 760 mm or 29.921 in mercury; e = boiling point at 760 mm.)

Name	(a) Chem symbol	(b) Molec wt	(c) Gm per liter	(d) Sp gr	(e) Normal boiling temp, deg C	Usual source in mines
Oxygen	O_2	32.0	1.4292	1.1055	−183	In atmosphere
Nitrogen	N_2	28.02	1.2514	0.9673	−195	" "
Carbon dioxide	CO_2	44.00	1.9768	1.5291	− 78	In atmos., in excess of normal 0.03%, from blasting, oxidation, mine fires, emanations
Carbon monoxide	CO	28.00	1.2505	0.9672	−190	Blasting, mine fires
Nitrogen dioxide	NO_2	46.01	2.0549	1.5895	.....	Burning of nitro explosives
Methane	CH_4	16.03	0.7159	0.5545	−161	Emanations from coal measures
Ethane	C_2H_6	30.05	1.3567	1.0494	−89.3	Component natural gas
Acetylene	C_2H_2	26.02	1.1621	0.9056	.....	From carbide lamps
Hydrogen	H_2	2 016	0.0898	0.0695	−253	Mine fires, explosions
Hydrogen sulphide	H_2S	33.98	1.5392	1.1906	− 10	Explosions and rarely from springs
Sulphur dioxide	SO_2	64.07	2.9266	2.2638	− 10	Combustion of pyritiferous ores or native sulphur
Aqueous vapor	H_2O	18.02	......	......	100	In atmos and from evaporation
Component elements of some of the gases named above						
Solid elements	(a)	(b)		(d)	(e)	
Sulphur	S	32.07	....	1.98 (x)	440	From pyrite in ore or coal
Carbon	C	12.00	......	2.1–2.3 (y)	(z)	From coal, methane or timber

x = sp gr with reference to water at unity; y = sp gr of graphite with reference to water at unity; z, carbon is known only in solid form. Wt of 1 liter of dry air at above temp and press is 1.2932 gm.

Gaseous impurities in mine air. Common impurities (Table 2) and sources of pollution are as follows:

Carbon dioxide, or carbonic acid gas (CO_2), occurs in the earth's atmos in remarkably constant proportions, except in and near cities and manufacturing plants; kept constant by plant life, which takes the C for its tissue, and gives off free O. In mine air, when in excess of the 0.03% in normal atmospheric air (Table 1), it is a product of both slow oxidation and rapid combustion of carbonaceous substances. Hence in closed places and in mines the percentages of CO_2 vary. It is colorless, odorless, and will not support life or combustion. (For physiological effect, see Art 5.) It is a variable constituent of blackdamp, which sometimes has a musty smell due to decay of timbers and to fungous growth. BLACKDAMP is due to slow oxidation and to absorption of O by coal, causing excess of N, and hence is composed chiefly of N, with 1 to 20% CO_2 (rarely over 12%, as it is absorbed by mine water; never CO_2 alone, as sometimes assumed). CO_2 is an important constituent of AFTERDAMP, produced by fires or explosions of gas or dust. "Blackdamp," "Afterdamp," "Firedamp" (miners' terms) are of variable composition (Art 15, 17).

CO_2 is given off in some metal mines, by the dissolving of limestone, or from carbonate minerals. The latter may be the cause of CO_2, which sometimes gives trouble in mines at Tintic, Nev, and Cripple Cr, Colo, requiring bulkheading and increased air press to force the gases back into crevices. Violent CO_2 outbursts, blowing out highly pulverized coal dust, occur in collieries near Alais, France, and in lower Silesia (12). Origin of the gas, though not definitely known, is probably in limestone strata below the coal measures, which have been intruded by igneous magmas that heat the carbonates and form cracks, through which CO_2 has entered so-called "nests" in the coal. CO_2 is a stable gas, but can be reduced to CO by burning coal, or charcoal. Its percentage changes through absorption by percolating water, by disappearance of O of the air, by reactions between O and coal, or timber (rarely by inflow of CO_2 from strata), by supplanting of original atmos, by ingress of CH_4, and to a slight extent by absorption of CO_2 by coal. Water at 0° C absorbs 1.71 of its vol of CO_2. Sp gr, 1.529; boiling point, −78° C; may be liquefied at 0° C by a pressure of 35 atmos. Critical temp, 31° C; critical press, 77 atmos. If the liquid is allowed to escape freely, evaporation cools the remainder to a solid which passes directly to gaseous state.

Carbon monoxide (CO). Appreciable quantities are produced by imperfect combustion. Some CO_2 is reduced to CO by incandescent C at temp above 500–600° C. The

higher the temp in presence of excess C the more rapidly is CO produced. It is incidentally formed to considerable extent in furnace firing. With bad firing or wrongly designed furnace it is in excess in chimney gases. It is the important constituent of artificial fuel gas, of water gas, and of blast-furnace gas.

CO is colorless and inodorous. Mixed with air in proportions of 15.5 to 75%, the mixture will explode if ignited. Combustion formula: $2\ CO + O_2 = 2\ CO_2$. IGNITION TEMP is about 600° C. CO burns in air with blue flame, but in mines is never found separated from other gaseous products of combustion; and, as unconsciousness would ensue after a few respirations when over 0.5% is present, the old idea that a miner unprotected by oxygen breathing apparatus could detect its presence by a flame "cap" in a safety lamp, is fallacious. Probably its association with steam and light-colored smoke in fumes from mine fires led to its being termed WHITEDAMP. As CO may be present in quantities dangerous to life, when there is no steam or visible fumes from a fire, or in afterdamp of an explosion, the term is misleading (Art 5). A portable CO detector, much used by rescue crews, is graduated from 0.05 to 1%, and has a bell alarm which rings when CO reaches 0.2%.

Nitrous fumes (NO_2,N_2O_3) not normally found in mines, are sometimes produced when nitroglycerin explosives accidentally burn instead of detonating; then reddish fumes are produced, very dangerous to life (Art 5). They have the smell of fuming nitric acid, even when greatly diluted.

Methane or marsh gas (CH_4) is the most important of the dangerous gases. By miners it is termed FIREDAMP, or simply " gas," but as these terms are used whether or not other gases and air are present, they are not synonymous with the term methane. It is commonest in coal mines; also found in tunneling in carbonaceous shales and sometimes infiltrates into metal mines at contacts or near carbonaceous rocks (Art 3). It is colorless and odorless; its occurrence in old workings of collieries, where air is musty from decaying timber, has given the idea that it has an odor; it burns with bluish flame. Even when air contains as little as 1% it is visible in flame of a safety lamp, when wick is drawn down, as a faint conical blue cap (Art 9); at higher percentages the cap becomes larger and more distinct. Effect on a flame of normal size is to cause it to " spire," or lengthen. When above 5.0% of the mixture and less than 13.9%, the mixture will explode if ignited. Max violence is attained when CH_4 is 9.4%. (Table 2a.)

J. S. Haldane states a mixture of air with 7.5% of CH_4, which explodes violently at atmos press, can not be exploded if the press is reduced to 200 mm (8 in of mercury). G. A. Burrell found that increasing the press to 5 atmos did not affect the low limit, 5.0%; also that if the mixture of CH_4 and air be heated to 500° C, the limit is lowered to between 3.75 and 4%. This lowering of explosive limit may be an important factor in the propagation of a firedamp, or coal dust and firedamp, explosion. Formula of combustion: $CH_4 + 2\ O_2 = CO_2 + 2\ H_2O$. Volumetrically, 1 vol CH_4 requires 2 vols O or about 10 of air, producing when ignited 1 vol CO_2, 2 vols aqueous vapor, and the unchanged 8 vols of N. Temp of ignition is 650° to 750° C. If the burning gas is cooled below ignition temp, the flame will go out. On this principle is based the construction of safety lamps.

Ethane (C_2H_6), **propane** (C_3H_8), **butane** (C_4H_{10}), and other heavier gases belonging to the CH_4 series, are components of " natural " gas, and are not normally found in collieries. They have a pronounced crude oil or natural gas odor, which, apart from the analytical information, gives warning that there is probable leakage from a neighboring gas or oil well. At the Bruceton (Pa) experimental mine it has been observed that the odor is very strong on entering a place containing 1% " natural " gas, but a person breathing it for some time no longer notices the odor. Ignition temp is 520° to 630° C; hence less than that of CH_4.

Ethane is found in gases contained in certain coals, as in B C and Belgium, and in much smaller proportions than the accompanying CH_4. Due, probably, to its greater density, it diffuses less rapidly through coal in situ than CH_4 or even CO_2 (12).

Acetylene (C_2H_2) is not found in mines under natural conditions, but is sometimes given off in small quantities from unlighted or extinguished acetylene lamps, or from accidental spilling on wet ground of calcium carbide (from which it is produced by agency of water). When mixed with air in percentages between 2.5 and 73%, the mixture is explosive. It ignites at a temp of 483° C (900° F), and can be ignited by a glowing pipe or cigarette. 1 lb of pure carbide yields 5.5 cu ft C_2H_2; commercial carbide about 4.6 cu ft. It is colorless and tasteless. Combustion formula: $C_2H_2 + 3\ O_2 = 2\ CO_2 + H_2O$.

Hydrogen (H) is not found in mines under normal conditions. It occurs in afterdamp from coal-dust explosions, as a distillation product of the hot excess dust, after the explosion flame has passed, and from coal fires as a product of destructive distillation. H is the lightest gas, 1 liter weighing 0.0895 gm. Ignites at 550° C, and burns in air with a blue flame. Mixed with air it is explosive between 4.1 and 74.2%. Combustion formula: $2\ H_2 + O_2 = 2\ H_2O$.

Hydrogen sulphide (H_2S) has been found, though rarely, issuing with CH_4 from gas "blowers" or "feeders" in coal mines. Being soluble in water, it is sometimes given off by stagnant water. Occasionally detected by analysis in small quantities in afterdamp from coal-dust explosions, and in fumes from fires in sulphurous coal. It has the odor of rotten eggs, is very poisonous, and burns in air with a pale blue flame.

Sulphur dioxide (SO_2) is found in coal mines only as a lesser component of afterdamp, but in sulphur mines and in mines having rich sulphide ores in which fires have started, SO_2 gas becomes a serious factor. Very soluble in water, colorless, and has a suffocating smell.

Diffusion of gases is a fundamental principle in the ventilation of mines. Gases diffuse into air at rates in inverse ratio to the square roots of their densities.

Density of CH_4 is about 8 and of CO_2, 22; rate of diffusion of CH_4 as compared with CO_2 is as 4.7 to 2.8, or nearly twice as rapid. Prussian Firedamp Commission made some tests, admitting methane through a top inlet into a compartment of a gallery in quantities corresponding to 3, 4, and 5%; diffusion proceeded slowly, was nearly complete in 3 hr, but not entirely complete until 4 hr. When diffusion is complete gases do not again separate. Diffusion is greatly assisted by mechanical air currents. If gases pass through a fan, as in case of an underground fan, the mixing is immediate, judging from tests at the Bruceton mine. When CH_4 is given off at the face, it immediately rises to the roof owing to its lightness, and if the outflow continues, a body of gas is likely to collect in high places, unless in a strong current of air. In such case, while gas is diffusing into the air along a bottom plane, if it flows in faster than the rate of diffusion the high place will continue to be filled with pure CH_4. A somewhat similar condition exists in pillar workings or old gobs where the roof strata emanate firedamp and the presence of bodies of gas in old workings constitutes a menace when the atmos press suddenly falls (Art 3). Tests by British Safety in Mines Research Board on movement of CH_4 in a mine passage showed that a stream of it will flow along the roof if inclined upward at 1 vert to 10 horiz, against an opposed air current flowing slowly along the floor. This indicates the slow diffusion of CH_4 in absence of agitation of the air and gas currents (88).

Table 2a. Inflammability Limits of Methane, Ethane and Natural Gas (87% CH_4) in Air Mixture (4)

	Lower limit	Upper limit
Mixtures tested in tubes, ignited at bottom:		
Methane, tube closed at upper end, mixture dry	5.24	14.02
" " " " " " mixture saturated	5.33	13.80
" " " " " " 2% water vapor	5.3	13.9
" " " " lower " 2% water vapor	5.0	15.2
Ethane, " " " upper " mixture dry	3.22	12.45
Natural gas (*a*), tube closed at upper end, mixture dry	4.80	13.46

" " " " " " " lower " 2% water vapor	4.7	.....
Mixture in horiz gallery, ignited by black powder (*b*):		
Natural gas, partial inflammation	4.6	.....
" " explosion	5.1	.....

(*a*) 87% CH_4. (*b*) Crawshaw. Fan agitation slightly raised the limits.

3. SOURCES OF IMPURITIES

Blasting. Gaseous products of explosives vary widely with type of explosive, kind of wrapper, and whether used in coal or other oxidizable mineral. Table 3 shows results of tests with a Bichel gage, using 200-gm charges with paraffined wrappers, including analysis when ordinary dyamite is burned instead of detonated.

Table 3. Gaseous Products of Explosives, in Percentages of Volume (U S Bureau of Mines) (5, 6, 92)

(See Sec 4, Art 2)	CO_2	CO	N_2O_2	H	CH_4	N	H_2S	Vol of gas in liters
								(*a*)
30% "straight" nitroglyc dyn	22.9	28.4	....	20.6	0.7	27.4	....	85.8

FFF black powder, when used in coal	19.2	28.2	....	10.0	0.4	35.4	6.8	(*c*)

(*a*) Incl 0.6% NO_2. (*b*) Not determinable under conditions of test. (*c*) Tested in a colliery.

Table 3 shows that the NO_2 red fumes, which in smallest amounts are dangerous to breathe, are produced when dynamite is burned instead of detonated. Also, in blasting coal with black powder, the products differ from those in the testing gage; more combustible gas is produced by presence of carbon and hydro-carbons of coal. In this test, CO, H, CH_4, and H_2S totaled 45.4% by volume. If gases thus produced are supplemented by CH_4 in the air and coal dust, they may aid in starting explosions. Smoke from the black powder can be ignited before diffusion by an open light. 1 lb black powder produces about 5 cu ft of gas; this in blasting coal gives about 2.3 cu ft inflammable gas. If the 5 cu ft be mixed with about 7 times its vol of air, the 40 cu ft of mixture may be explosive if there is coal dust or firedamp in the air. Besides gases some Na_2SO_4 and Na_2CO_3 are always present in form of smoke. Explosion of 1 lb 60% dynamite produces 10–13 cu ft gas, with considerable variations in percentage of CO, CO_2, and N. CO is produced from dynamite in proportions and volumes dependent on kind and quantity of explosive, and whether or not it is properly detonated. It is the principal poisonous gas in powder smoke, and, being dangerous to breathe (Art 2, 5), the practice of returning quickly to a working place after blasting may be injurious (5, 6, 92).

In using PERMISSIBLE EXPLOSIVES in a gaseous or dusty colliery, a requirement (U S Bur Mines) is that not more than 158 liters poisonous gas may be produced per 1.5 lb, the permissible CHARGE LIMIT. About half of all permissibles (Jan 1, 1925) give less than 53 liters (92). LIQUID-OXYGEN EXPLOSIVES were used largely in Germany during the world war, except in gaseous collieries (as they give a flame like dynamite). L.O.X., as commonly termed, has never been used in U S coal mines, because its long flame may ignite gas or coal dust (7). Its use in metal mines in U S, Mexico and Perú was stopped by accidents from premature firing due to ignition by miners' lamps of the carbonaceous powder in the cartridge, which was blown out by vaporizing O. Now used underground only in iron mines of Lorraine, France, but widely used in open-cut work in various countries, and in stripping shallow U S coal seams. Premature blasts have occurred in open cuts, quarries and stripping, from frictional sparks in tamping, in deep holes, where wooden tamping bars were not used; also by impact, when the combustible absorbent was too sensitive. They produce CO when delays occur, as in firing rounds of shots; may also produce SO_2 and H_2S, when fired in sulphide ores.

Oxidation and oxygen depletion are important factors in the condition of mine air, not only in collieries, but also in metal mines containing carbonaceous shales, as in some Michigan iron mines, or those in which large amounts of timber are used.

While all coals oxidise slightly, some, like those of central Illinois and Iowa (including carbonaceous roof shale) oxidise rapidly when broken into small pieces. Hence, spontaneous fires frequently occur in old gobs. Furthermore, oxygen is absorbed by coal. From these two causes the depletion of O in the air circulating through old workings often amounts to over 2%. If a mine room is tightly sealed up, the O is rapidly absorbed, so that, in a few weeks or months, practically all of it may have disappeared. This condition assists in extinguishing thoroughly sealed mine fires.

Timber decay is due to fungus growth, requiring some O; bacteria play a secondary role. The action is hastened by hot, humid air, and probably by the crushing of timber, as in the timber mats employed in various caving systems, in the Lake Superior iron mines and Ariz copper mines. Adjacent to crushed masses of timber the depletion of O, and production of CO_2, accompanied by heating, is so marked as to cause discomfort to the miners.

Exhalations of men and animals in well-ventilated mines are of small importance relative to other sources of gaseous impurity, but are a large factor in metal and other mines without artificial ventilation, especially in headings or stopes unconnected near the face with other workings. An aver man under different conditions, from complete rest to extreme hard work, consumes 0.25 to 4 liters of O per min and exhales, together with N and unused O, 10 to 20% less CO_2 than the O consumed, or 0.2 to 3 liters. For aver working conditions in mines the aver exhalation per man is between 2 and 3 liters of CO_2 per min, and he inhales 30 to 60 liters of air per min. If the CO_2 content of adjacent mine atmosphere is to be kept to 1% or less, then 7 to 10 cu ft of pure air per man per min are required, and about 3 times this amount for each draft animal (Art 5).

Combustion of lights, other than electric, has important effect in inner workings of mines where ventilation is slow, particularly in metal mines with only one outlet. According to J. W. Paul (Bureau of Mines tests): a sperm candle, burning 1 gm, consumes 0.614 cu ft O per hr; a miner's brass lamp, burning 4 to 6 gm oil, consumes 0.8 to 1.2 cu ft; a driver's lamp, burning 8 gm oil, 2.16 cu ft; a driver's lamp, burning 6 gm "sunshine," 2.20 cu ft; ordinary type of miner's carbide lamp, using 12 to 14 gm carbide, 0.36 cu ft O per hr. These tests show that a lamp consuming 1 cu ft O per hr uses up all the O in 5 cu ft of air; and, to keep the depletion of O within the safe limit of 1%, such a lamp requires 100 cu ft air per hr. The amount of gaseous impurity given off by large open lights in close places is so considerable that, where air currents are feeble, the use of miner's electric lamps is advisable.

Mine lighting has greatly changed in the last 2 decades, especially in coal mines, where open lights may ignite CH_4. Moreover, permissible cap-lamps give better light, and many are used in metal mines, as they are safer than carbide or oil lamps.

Emanations from strata. CH_4 (Art 2) is the most important and dreaded gas encountered in collieries. It is probably derived from coal-forming material by distillation due

to heat and long-continued pressure. There is no apparent relation between the amount of gas retained in the strata and the geologic age of formation; the quantity seems to depend more on geologic structure. From Carboniferous to Eocene the coal measures when opened are liable to give off CH_4.

Highly flexed regions, especially the contorted Appalachian anthracite folds, produce more gas than the flat practically undisturbed beds of the middle interior fields. Also, in the sharply-folded beds of the Rocky and Cascade Mts, more gas is found than in the gently-folded beds of central Wyoming. But this rule is not invariable, and seems to be less important than depth of impervious cover, giving vertical pressure and less chance for escape of gases.

Pressure of CH_4 in the strata appears to bear a rough relation to the press of a water column equal to depth of bed below water level, but this is subject to wide variations according to permeability of strata. CH_4 is held in the strata in the pores or adsorbed in the coal, from which it is only slowly liberated on exposure in mining, and more rapidly as it is broken or crushed; also in crevices, fault zones, and porous strata above or below the coal bed, which liberate gas as " blowers " or " feeders," lasting minutes, days or years.

Violent outbursts of CH_4 have thrown out large quantities of coal and dust from the face, usually in folded seams, though Rice (12) reports severe "bumps" in B C and Nova Scotia, unaccompanied by gas outbursts. To prevent the latter, 3 or more radiating holes 10 to 20 ft long have been kept in advance of the heading, but this remedy sometimes fails. Practice in mines near Alais, France, where instantaneous outbursts of CO_2 occur, is not to pick or cut into the face, but to drill and prepare shots, and, at end of shift when all men are out of mine, to fire simultaneously by electricity from the surface. The object is to induce blowouts from any possible high press ahead, by concussion due to blasting. In recent years this safer method, termed "shock blasting," was adopted in mines in Belgium, the Ruhr and Silesia (12), subject to outbursts of CH_4 and CO_2. One theory is that the coal is under great press, and upon release flies into powder, liberating gas. Samples of Belgian coals at ordinary temp yielded on successive crushing 69.1 to 84.65% CH_4, remainder being chiefly N and air. Vol was 2.5–5.5 times that of coal crushed. Coal from Saarbrücken, Germany, is stated to have given off 2 to 2.5 its vol of gas. Differences in laboratory methods make direct comparisons difficult. Tests on U S coals (8, 9) show that the total gas from crushed coals at ordinary temp is from 1 to nearly 2 times the vol of coal. Most gas is given off slowly, but with fine crushing, more rapidly. Monongah coal (W Va), crushed to 30 mesh, gave off CH_4 in a few hr equal to 0.86% of the vol of coal, while that crushed to 10 mesh gave off only 0.4% (60). By allowing the gas to drain off in vacuum for 26 weeks, the Monongah coal gave off 1.83 volumes. In tests of American coals without heating, nearly all gas is CH_4; amount of CO_2 is from 5 to 10% of total gas. Samples from a very gaseous mine, Coalfield, B C, and from the Pittsburgh seam, were ground by Fieldner in vacuo, at room temp. Former gave 200 cc occluded gas per gm; the latter, 49 gm. Of the former, 18.8% was methane, 62.0% ethane; Pittsburgh gas, 13.5% methane, 5.1% ethane. Total paraffins gave 2.12 and 0.12 vol. respectively, of vol of coal crushed (12).

Quantity of CH_4 when liberated from the coal. If ventilation is effic, CH_4 is given off too slowly to be dangerous. The greatest menace is the gas stored in open crevices, porous strata, and goaves of unsealed old workings, which may be released by roof falls, or sudden fall of barom press.

Analyses of the return current of many mines show a little less total CH_4 when a mine is idle than when working; in others, no appreciable difference; indicating that the quantity of gas from coal broken in mining is small compared with that issuing from the solid face and contiguous strata (Sec 14). Total steady inflow of CH_4 in individual mines (Table 4) is obtained by multiplying vol of current by % of CH_4 determined by analysis, and reduced to a common basis of cu ft of pure CH_4 per min, irrespective of vol of ventilating current (9). Table 4 does not exhibit aver conditions, which are difficult to obtain; those for the Liévin mines show wide variations in the same mine. It is uncertain whether flow of CH_4 into a gaseous mine is naturally affected by advance of the faces; it appears to depend on structure of the coal basin and origin of gases. In some mines the flow changes little on idle days; in others, it changes much (12).

Haas (9) suggests that gases of occlusion, adsorption, or even volatile matter in the coal itself, are insufficient to explain the enormous volumes of gas exhausted from our mines; that most of the hydrocarbon gases are natural gas, and that the coal seams are simply the reservoir and path of flow from other strata. His graphs of flow indicate an increase with size of mine, but are independent of the ratio of coal production. As anthracite dust is not explosive in itself, the highly gaseous conditions prevailing in many Penn anthracite mines are less serious than in less gaseous bituminous mines, where pure coal dust is very explosive (Art 14). A bituminous mine giving off 200 cu ft pure CH_4 per min, even if ventilation is strong, would ordinarily fall in the class of gaseous mines, requiring safety lamps because concentrations of gas are likely to be found at the face or in old workings. Often, not over 25% of the air reaches the last break-throughs; the rest lost by leakage (81). Bituminous mines making over 500 cu ft CH_4 per min are considered very gaseous; few in the U S make as much as 1 000 cu ft per min. Multiplying by 18, the figures of Table 4 for pure CH_4 gives vol of firedamp per min at lowest explosive limit, 5.0%.

* Disastrous explosions, with firedamp probably a contributory cause.
† From diagrams in "Occurrence of Firedamp in Bituminous Coal Mines," by Frank Haas (using max amounts) (8).
‡ Max recorded.

Effect of barometric press on issuance of CH_4 is a debatable question. British Royal Commission on Mines deprecated "colliery warnings" of low barometer, on the ground that explosions were generally caused by carelessness or other conditions, rather than by temporary increase of firedamp, and that between such warnings care might be relaxed. Observations by the Bur of Mines, in gaseous Penn and Ala mines, indicated that falling barometer was generally followed by increase of CH_4 in the return current, but the correspondence was not exact. When a gaseous mine has extensive old workings, poorly ventilated, especially if the roof be broken, much gas may accumulate, and when the atmos press falls the gas diffuses into the air currents. It is not generally believed that gas inclosed in the pores of coal, or stored under high press, and issuing in blowers, is affected by atmos press changes, since these rarely reach 0.5 lb per sq in, as compared with the far greater press under which gas exists in the coal.

Outbursts of CO_2 from the strata have been of importance in certain coal basins of Central France; miners smothered, and masses of coal and dust dislodged, and even blown to the surface. As outbursts are especially liable to result from blasting, shots are sometimes fired electrically from the surface; refuge chambers are also provided. Outbursts are due either to heat of igneous intrusions or to acid waters acting on limestone; the latter is probably true of CO_2 sometimes found in fissures and crevices, in the S W Wisconsin lead and zinc district. Cripple Creek mines have had

difficulty with CO_2 filling fractures of volcanic rocks after drainage, until it could be kept back by bulkheading and blowing in air under pressure (9).

Nitrogen occasionally emanates from the strata. A well in Washington and some in Texas gave off almost pure N. The natural gas used in Fort Worth, Dallas, and other Texas cities, contains about 14% N. Generally an excess of N in mine air is due to absorption of the O by coal or carbonaceous material.

Gases from coal mine fires. After the incipient stage, fires in collieries are too serious to permit men, other than fire-fighters, to work; but in the non-gaseous mines of central Ill, Iowa, and Mo, spontaneous fires are common, and when shut off by fire walls are apt to be disregarded, though some fumes often escape through or around the walls. These gases are chiefly CO_2; frequently accompanied by CO which would cause trouble if ventilation were not properly managed. Similar conditions prevail in some thick-bed anthracite districts, where fires in abandoned mines threaten adjacent active mines. Spontaneous fires are so common in the thick coal bed of So Staffordshire, that fire-stopping material is kept on hand at entrance to panels.

Gases from fires in metal mines, as in the carbonaceous and sulphurous roof shales of some Michigan iron mines, may be serious when the fires can not be extinguished by ordinary means. Such gases consist of CO_2, SO_2, and some CO and H. In rich copper sulphide ores of Ariz and Mont, fires have sometimes started spontaneously in old stopes, producing much SO_2 from burning ores, and CO_2 and CO from burning timber.

Hydrogen sulphide (H_2S) may be produced by the heating of sulphurous coal in a mine fire, by action of acid waters on sulphide ore, or by the reducing action of bacteria on sulphates in stagnant water. It may also occur in the products of explosion of black powder. H_2S is very soluble, but may be liberated in dangerous quantities by stirring up stagnant water in traversing old mine workings.

Gases from internal-combustion engines, as gasolene-driven pumps, hoists and locomotives. CO_2 and CO are produced in amounts varying with carburetor adjustment and size of engine. O. P. Hood (14) states, as result of tests on 2 types of gasolene locomotive, that the CO in the exhaust under worst conditions is about 13.5%, while under normal running conditions it seldom exceeds 6%. For safety and health the max should be used in estimating the quantity of air required to dilute the gases to a safe point; or conversely the size of engine may be limited to the max air current possible to maintain. Engines driven by inflammable liquids should not be used underground unless a definite vol of air current is maintained, while engine is running, sufficient to dilute the max output of CO under worst conditions, down to 0.02% or less (Art 5). In Europe disasters therefrom have led to their replacement by storage-battery locomotives, or by the effic Diesel locomotives, which give off little CO (15). Diesels for mine use have devices to spray the exhaust, and prevent back-firing flame from igniting explosive mine gases.

Solid impurities in mine air. ROCK DUST fine enough to remain suspended for a time in air currents (26, 27), is produced by: (*a*) drilling dry holes or "uppers," with ordinary machine drill; (*b*) blowing out holes with compressed air; (*c*) squibbing, or enlarging the bottoms of holes to hold large charges; (*d*) adobe shots (Sec 4, Art 9) or shallow blockhole shots; (*e*) loading dry ore by shoveling or from chutes. Causes *a*, *b*, *c*, and *d* may produce much dust.

To keep rock dust out of the air (referring to above items): (*a*) Water sprays alone are inefficient. In collaring, use full bore of the hose to supply water. Wet the face thoroughly before drilling begins. Water-injection drills are now generally used. Devices to cover the hole while drilling, the bits passing through them, have had limited success. Those connected by a suction hose to dust traps for filtering out dust, though good, are usually limited to headings. Respirators (wet sponge or cloth) catch only part of the dust (tests of Bur of Mines). Fine dust, less than 10 microns diam, remains suspended for hours and is dangerous to breathe (26, 27). Respirators throttle breathing and may cause rebreathing some CO_2 of exhaled air. Masks (developed from war masks) are better, but do not intercept finest dusts and are cumbersome. Recently they have been improved in filtering effic and 9 types are approved by U S Bur of Mines. Latest practice in So Africa, Australia, and most metal mines in U S: 1. Use water drills. 2. Wet working places by hose. 3. Turn on "water-blast" atomizers after blasting (46). 4. Use positive ventilation, with strong air currents to sweep away fine suspended dust. (*b*) Do not blow out dry drill holes; use scraper. (*c*) Do no squibbing and blockhole shooting while men are working nearby; do it at shift end, or midshift; or, after wetting down and cleaning dry dust out of hole; for adobe shots, dynamite should be covered with damp clay or dirt; with no tamping. (*d*) Dust from shoveling is prevented by sprinkling. Coal dust comes from: (*a*) cutting coal by pick or machine; (*b*) blasting, especially "blasting-off-the-solid"; (*c*) loading, especially when by loading machine; (*d*) conveyers and chutes; (*e*) in haulage by grinding of coal jolted under car wheels. REMEDIES: for (*a*), wetting the face before cutting, and spraying cutter bars; (*b*) wetting face before blasting, having the face well

undercut or sheared and firing one shot at a time; (c) wetting broken coal in mechanical loading; (d) use of suction dust-collectors at loading chutes; (e) automatic car sprinkling at gathering sidings. Greater recent use of mechanical loading has increased dust. Coal dust is distributed by ventilating currents; hence need of using water at face, and rock-dusting with limestone or other non-silicious dust in haulage ways (Art 14). Coal dust in light clouds in the air, unaccompanied by silicious dust, is not injurious (Art 5).

Inflammability of coal dust. Bituminous and lignite dusts, when stirred into the air by blasting, CH_4 explosion, wreckage of cars, or fall of roof, may be ignited by flame of a non-permissible explosive, or an electric arc, or even by a torch flame (Art 14). Inflammability increases with percentage of CH_4; decreases when mixed with non-combustible dust. Anthracite dust is not explosive. Remedies to prevent bituminous dust explosions are similar to those cited in preceding paragraph. Inert content of mixed coal and rock dust should exceed 60%, and 5% more for each per cent of CH_4 present (Art 14).

4. TEMPERATURE AND HUMIDITY

Temperature of air in mines approximates the temp of adjacent mine walls. A continued lower or higher temp of air current, even if rapid, modifies that of the walls only a few degrees, to a max of about 10° F.

Seasonal changes of temp affect the temp of the strata for a comparatively short distance below surface (rarely more than 20 or 30 ft, Art 2), unless open fissures admit air currents or streams of water. The Alaska gold-bearing gravels remain frozen the year round, below a few ft in depth, though vegetation in summer is abundant.

Temperature due to locality. Though frost goes to considerable depths in polar regions, geologic conditions have much greater effect on temp of the strata, at depths over 200 ft, than climatic conditions. In the Lake Superior copper mines, the walls are cool at much greater depths than in most mining districts.

Changes of temperature with depth. Rate of increase of temp varies widely.

In Great Britain (25) the temp gradient (depth per deg F rise in temp) is 54 to 95 ft; in Belgium, 56 to 93 ft (isolated case, 22 ft); in Germany, 63 to 67 ft. In Alpine tunnels the temp gradients, measured from mountain crests, are: Simplon, 72 ft; St. Gothard, 84.7 ft; Mont Cenis, 80.4 ft. In Comstock silver mines, Nev, the gradient is stated as only 29 ft per deg, due to hot springs; in Ohio-Tonopah mine, Nev, 33 ft per deg; Grass Valley mines, Cal, 107 ft; Rand mines, Transvaal, 167–220 ft per deg. Deposits due to action of thermal waters, in districts where this action is still going on, will have higher and more variable rock temp than where such changes have long since ceased, or in uncontorted sedimentary strata where increase in temp is due to thickness of covering or former igneous intrusions. Increase of temp is often the controlling factor as to depth attainable (Table 4a). At great depths, even where the temp gradient is low, mining difficulties increase. In coal mining the seams are in sedimentary formation and, while the temp gradient is often high, intrusions have been rare. The deepest mines in Belgium and England are about 4 000 ft, with rock temp below 100° F; conditions readily met by strong ventilation. In the shallower coal mines of the U S, the temp problem is not yet serious.

Table 4a. Mine Temperatures and Rock Temperature Gradients

Mine	Country	Mineral	Depth of temp reading, ft	Rock temp, deg F	Rock temp gradient, ft per 1° F
(a) in Lancashire	England	Coal	3 783	113	59.6
(b) Morro Velho	Brazil	Gold	6 426 8 051	118 130	120
Village Deep	Rand, S A	Gold	7 062	97	220
(c) Robinson Deep	Rand, S A	Gold	3 848 6 214	80.2 93.0	185
			7 349 7 833	99.8 102.7	167

Champion Reef	India	Gold	6 194	119	141
(e) Calumet & Hecla	Mich	Copper	3 562 5 679	74.8 95.3	108.5
(f) Magma	Superior, Ariz	Copper	4 000	140	53

(a) Lancashire mine, unnamed. Observations reported 1933 stated this was highest temp yet found in British mines. In 1935, a temp of 115° F was recorded in a deep Lancashire mine.

(b) Surface cooling plant (See 14), installed 1921, reduced wet-bulb temp 10° F. Another cooling plant at 6 000-ft level in 1929.

(c) Surface cooling plant installed 1937 (W. H. Carrier, *Trans* A I M E, Feb, 1938). Wet-bulb temp in main airway at 8 000 ft, which had been 85° F, was lowered 8 to 9° F (See 14). For temp in deep bore holes, see *Jour* Chem, Met & Mining Soc S A, Mch, 1936.

(d) Descriptive article, *Mine & Quarry Eng* (London), June, 1938.

(e) Fisher, Ingersoll and Vivian, A I M E *Tech Pap* 481, Feb, 1932.

(f) C. B. Foraker. *Jour*, Min Cong, Nov, 1937. Cooling plant installed at 3 600-ft level.

Temperature of mine atmosphere may locally rise above the wall temp because of: (*a*) inflow of hot waters; (*b*) active fires of broken sulphurous ores, or of coal, carbonaceous shales, or timber; (*c*) oxidation of sulphurous ores, coal or shales, too slow to raise the temp to point of ignition of the material; (*d*) decay and oxidation of timber, due to fungi and bacteriological action, which is very active in crushed timber, as in the block-caving system, and where the air is warm and humid. Tests in the Monongah colliery, W Va, showed that in traversing 4 000 ft of double entry, 30 000 btu per min were transferred to the ventilating current. In other cases intake air averaged 27° F, aver velocity 453 ft, volume, 66 432 cu ft per min; at 1 400 ft from the entrance the aver temp of the air was 45° F, and at 3 800 ft 50°, or within 5° of the temp of the return current (Sec 14).

Seasonal temperatures have little affect on the temp in large mines. Tests lasting 1 year, in 20 Illinois collieries, showed in one a max fluctuation in temp of return current of only 1.5° F, due partly to relative tightness of stoppings and doors (1). In any climate, workings below 50 ft under solid strata, and over 1 000 ft from openings, are not sensibly affected, unless there is a strong current.

(*a*) = longwall mines; others are room and pillar.

Hot metal mines, Comstock Lode, Nev. According to Young (25), air entering at 46° attained a temp of 71.6° at 5 200 ft from the Sutro tunnel entrance, 91.9° at 10 000 feet, and 95° at 13 000 ft, in a swift air current. Aver water temp entering the tunnel was 94 to 95° F, which presumably represented aver wall temp at that level. Locally the water temps were much higher.

Adiabatic compression of intake air, produced by wt of the column of descending air, causes increase in temp of 5.5° F per 1 000 ft depth; independent of veloc of air-current. Conversely, uptake air loses heat (see Sec 14). If rock temps were the same at all depths of a shaft, the heat due to this compression would exceed that of the rock and flow into the strata, which acts as a heat reservoir with constant temp (for any specific locality) at any given depth. But rock temp generally rises faster with increasing depth than the temp of air current. In absence of a hot igneous mass, or hot water, virgin-rock temp gradient below 20 or 30 ft from surface is nearly constant for considerable depths, but varies widely in different regions, and normally increases slowly with depth (Table 4a).

As adiabatic compression of dry air theoretically causes a temp rise equivalent to a rock temp gradient of 182 ft, heat flows from the strata into the air current in most deep mines; the rock walls gradually cooling to a thickness depending on their thermal conductivity, which is low (for conductivity of rock, see Smithsonian Physical Tables). In a mine 6 000 ft deep the adiabatic compression-increase of temp is 33° F; hence, if the aver surface temp is 65°, that at 6 000 ft would be (theoretically) with dry air 98° F. Besides the influence of temp of the walls on the air temp, is the effect of cooling the air current by vaporizing the moisture encountered in its passage. In most districts the intake air is less than 50% saturated, and, at 65° F, carries about 4 grains water vapor per cu ft. If the current descended through a dry shaft and attained a temp of 98°, it could take up about 14 grains more water in becoming saturated, and evaporation of this water would lower the air temp about 10°. This would further cool the mine walls, but cause bad physiological conditions (19) (Art 5).

Reduction in temp of mine air can be effected locally by spraying with cold water (with the disadvantage of increasing the humidity), or by active circulation of cool air. At long distances from the intake the latter plan will reduce the temp of working places only a few degrees, rarely as much as 10°. But, if certain places in a mine are heated by fires or by crushing and pressure, as in the caving system, the air can be improved by diverting a current of cooler air from a neighboring working. This is done by brattices or pipes, sometimes aided by supplementary blowers or "booster" fans (Sec 14). The return air from a hot area should pass direct into the main return current. This method has not been as much employed in metal mining as it should be. In coal mining, intermittent use of auxiliary fans or blowers in gassy or slightly gassy mines is dangerous, as CH_4 accumulated during a stoppage may later be blown to a point where there is a source of ignition. Auxiliary fans driven by open motors have also caused explosions; European practice permits them in headings, if driven by compressed air and operated continuously.

Refrigeration of mine air in deep, hot mines has been much discussed for use in mines too hot to get material advantage from such ventilating currents as can be forced through extensive workings or restricted passages. As mentioned above, the limiting depth of mining is determined by the air temp and humidity obtainable (for details and Bib, see Sec 14).

Humidity of air in metal mines varies more than in collieries. Absolute humidity (wt of water vapor per unit of volume) of an intake current cooler than the mine temp never diminishes, and unless already saturated is increased by presence of water. As the temp of mine walls and the contiguous air increases with depths, relative humidity decreases unless water is encountered.

The great variability in relative humidity possible in a metal mine is shown in the Comstock mines, Nev (25). In one tunnel, where intake air did not come in contact with drainage water for first 6 800 ft from portal, the moisture probably came mainly from walls. Rate of evaporation was 43.8 grains per hr per sq ft of exposed surface. From 6 800 to 10 000 ft, the air current was in contact with drainage water and became almost saturated. On basis of 6 ft aver width of exposed water surface, the accession of water vapor was 798.5 grains per hr per sq ft. Relative humidity of working places, 22 to 100%.

Control of relative humidity, when approaching saturation, is comparatively easy. In coal mines this has been used to prevent drying out of inflammable coal dust. VENTILATING CURRENT may be humidified by spraying, separately or combined with artificial heating of the intake by steam pipe coils, or steam jets (64). This method has been employed in So Wales and certain American coal mines to make coal dust less explosive, but as the effect of wetting was limited to a short distance from the intake entrance, and failed to prevent explosions, rock-dusting was successfully substituted. Heating the intake by steam coils at some Middle West mines, where coal is hoisted in intake shaft, has improved winter conditions for men working in shaft bottoms.

Increase in temp *gradient* with depth, found in the Robinson Deep (Table 4a), is confirmed by tests with special recording apparatus in U S oil and gas wells, probably representing original rock temps better than tests in mine workings, where wall heat is lost through constant ventilation. See Table 5a and Bib 19, 20.

(*a*) Estimation of Temperatures at Moderate Depths in the Earth's Crust. C. E. Van Ostrand, *Trans* Amer Geophysical Union, 1937.
(*b*) Figures for different depths are based on the least-square adjustment of the straight-line equation, $y = a + bx$, where y is the Fah temp and x the depth.

Lowering relative humidity is difficult, and in most cases the only practicable way is to force cool air to working places through pipes, so it may not absorb moisture en route; or, by refrigerating mach'y, to condense the moisture in air current.

Most coal mines in the U S are comparatively shallow, and the temp of working places rarely exceeds 75° F, at which saturation is neither uncomfortable nor objectionable (Art 5). At depths exceeding 3 000 ft, as in certain coal mines in Lancashire, Belgium, France and Germany, high air temp occurs, and the miners' shifts are shortened when wet-bulb temp exceeds about 85° F. On the Comstock lode the temp in some drifts reached 130° F (25).

MINE HYGIENE

5. EFFECTS ON HEALTH OF IMPURITIES AND CONDITIONS OF MINE AIR

Quantity and quality of air for breathing. For good health the percentages of O, N, and CO_2 should not vary widely from normal, though in the matter of wt or density of air, the lung action adapts itself readily to variations produced by changes in press from 0.5 atmosphere at high elevations to 3 atmos in some caissons.

In deep diving a press of 6 atmos has been reached (Art 16). In case of low press, since there is less O in a unit of vol, the lung action must be quicker. N is inert and a diluent only; the same vol and wt is exhaled that was inhaled, when both are measured at same temp. O is the life-supporting element in air, and by its combination with the C of food, through agency of lungs and blood, maintains bodily heat and energy. The irritating effects of O are found only after 48 hr continuous exposure to an atmos containing over 80% O_2 (30).

Table 6. Quantity of Oxygen Consumed and Given off During Resting and Working, and Number and Volume of Respirations, at 760 mm Barom and 32° F. (J. S. Haldane)

	O_2 consumed per min, liters	CO_2 exhaled per min, liters	$CO_2 \div O_2$, %	Air breathed per min, liters	Av vol of each breath, liters	No of breaths per min	Inhaled air consumed, %
Rest in bed	0.237	0.197	0.83	7.7	0.457	16.8	3.08
Rest, standing	0.328	0.264	0.81	10.4	0.612	17.1	3.14
Walking 2 miles per hr	0.780	0.662	0.85	18.6	1.270	14.7	4.17
" 3 "	1.065	0.922	0.87	24.8	1.530	16.2	4.28
" 4 "	1.595	1.395	0.88	37.3	2.060	18.2	4.25
" 4.5 "	2.005	1.788	0.89	46.5	2.520	18.5	4.38
" 5 "	2.543	2.386	0.94	60.9	3.140	19.5	4.15

U S Bur of Mines made tests closely agreeing with above figures. The O consumed is about 20% of that inhaled. Tests of breathing nearly pure O under different conditions of work showed a reduction of 2.11 to 5.44% O, indicating consumption of O is not affected by enriching the air with O. The proportion of CO_2 exhaled to O consumed (the respiratory quotient) increases from 0.8 for a person at rest to 0.95 for a person at hard work, and when over-exerting may rise above 1.00. Ordinarily a person uses only the upper portion of the lungs; but during violent exertion the full lung capacity is required, increasing the respiratory quotient. Though Table 6 indicates that less than 3 liters of O per min is generally required, tests with O rescue apparatus show that to take care of especial exertion 3 liters of O per min should be supplied. This is equivalent to 14.5 liters of air, or about 0.5 cu ft per min, of which the O has been completely consumed, but this is never the case, as indicated above. If in a closed space, like a mine, the O is to be maintained with a loss no greater than 1%, the air supply per man must average about $0.5 \times 20 = 10$ cu ft per min; for draft animals, about 30 cu ft per min.

Classification of conditions and impurities, as to effect on human system:

(*a*) Conditions due to altitude, high temp and humidity; enervating, but not dangerous unless extreme.

(*b*) Impure air, not toxic, as air depleted of O; not dangerous unless O deficiency is great.

(*c*) Gaseous impurities having toxic effect; not serious unless from long exposure to large quantities.

(*d*) Gaseous impurities acutely poisonous, and difficult to recover from.

(*e*) Solid impurities leading to lung diseases.

Effect of high altitude: deep and rapid breathing and marked increase in number of red corpuscles. As much coal and metal mining in the U S is done at elevations between 5 000 and 11 000 ft, and some metal mining up to 13 000 ft, the consequent decrease of O

per unit of volume to 1/3 or nearly 1/3 that at sea level reduces working effic. Men should be examined to see that their heart and lungs are sound before giving them employment.

Effect of high temp and high humidity within certain limits of temp. Either condition alone is bearable, but when combined, discomfort or injury to health results. At moderate temp, say under 70° F, relative humidity up to 100% is unobjectionable, and a nearly saturated atmos is not serious at a temp of 80°, in a good current of air; otherwise it is oppressive and a day's work rapidly diminishes with a further rise in temp and saturation.

Haldane states: "At temp of 93° in still, saturated air I found that, though I was stripped to the waist and doing practically no work, my temp rose 5° in 2 hr, and was still rising rapidly when I found it necessary to come out." Church (monograph on Comstock mines, 1880) reports that "the immediate results of high temp and hot vapors are absent-mindedness, dizziness, fainting, vomiting, and as graver results, insanity and death." Casualties in the Comstock mines at that time positively traceable to heat were 12% of the whole. Probably heat increases the bad effects of powder fumes and natural gases. Lord, referring to the same mines (1883), states that the ultimate effect of extreme heat is not easily noted. Power of recuperation appears to be extraordinary; and unless the strain is intense and frequent, there may be no lasting injury. Young states (1909) (25): "Local physicians say that the aver working life of Comstock miners approximates 25 years, and that they show no greater susceptibility to disease than the town residents." Miners stripped to the waist should keep out of cold drafts; on passing from a hot to a cold place a heavy coat is used. Wet clothes are removed before going to surface, or trousers and coat are worn over them. Miners take hot and cold showers after coming off shift. Frequent drinking of, and bathing hands, wrists, arms, and head, in ice water are resorted to. Temp of 95 to 105° F, with 50 to 70% relative humidity, and air moving 200–300 ft per min, does not prevent effic work; temp of 110 to 115°, with above conditions, considerably reduces effic. Same temp, at high humidity and moderate air veloc, greatly impairs effic; higher air veloc renders workings more bearable, but shifts must be short. Physiological tests of effect of high temp and humidity, with and without movement of air, made at Butte by Sayers and Harrington, gave further precise data (19). They found that the bad effects of almost saturated air, with temp between 90° and 98° F, are much less in moving than in still air. But, at 98.6° to 100° F, there was no benefit from saturated air in motion, even at high veloc; and apparently some disadvantage. It would thus appear that the economic LIMIT OF DEEP MINING is reached when the wet-bulb temp reaches blood-heat (98.6°).

In work at high temp and humidity, the Safety in Mines Committee, England, found that sweating removes salt from body secretions and weakens the subject, beside causing the effects previously mentioned. Total chloride given off from the skin may be a measure of amount of sweat. To supply the deficiency, salt may be taken into the system through liquids and foods. In the Crown Mines, Rand, barrels of a saline solution are distributed through the workings, containing 1 oz lime juice and 10 oz salt to 60 gal water (17). In some U S mines, tablets of salt in pocket containers are furnished the men.

Gaseous impurities without toxic effect, but causing oxygen deficiency, include N and CH_4. EFFECT OF OXYGEN DEFICIENCY near sea-level or below it is the same as reduction of O due to lower atmos press; as in mines at high altitudes.

A press of about 1/5 less than at sea-level, say 5 000 ft, is not noticeable; but at 1/3 less (10 000 ft) violent muscular exertion causes rapid breathing and heart action; continuous exertion causes faintness. The O present in a unit of volume at Leadville (10 000 ft) is the same as that in a sea-level mine, where the O has been reduced from 20.0 to 13.8%. At top of Pike's Peak (14 147 ft) the barometer registers 17.4 in, and the O present corresponds with but 12% O in air at sea-level. People become acclimated at these and higher altitudes. In Perú, Bolivia, and Northern Chile, there are many inhabitants above 15 000 ft.

Haldane states that a person not exerting himself will rarely notice anything unusual until the O falls to 10%; breathing then becomes deeper and quicker, pulse faster, and the face somewhat dusky. At 7% there is usually distinct panting, with palpitations, and the face assumes a leaden blue color; the mind becomes confused, and the senses dulled, though the subject may be unaware of the fact. IN AIR CONTAINING NO O, loss of consciousness occurs within 40 sec, without warning symptoms. Miners accidentally putting their heads up into a roof pocket of CH_4 have almost instantly become unconscious. In a test made at the Pittsburgh station of U S Bur of Mines, on one of the rescue corps, WHEN O WAS REDUCED TO 7%, in a mixture of air and N, the subject lost consciousness without much warning. The test being immediately stopped, the subject at once recovered consciousness in the open atmosphere, feeling no real distress until the next day, when he was decidedly unwell. Haldane says: "Loss of consciousness in air deprived of O is quicker than in drowning; not only is the supply of O cut off, but that previously in the lungs is rapidly removed; loss of consciousness is quickly followed by convulsions, then by cessation of respiration." In the case of cats and dogs, the heart continues to beat from 2 to 8 min; in men this period is probably much longer. SO LONG AS THE HEART BEATS, HOWEVER FEEBLY, ANIMATION MAY BE RESTORED BY ARTIFICIAL RESPIRATION. This may have to be long continued, and the respiratory center may not soon recover. Whereas CO_2 in excess carries its own warning (distinct panting) before danger is imminent, O may be so deficient as to imperil life before a person realizes it (32).

Since an ordinary oil-fed lamp flame is extinguished at about 17% O, the diminishing and flickering of the flame warns that the O is below normal. An acetylene flame is not a good guide to a condition of the local atmos dangerous to life, as it will burn when only 12 or 13% O is present.

Gaseous impurities having toxic effect, but not serious unless with long exposure. Excess of CO_2 is frequent (Art 2, 3). Slight distress begins when it exceeds 1 or 2% of the atmos, but is not serious until over 3%. WITH 3 TO 4% CO_2 BREATHING IS LABORED; with 6%, marked panting and increased frequency of pulse or palpitation of heart; throbbing head and flushed face; headache is particularly noticeable on return to fresh air. With 8 to 10% there is narcotic effect.

Haldane states that AT 11% CO_2 UNCONSCIOUSNESS OCCURS, but death does not result unless there is exposure to this amount for some hours. When CO_2 drifts out from old workings, owing to its being heavier than air, it sometimes lies along the floor, diffusing but slowly in weak air currents; hence a person overcome should have his head held up until he can be taken to fresh air. But, since irrespirable gases from fires may include much CO_2, and being heated and containing aqueous vapor generally drift along the roof, persons not protected with breathing apparatus should keep their heads down. CO_2 in itself has little effect on a lamp flame, but extinguishment of a flame indicates the deficiency of O which always accompanies presence of CO_2. Remedy for effects of CO_2 is prompt removal to fresh air, in serious cases administering O, or first aid treatment or both (Art 20).

Acutely poisonous gases. For their nature and sources, see Art 2 and 3; their hygienic effects are as follows. CARBON MONOXIDE (CO) is the commonest of the deadly mine gases. It is daily encountered in mines having weak ventilation, when blasting is done during shifts; also in fighting mine fires, and in return air currents from imperfectly sealed fire areas. The latter conditions are more prevalent in coal mines in which gob fires occur. CO always exists in dangerous amounts in the afterdamp of explosions (Art 14).

Oxygen necessary to maintain life is absorbed in the lungs through the agency of HÆMOGLOBIN (red-colored matter of the blood); O forms an unstable chemical compound with hæmoglobin, and is thus carried to the tissues. Hæmoglobin has much greater affinity for CO than for O (250 times greater, Haldane says), and when it has taken up CO can no longer take up O. It becomes more or less saturated in a ratio proportionate to the percentages of CO and O present, taking into account the relative affinities for these gases. When the atmos contains 0.04% CO, hæmoglobin finally becomes $^1/_3$ saturated; with 0.08%, $^1/_2$ saturated; with 0.16%, $^2/_3$ saturated. An average man has about 3 liters of blood, which is capable of combining with 600 cc of CO. If the atmos contains 0.2% CO, and the man is at rest, he breathes about 7 liters of air per min, of which 5 liters reach the lung cells. As he absorbs not more than $50 \times 0.2 = 10$ cc CO per min, it will be 0.5 hr before his blood becomes half saturated. In an experiment in which 0.2% CO was present the hæmoglobin did not reach 50% saturation for 70 min.

A percentage of CO far too small to form a "cap" in a safety lamp, or to be at all noticeable (Art 9), *may be very dangerous*. Men often become unconscious without warning.

In recovery work following an explosion in Alabama, an entire party waiting at a base was nearly overcome, and barely rescued by diverting a fresh current of air to them. Though the safety lamps were burning properly, and no one had noticed the effect on himself, several finally sank back unconscious. With 20% saturation there is tendency to dizziness and shortness of breath on exertion; with 50%, it is scarcely possible to stand, and slight exertion causes unconsciousness. Symptoms resemble those caused by alcohol. If death approaches gradually, the hæmoglobin is usually about 80% saturated with CO. The percentage of CO that is fatal if breathed for a long time varies with individuals. Anything above 0.15% is dangerous, and 0.4% may quickly cause death. For continued exposure 0.03% or over is unsafe, as the effects of CO are to an extent cumulative because of the greater affinity of hæmoglobin for CO than for O.

In case of persons rescued after becoming unconscious, recovery is often slow due to injury to the tissues, and serious ailments sometimes ensue. A person may not realize he has been exposed until he reaches fresh cool air, when he may suddenly collapse. Saturation of hæmoglobin with CO gives the blood a pink color, the greater the saturation the deeper the color, and this continues after death; so that a person killed by CO has bright red blood instead of the dark colored blood of one dying from suffocation or violence. In N Y–N J vehicular tunnels under Hudson River, extensive tests were made to determine safe limits of CO (from motor vehicles) in ventilating current. It was found that 0.04% for an exposure of 1 hr was safe (30). Tests on men and animals at Bur of Mines Experiment Station, Pittsburgh, Pa, showed that CO saturation up to 30% was disposed of by the body only after several hr, varying with activity of the man (33).

Remedy for CO poisoning is prompt removal to fresh air, in a warm place, and administration of pure O. If patient is breathing faintly or not at all, give first aid treatment and administer O.

Immediate indications of small percentages of CO are given by the behavior of canaries and small animals. Canaries are so sensitive and certain that they have been officially approved for rescue work in Great Britain, and in the U S by the Bur of Mines. Burrell found that canaries are much more

Table 7. Burrell's CO Tests on Canaries (54)

CO, %	Effect
0.09	Very slight distress at end of 1 hr
0.12	Weaker at end of 1 hr than after exposure to 0.09%
0.15	Distress in 3 min. Fell from perch in 18 min
0.20	Distress in 1.5 min. Fell from perch in 5 min
0.29	Fell from perch in 2.5 min

sensitive than white mice (Table 7). A canary will drop from its perch in an atmos in which a man could remain for some minutes without serious effect, though such warning should cause immediate withdrawal from the place, unless breathing apparatus is used. In a chamber containing 0.25% of CO, a canary showed distress in 1 min and fell from its perch in 3 min. Burrell remained in this atmos 20 min, which caused a slight headache. After withdrawal to fresh air he had nausea and headache for several hours.

Hydrogen sulphide (H_2S) is more acutely poisonous than CO, but is rarely found in mines. According to Lehmann, air containing 0.07% will cause death after 1 hr exposure; in an experiment on a man, alarming symptoms were produced within a few minutes in breathing air containing 0.05%. He found 0.2% would kill dogs and cats in 1.5 min. Haldane says it acts locally as an irritant, and after absorption affects the brain and other parts. It makes no characteristic change in the blood. With very small percentages the first symptoms are irritation of the eyes and air passages; with more, eye inflammation results, accompanied by intense pain, particularly the next night; with 0.05%, giddiness, vomiting and catching of breath are soon caused. Men are quickly stricken on entering an atmos containing much H_2S, as in sewers.

Oxides of nitrogen or " red fumes " (chiefly NO_2) must be carefully guarded against in tunnels or mines using large quantities of dynamite, since they may result from a weak detonation of a blasting cap, causing the dynamite to burn.

In a western tunnel, 13 men exposed to NO_2 by a change in the ventilating current experienced a slight choking, nausea, profuse perspiration and headache, but revived on reaching open air. But they soon began to cough up bloody mucus, and showed NO_2 poisoning. In 3 days 9 men died. The others, including the rescuers, were ill for months. As many as 20 lives have been lost at one time from NO_2 fumes produced by the burning of a box of dynamite. Air containing enough NO_2 to produce irritation in the nose or air passages is very dangerous. The after-effect is often an intensely acute bronchitis. Hence avoid going back too soon into dynamite smoke, if there is any characteristic smell of NO_2. Men who have been exposed to either NO_2 or H_2S, should, after removal to good air, be placed under a physician's care.

Siliceous dust (Art 3) causes phthisis (miners' consumption or silicosis), whereas dusts from limestone, shale, coal and some metallic ores do not. Mortality from siliceous dust is far greater than from all mine accidents. It is very high in the cherty " sheet-ground " of the Joplin zinc mines, where studies by U S Bur of Mines and U S Public Health Service were instituted and marked improvement made. The siliceous-dust problem in Butte copper mines is complicated by poor ventilation, high temp and humidity.

Physiological effects of breathing SiO_2 dust. By inhalation, the coarser particles are caught by mucus in nose, throat and pulmonary passages, and expelled by coughing; but particles of less than 10 microns diam enter lung cells and cause lesions. Fibrous nodules form, increasing in number and size with exposure, producing general fibrosis, which seals cellular lung tissue and checks aeration of the blood. Breathing becomes increasingly difficult, with susceptibility to pneumonia or tuberculosis. Following terms are used for lung diseases (26): PNEUMOCONIOSIS, covering all dust diseases, fibrous or non-fibrous; SILICOSIS, caused by free SiO_2 or quartz dust; SILICATOSIS, by silicates (distinct from the sharply defined, coarse, nodular fibrosis due to SiO_2 dust); ANTHRACOSIS (anthraco-silicosis), a coal miners' disease, is silicosis modified by presence of coal dust; SIDEROSIS, a dust disease found in some metal workers; ASBESTOSIS, caused by breathing asbestos dust (silicate of magnesia) (27, 28).

Dust-disease symptoms are arbitrarily divided into 3 stages by Amer Public Health Assoc, " for convenience of description and possible compensation purposes ": **Stage 1**, man may look well, but has slight shortness of breath on exertion, dry cough and recurrent colds, some indication in radiograph of fibrous nodules; Stage 2, definite shortness of breath, pains in chest, dry morning cough and sometimes vomiting, recurrent colds, chest expansion decreased, movement sluggish, capacity for work reduced, radiograph shows mottling in lung fields; Stage 3, distressing shortness of breath, cough more frequent, expectoration generally slight (sometimes copious), capacity for work permanently impaired, forced inspiration, pulse rate increased, heart may be dilated, radiograph appearances accentuated, mottling more intense, nodules larger, large shadows corresponding to areas of dense fibrosis (27).

Quantities of rock dust in mine air. Thomas and MacQueen (Dolcoath mine, Cornwall, 1904) found the amount of dust in the air, from dry, machine-drilled holes, to be from 0.05 to 1.14 mg per liter, aver 0.46 mg; in wet holes, aver was 0.22 mg; in hand-drilled dry holes, 0.01 to 0.41 mg; in filling cars with dry ore, 0.06 to 0.34; at a rock breaker, when sprinkler was not used, 0.92; in dead ends and raises, within 3 to 5 min after blasting, 0.06 to 0.34 mg (39). U S Bur of Mines found that in certain iron mines 208.85 mg dust per cu met of air were produced by dry drilling, as compared with 12.88 mg by wet; and dry drilling in " chert " produced 74.2 mg of dust as against 7.78 mg from wet.

Coal dust mixed with siliceous dust. Although it is generally agreed that anthracite and bituminous dusts do not produce lung disease, they do cause asthmatic conditions

when breathed over a long period. But, as anthracite seams are much folded and interbedded with sandstone, siliceous dust is often mixed with anthracite, especially in driving cross-headings and slopes, or brushing roof and floor (27). See also Art 3, under "Solid impurities in mine air."

In three anthracite mines the dusts contained the following percentages of total silica: all men in face workings, 11.1%; rock workers, 63.2%; all others underground, 33.7%; breaker workers, 13.5%. Size-frequencies, in microns, of dusts suspended in mine air: 0–0.49, 11%; 0.5–0.99, 60%; 1–1.49, 17%; 1.5–1.99, 7%; 2–2.49, 3%; 2.5–3.49, 1%. Number of particles per cu ft, to which certain inside workers were exposed was 6.9 millions; those at faces, an aver of 480 millions. Of the 2 711 workers in these mines, 22.7% were diagnosed as having anthracosis; in Stage 1 of the disease, 18.8%; Stage 2, 3%; Stage 3, 0.9% (46, 77). No cases found in a control group of miners, whose dust exposure aver less than 5 million particles per cu ft of air. Its prevalence in the entire working force was about 23%; among all except rock workers, less than 2% were affected when duration of employment was less than 15 years, regardless of amount of dust in the air.

Remedies. Strong ventilation and water sprays, and not using explosives for squibbing and pop shots, without first withdrawing the men or wetting down until the dust settles; also, use of masks, filter respirators, and dust traps (29). See also Art 3, under "Solid impurities in mine air."

Poisonous metallic dusts require special treatment. Precautions must be taken in case of $PbCO_3$ dust, to prevent lead poisoning, either by inhalation or through the mouth. In mining cinnabar (Hg_2S) great care must be taken to protect workmen from poisoning. Arsenical ore dust, said to cause cancer of the lungs, must also be guarded against.

Tests for quantity and character of mine air dusts: (*a*) filter through a tube, or granulated sugar in a tube; (*b*) count dust particles in a certain microscopic field (adopted in So Africa and elsewhere). Bur of Mines used this and also the IMPINGER method, by which dust is collected in water or other liquid from a unit vol of air (28). Dust over 10 microns is determined separately from dust under 10 microns. Sampling dust in mine air has been studied by Haldane, Sayers, and So African investigators (28). By the konimeter the particles of dust are rapidly estimated. A small quantity of the air is forced at high veloc upon a greased slide, on which the size and number of adhering particles are estimated by microscope. Modifications have been developed; such as a microscope attached to an instrument operating on this principle, so that the inspector can make determinations on the spot.

6. PERMISSIBLE PERCENTAGES OF IMPURITIES

Volume of air circulated. The older method, still general, is to increase the ventilating current by artificial means until the air in working places seems good. In coal mines in the U S, practice now requires circulation of a definite volume of air, based on number of men and draft animals. Under most state laws the air may be measured near the mine intake; in other states the more intelligent requirement prevails of measuring it in the crosscut or breakthrough nearest the face. The volume is generally 100 to 150 cu ft per min per underground employe, and 500 cu ft for each animal. In the anthracite region, owing to large amount of firedamp, 200 cu ft per man are required. In most collieries these limits are exceeded at the intake, but even in best practice, owing to leakage of stoppings or doors, only 65 to 70% reaches the last crosscut; in some mines, not over 15 or 20%. The stipulated volumes exceed breathing requirements, which are about 10 cu ft per min per man, and 30 cu ft for a mule or horse (Art 5). The added amounts are considered advisable for sweeping away firedamp, and to provide for leakage and slow oxidation of coal and shale. When firedamp is present, enough air must be circulated to prevent accumulations of gas.

Federal requirements for coal mine lessees (34) (made by Dept of Interior for Alaska, 1916, and modified in 1921 for public coal lands, chiefly in Utah, Colo, Wyo, Mont, N and S Dak, and Wash), not in conflict with Territorial nor State regulations: FOR INTAKE AND RETURN-AIR SYSTEMS, mech vent, reversible fans, housing and connections of noncombustible construction, and fans offset from mine opening and with explosion relief doors are required. GASSY MINES must have a duplicate engine or motor for the fan. In MINES EMPLOYING MORE THAN 200 MEN PER SHIFT, shafts must be fireproofed. When part of a mine employing MORE THAN 100 MEN PER SHIFT is over 4 000 ft from nearest airshaft, entries and airways reaching it shall be not less than 4 in number. Crosscuts or breakthroughs must not be over 100 ft apart. No rooms or branches are to be turned ahead of last crosscut. Stoppings in entry crosscuts to be of incombustible material and as airtight as possible.

Worked out and abandoned areas that can not be ventilated to prevent gas accumulations must be sealed off by strong fireproof stoppings.

When gas in sealed areas is under high press, vent holes must be bored to the surface; or, if not feasible, a pipe line made through a stopping and conducted into the return airway beyond any live working or haulage or traveling way.

Quantity of air to be not less than 100 cu ft per min per man, measured at the last entry crosscut of a split, and there shall be not more than 75 men on a split.

Quality of air shall be fit for work or travel. Air must not contain more than 1.25% CO_2, and not less than 19% O_2, as determined by sampling and analysis by U S Mining Supervisor.

A mine or portion of a mine shall be deemed gassy, as defined by State Inspector or by Mining Supervisor, if on 3 occasions not less than 2 days apart, 2% or more CH_4 is found in working places by safety lamp or chemical analysis, or if return air in any split shows 0.5% CH_4.

Electric-driven auxiliary or booster fans may be used in NON-GASSY MINES, where there is no inflammable material within 10 ft of motor. IN GASSY MINES these fans may be used only on intake air, the motor and switch being explosion-proof, and hourly inspection made. When auxiliary or booster fans are driven by compressed air, they may be used in either gassy or non-gassy mines. In a gassy mine, or one in which more than 0.25% CH_4 is present in the air current, trolley or non-permissible storage-battery locomotives may be used only in intake air, not receiving the return air of rooms or abandoned areas.

Classification of non-gassy, slightly gassy and gassy coal mines, recommended in 1926 by U S Bur of Mines (35, 90).

Class 1: a practically non-gassy mine, in which inflammable gas in excess of 0.05% can not be found by systematic search.

Class 2: a slightly gassy mine, in which (*a*) inflammable gas has been found* but in amount less than 2% in still air in any active or unsealed abandoned workings; or (*b*) inflammable gas can be found,* but in amount less than 4%, in some place from which the ventilating current has been shut off for a period of 1 hr; or (*c*) inflammable gas can be found, † but in amount less than 0.25%, in a split ‡ of the ventilating current; or (*d*) inflammable gas enters a split at a rate § of not more than 25 cu ft per min.

Class 3: a gassy mine containing more inflammable gas than specified for Class 2.

Modern practice in European coal mining countries has been to analyse the air in mine workings and return current. This has been extensively done by the French Mine Inspection service. In later FRENCH MINING REGULATIONS, no minimum vol of air is stipulated. The practice is about 3 cu m (106 cu ft) per min per man, but the return air of an advance heading must not contain more than 1.5%, and any other return, 1% of CH_4. IN GREAT BRITAIN, the vol of air is not specified, but certain max limits for impurities are set which require analysis for determination. No lamp or light other than a locked safety lamp (including permitted portable electric lamps) can be used when the air has normally over a 0.5% inflammable gas. If the percentage is 2.5 or over in the general body of air in a working place, workmen shall be withdrawn from that place. Other limits are that "a place shall not be deemed to be in a fit state . . . if the air contains less than 19% O or more than 1.25% CO_2." IN THE U S many collieries regularly analyse their return currents, but no chemical limits are set in state regulations for either coal or metal mining. IN SOUTH AFRICA, AUSTRALIA, AND NEW ZEALAND, mining commissions have recommended the establishment of certain max limits of impurities, temp, and humidity (Table 8).

Table 8. Limits of Impurities in Mine Air, Established Abroad by Analysis

	Minimum % O	Maximum %		Maximum temp	
		CO_2	CH_4(*g*)	Dry bulb	Wet bulb
Coal, French regulations of 1911	....	....	2.00 (*e*)	95° F (*d*)	86° F (*d*)
" British act of 1911	19	1.25	2.50 (*f*)	....	....
Metal, Transvaal	....	0.20	....	....	....
" New South Wales (*a*)	19	1.00	....	....	....
" Victoria	20	0.20	....	87°	80°
" West Australia	....	0.25 (*c*)	....	....	....
" New Zealand (*b*)	19	1.00	....	....	80°

(*a*) Proposed. (*b*) All operations in Thames and Waihi gold fields below 800 ft, 200 cu ft air per min per man: 500 cu ft per horse. In other districts, 150 cu ft per man; 500 cu ft per horse. (*c*) Except for 30 min after blasting. (*d*) Men forbidden to work when wet and dry-bulk readings are higher, except in case of necessity. (*e*) Return air of a working place must not contain over 1.5% CH_4 for advance headings, and not over 1% for all other currents. (*f*) Open lights must not be used when the return air contains over 0.5% CH_4. (*g*) Causing withdrawal of men.

* By employing an approved safety lamp, with flame drawn low, or approved gas detector, or by sampling and analysis with an approved gas analytical apparatus.

† By sampling and analysis with an approved gas analytical apparatus, or employing an approved gas detector.

‡ If there is but one continuous ventilating current, this shall be considered a split for purpose of this definition.

§ Determined by sampling, analysis, and ventilating-current measurement.

7. SPECIAL MINERS' DISEASES

Ankylostomiasis, or miner's anemia, practically the same as "hookworm disease," is due to a thread-like, blood-sucking worm. It attaches itself to the walls of the intestines by hooklets and sucking disks on its head. Length varies in different species and stages of growth; hookworm of southern U S (Uncinaria Americana) attains a length of 0.3 to 0.6 in (36).

The larva, from a microscopic egg, hatches in 1 or 2 days under favorable conditions of air, heat, and moisture, into an active worm-like embryo. Lacking opportunity to enter the human body, it may live a year in soil with suitable environment. HOOKWORM LARVA usually enters the body through the skin. If a person treads on infected ground with bare feet, or gets particles of it on hands or other parts, the larva begins to bore, especially in tender places, as between toes or fingers. This causes local inflammation, called "ground itch." The larva enters a blood vessel, and is swept through the heart into the lungs; but, being too large to pass through the lung blood vessels, bursts out into the air spaces. It wriggles along these and up the windpipe to the throat; then it is swallowed, entering the stomach. Or it may enter directly with infected food. From the stomach it passes into the small intestines, where it grows and becomes a hookworm. A person seriously affected will have several thousand worms clinging to the intestines. They bite into the tissues, suck blood, and more is lost by bleeding. A poisonous fluid given off by the worm causes anemia and catarrh of the bowels. Fortunately, it does not multiply in the intestines, but mates and the eggs pass out with the stool. If a person is not reinfected the worms ultimately die off, but their lifetime in the body is 10 to 15 years.

The disease is widespread in agricultural districts of southern states, where investigations have been made by Rockefeller Sanitary Comm. First observed in Europe about 1880, in driving the St Gothard tunnel. In 1896 many cases occurred in German coal mines, and the disease spread so rapidly that drastic gov't measures were enforced. By 1910, only 1% of miners were affected. Stringent precautions have been taken elsewhere in Europe, where the disease became epidemic.

Some coal mines in the southern states have been affected, but most U S mining districts are free from it. For more details, see 2nd edn of this Handbook.

Symptoms: pain in stomach, capricious and perverted appetite (as dirt-eating), obstinate constipation followed by diarrhoea, palpitations, weak and unsteady pulse, and, in fatal cases, dysentery, hemorrhages, and dropsy. A person seriously affected looks bloodless; skin is tallow-like, and body appears starved. Distended abdomen, sometimes with bloating of face, body, or legs, is characteristic among children, causing stunted growth, an old-appearing head, and other abnormalities; hence the importance of eradicating the disease, whether in a mining or other community. MILD CASES are more common and show less definite signs; positive knowledge is obtainable only by examining stool with a microscope for hookworm eggs.

Preventive means: use of shoes or boots without cracks or holes and leather gloves, cleaned frequently with antiseptic solutions; rigid sanitary precautions in and about mines and homes; neither children nor grown persons to go barefooted; compulsory use underground of portable sanitary latrines, daily cleaned and disinfected (Art 8). If the disease is suspected at a mine, there should be bacteriological inspection of defecations. Malefern, santonine, thymol, and other vermifuges are prescribed; epsom salts and thymol, taken alternately, are common remedies. The disease yields easily to treatment and mild cases are quickly curable.

Nystagmus, peculiarly a miner's disease, affects the muscles and nerves of the eyes, and causes oscillation of the eyeballs. In severe cases the victim is unable to walk straight, owing to an apparent rotary motion. Except in severe cases it is considered curable (37). ALLEGED CAUSES: insufficient light, and work of bottom-holing, or undercutting, while working in a strained position, with eyes fixed on one point. Another cause is said to be working in thin seams, where the head is thrown to one side, and looking diagonally upward to observe the roof as the miner walks along. Consensus of medical opinion is that the chief cause is poor lighting, as by safety lamps, particularly the older types, which have less than 0.6 c p. A German investigation showed that 91% of those affected used safety lamps; in 2 mines using open lights, only 0.35%.

Since the Workmen's Compensation Act became effective in Great Britain, nystagmus has been brought forcibly to the attention of the British mining industry. In 1909 compensation was allowed in 631 cases; 1910, in 956 new cases. General use of the pick in undercutting coal, and necessity in most European mines of regular use of safety lamps, made the disease serious in the past, but the improvement in portable electric lamps has brought improvement. It has been stated that men with nystagmus can not see a "gas cap" in a safety lamp, and hence were a menace in a gaseous mine. Dr. J. Court tested 106 miners; though 58 had nystagmus, all but 4 could detect 2.5 to 4% of CH_4 (15).

Remedy is better illumination. At Cockerill colliery, Belgium, twenty miners were each given 2 benzine safety lamps, instead of one, and examinations at end of a month showed general decrease

of nystagmus. To decrease danger of igniting firedamp by a broken safety lamp, it is better to provide only 1 lamp and a permissible storage-battery light, having reflectors that give a conical angle of lighting of at least 130°, and have aver strength of illumination greater than 1 c p (Sec 42, Art 15). See discussion, *Coll Guard*, June 6–Oct 31, 1930.

In U S few thin coal seams (say less than 36 in thick) are worked, and except in long-wall workings in Northern Illinois little hand undercutting is done. Safety lamps are used in few collieries, except by "fire-bosses" or "gas examiners;" open lights were the rule until supplanted by miners' permissible cap lamps with strong illumination. In gaseous mines, fire-bosses generally use elec cap lights, which are turned off while testing for gas with safety lamp. No extended investigation of nystagmus in U S has been made, but if there were many cases, they would have been noted. In Illinois, 1911, 500 miners were examined, without finding a case.

Color-blindness, though not specifically a miner's disease, is of serious importance in gaseous mines. The faint blue firedamp cap in the safety lamp, when the fuel flame is drawn down, is indistinguishable by those seriously afflicted with color-blindness; hence the advisability of examining for this defect all applicants for positions intrusted with detection of firedamp, as "fire-bosses," mine examiners, underground managers, and State mine inspectors, rejecting those who can not clearly detect the small firedamp cap.

8. UNDERGROUND AND SURFACE SANITATION (see also Sec 22)

Requisites underground, (*a* and *b* being summarised from Art 5):

(*a*) Good air, containing not less than 19% O, not over 1.25% CO_2, and no CO or other poisonous gases. Air temp should be below 80° F, if possible. In coal mines, for safety rather than sanitation, the body of air should contain not over 0.5% CH_4. These conditions are usually attainable by having good ventilation.

(*b*) In mines producing siliceous dust the air should be sprayed. Drilling at the face should be done with water-injection drills, or accompanied by spraying. Dry holes should be cleaned with scrapers and not blown out with compressed air. Adobe shots should be covered with wet stemming material, and dry ore wetted with hose before shoveling.

(*c*) Sanitary latrines should be provided (38), especially in metal mines, and should be so located that one may be reached in not over a 5-min walk, climb or hoist from the working places; where possible the stations should be lighted by incandescent lights. The latrines should be taken daily to the surface, thoroughly cleaned and fumigated. An excellent latrine is a water-tight iron body mounted on a mine truck so that it may easily be taken in and out on cages. Where skips are used tub latrines are preferable, if of porcelain with tight-fitting covers. The Butte latrine, when taken into the mine, is partly filled with water to keep the excrement fluid; it has valve fittings, for flushing out thoroughly by connecting it to a water main. After flushing, latrines should be rinsed with an antiseptic solution. Water-flushed closets sometimes installed at shaft stations, the excrement being flushed into the sump and pumped out with the mine water. If the quantity of water be large, and is not discharged into ponds near habitations, the plan is unobjectionable. In a Canadian mine, the effluent from closets serving 150 men runs into an underground septic tank, the clear water being discharged into the sump. Destructible latrines are sometimes used (wooden boxes about 10 by 18 by 20 in deep); at each latrine station there is placed dry dirt and a scoop, also disinfectant for sprinkling over excrement. When the box is nearly full, the cover is nailed on and it is sent out to be burned in a furnace. In coal mines, near gathering points, as at haulage sidings or on main levels, latrines are badly needed to prevent dangerous pollution in vicinity, but at the "face" in most collieries there is more or less shale or clay refuse, which is stowed in the "gob." In this case the fecal matter can be buried deeply, and thus safely cared for, if inspection is rigid.

(*d*) Underground cabins, pump rooms, engine rooms, stables, and other places where men may gather, should be frequently whitewashed or painted.

(*e*) Miners should be required to take their lunch leavings out of the mine in their dinner buckets; in some cases they may be permitted to throw the scraps into cars of waste rock or refuse to be dumped on the surface. Such measures prevent feeding of rats, which may come in with hay and other supplies, and are liable to transmit diseases.

(*f*) In mines where ankylostomiasis (Art 7) is found, lime should be sprinkled along gangways, or entries, and the resting places where lunches are eaten, whitewashed. In collieries, calcium chloride answers same purpose, and helps to compact coal dust.

(*g*) Good lighting aids sanitation, and haulageways, manways, shaft bottoms, and landings should be whitewashed. Electric lights should be installed, except where not permitted, as in return air of gaseous collieries. They should have wire cages.

(*h*) Shelter should be provided for heated and perspiring men, while waiting at shift ends at landings in down-cast shafts, and cages for hoisting men in such shafts should be inclosed.

(*i*) Drinking water must be of good quality, and provided preferably by fountains not requiring the touch of the lips, as in case of a faucet. As it is rarely feasible to provide running water for drinking throughout a mine, tank cars, kept in sanitary condition, should be provided, each man should have his own drinking cup, and the faucet so placed in a recess that a man can not use his lips, but must use his cup.

Requisites on surface are same as the elemental sanitation underground. In addition, miners coming from a warm mine must avoid prolonged exposure to cold air, while in light-weight working clothes. Hence, within 100 ft of the mine entrance, there should be a warm building, where the miner may be checked in and out, and which adjoins or connects, by covered passage, with the bath

and change house (Sec 22). Men coming up wet with perspiration from a deep, hot mine into cold outside air, are subject to colds and pulmonary troubles. Well-managed mines now have bath and change houses under state supervision. In Great Britain this is done through the Welfare Fund, which, with the Mine Safety Research, is maintained by tax on mineral production. In or close to the change house there should be a safety station, with mine-rescue oxygen breathing apparatus, gas masks, oxygen inhalators, stretchers and "first-aid" equipment and nearby, fire-fighting equipment, portable extinguishers, hose, rolls of brattice cloth and bags of limestone dust (Art 17).

MINE LAMPS AND APPARATUS FOR DETERMINING IMPURITIES IN MINE AIR

9. SAFETY LAMPS

Purposes: (*a*) in gaseous mines to provide means of illumination which, properly used, will not ignite firedamp; (*b*) a quick means of testing for firedamp (by characteristic appearance of flame), whether in gaseous or in " open-light " mines. It is possible but dangerous to test with an open flame. Among the numerous safety lamps the following are representative.

Davy lamp, invented in 1815 by Sir Humphry Davy, was the first safety lamp; now superseded. Its oil flame is surrounded and separated from the external air by a wire gauze mantle (6 in high, 1.5 to 2 in diam, 28 wires per linear in, 784 apertures per sq in) which by its rapid conduction cools the hot gases inside the lamp below the ignition temp of CH_4, thus preventing spread of ignition from the lamp interior to gas outside. The behavior of a safety lamp in a firedamp mixture depends chiefly on its arrangement of air inlets and of outlets for hot gases. In the Davy, air may enter or gases escape from any part of the gauze, making the lamp convenient for quick testing, but introducing an element of danger, since if the lamp is put quickly into an explosive atmos, a strong explosion occurs inside the gauze and may pass flame to the outside. Also, the lamp is dangerous in a current of explosive mixture if veloc exceeds 300 ft per min; at 450 ft per min, flame passes through the gauze in less than 2 min; at 600 ft, in 10 or 15 sec. In a quiet atmos if gas is flaming in the lamp, and it is dropped, flame may pass the gauze. It is therefore not a safe lamp, and in most countries it is not permitted in gaseous mines. Illumination given by the ordinary Davy is small, 0.16 to 0.20 c p.

Stephenson or Geordie lamp, invented by George Stephenson, followed the Davy. Though now obsolete, its cylinder and under air-feed are used in some modern lamps.

Clanny lamp has a glass cylinder around the flame, surmounted by a gauze cylinder, and the air enters lower part of gauze, passing downward to the flame. This causes baffling, which tends to smoke the glass.

Marsaut lamp has 2 or 3 concentric gauzes above the glass cylinder, with small air spaces between them, which widen toward the top by reducing the diam of the inner gauzes. The gauzes retard escape of the burned gases, which form a blanket of non-explosive gas restricting internal explosion. Fig 3 shows a BONNETED MARSAUT.

Parts of the lamp: *a*, steel hood; *b*, steel bonnet; *c*, outer iron gauze; *d*, inner iron gauze; *e*, upper brass bushing; *f*, copper rings attached to gauze; *g*, asbestos washer; *h*, 5 brass standards; *i*, glass globe; *j*, flat cotton wick; *k*, copper wick adjuster; *l*, copper wick holder; *m*, lower brass ring; *n*, brass ring; *o*, brass ring; *p*, brass oil fount; *q*, asbestos washer; *r*, brass ring for washer; *s*, key lock; *t*, vertical openings for air inlet. From his experiments, Marsaut concluded that: (*a*) a small-diam lamp, like the Davy, does not readily pass an explosion, as the volume susceptible to explosion is small; (*b*) a lamp without a glass is safer in case of internal explosions, because the glass confines the gases and acts like a cannon (hence, it is best to reduce diam and height of glass); (*c*) a conical mantle is safer against transmission of internal explosions than a cylindrical mantle of same capacity; (*d*) retention of gases of combustion tends to prevent internal explosions, and it is not advisable to guide them by a chimney. An iron body is better than brass, a brass lamp giving only 70% of the luminous intensity of an iron lamp of same design. Brass has higher conductivity, becomes hot, and makes oil viscous; it is easier to cast, and therefore generally used.

Improved Marsaut lamps. The original Marsaut has the Clanny fault of a baffling air-feed, which is very marked in a strong current; hence the glass may be smoked, giving poor illumination. But it is good for testing gas.

Combustion and illumination have been improved by various devices, and modified Marsauts are today the most favored safety lamps in Great Britain. Among them are the DEFLECTOR and PROTECTOR TYPES. These are similar in principle, the air feed being separated from the gases of combustion. In the earlier modifications the lower part of the gauze is shielded, and an angle diaphragm

ring above top of shield extended to the gauze. There is a perforated air inlet ring over the glass. The entering air is deflected upward, then strikes the ring, and is thrown downward through the gauze and along the glass cylinder. Burned gases pass out through upper part of gauze. Most of the later modifications use the full bonnet, with holes around the top for escape of burned gases, and either 1 or 2 gauzes, 2 being safest. In some, a diaphragm or angle ring separates upper and lower part of the gauze for outlet and inlet, air entering under the bonnet through slotted holes in the ring to which the standards are affixed.

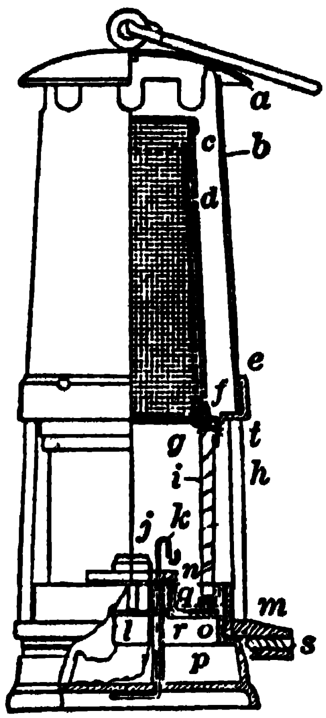

Fig 3. Bonneted Marsaut Lamp

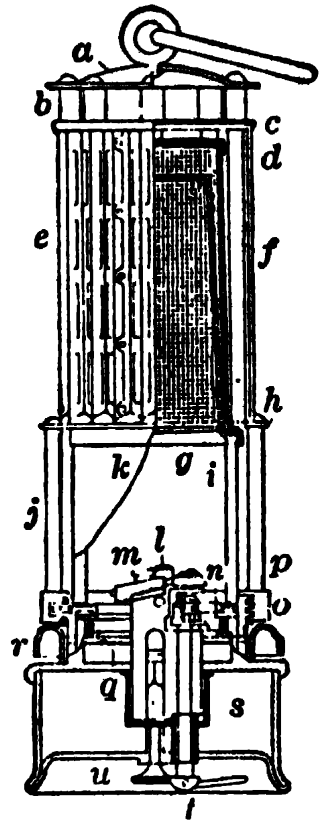

Fig 4. Wolf Safety Lamp, Type 1 B

Wolf lamp (Fig 4) uses benzine, naphtha, or gasolene, has bottom feed, and a wick-feed screw, instead of the pricker used on heavy oil lamps, which require frequent removal of crust forming on wick.

Parts of the lamp: *a*, steel hood; *b*, 5 brass covers on standards; *c*, steel ring, upper; *d*, 5 steel standards; *e*, brass bonnet corrugated; *f*, iron gauze, outer; *g*, iron gauze, inner; *h*, steel ring for standards, middle ring; *i*, asbestos washer; *j*, 5 brass standards; *k*, glass globe; *l*, cotton wick; *m*, wick holder; *n*, expansion ring; *o*, brass ring, lower; *p*, asbestos washer; *q*, brass gauzes, inlet; *r*, brass baffle ring; *s*, brass naphtha fount; *t*, ignition turnbar; *u*, wick adjuster. Air enters slotted holes level with top of the oil vessel, passing thence through a narrow gauze ring to the flame. The wick, now usually flat, about 0.5 in wide, to give more light, is in a metal tube extending about 1 in above the base, with an adjacent tube containing the screw for raising and lowering a clip which holds top of wick. This adjustable bottom is advantageous in testing for firedamp, as the lamp flame is readily drawn down until the yellow has disappeared. The light oil is advantageous for relighting, as internal relighters can be used. The relighter consists of a coil of paper matches, with clasp and striker operated by a rod projecting through the bottom. An alternative arrangement is a flint rubbed by a milled wheel. Care must be taken that the wheels do not contain cerium or other substances which remain hot longer and make lighting easier, because tests show that hot particles from some composition wheels pass through the gauze, and may ignite firedamp. The fuel vessel is packed loosely with wool to prevent gasolene from slopping. The glass rests on a flexible ring to permit expansion, with asbestos gaskets above and below. There are 2 wire gauzes, of 30-mesh, and a plain or corrugated bonnet. The miners' lamp is of brass, weighing 3 lb 4 oz; made of aluminum, 2 lb 3 oz. The round wick lamp gives illumination estimated at 1 to 1.5 cp; flat wick, 1.2 to 1.8 cp.

The Wolf type is excellent both as a working lamp and for testing. With low flame a trained observer can detect 1% firedamp, and an ordinary observer easily detects 1.5 to 2%. This lamp has not been popular in Great Britain, as use of naphtha is disliked, and individual relighters in gaseous mines are not approved. It is more used in U S than any

other. Other lamps of this type in U S, are the Shenk, Seipel, and Koehler. Some Wolf lamps for mine officials have special devices to measure the height of CH_4 " cap."

British Mines Dept report for 1937, 209 539 flame safety lamps used in British mines, of which 102 662 were Marsaut; 105 981 had an inner metal chimney. There were also 407 318 electric safety lamps.

Kind and quantity of oil for safety lamps. At first sperm, seal, and lard oils were used; then vegetable oils, from rape, cabbage or cotton seed; finally mineral oils have been increasingly used; more recently, benzine, naphtha, and gasolene. British authorities require oils which do not vaporize at temp to which they are subjected in the oil-vessel. In the U S, for Davy, Clanny, and other British lamps, high-test gasolene is commonest; sometimes railroad signal oil (a low-proof mineral oil, with little incrusting residue). For the Wolf type, gasolene of 70 to 76° is usual. QUANTITY OF OIL BURNED in safety lamps in 10 hr generally ranges from 500 to 700 gm. A lamp of the Wolf type with flat wick uses about 738 gm benzene.

Table 9. Characteristics of Representative Safety Lamps

Name	Oil used	Air entering with reference to flame	Combustion chimney	No of gauzes	Bonnet orig'l lamp	Candle power (b)
Davy.........	Heavy oil	Below or above	None	One	No	0.15 to 0.25
Geordie.......	"	Below	"	"	No	0.1 to 0.2
Clanny........	"	Above	"	"	No (a)	0.3 to 0.4
Mueseler......	Heavy oil or naphtha	"	Chimney	"	No (a)	0.4 to 0.5
Marsaut.......	Heavy oil or naphtha	"	None	2 or 3	No (a)	0.3 to 0.5
Evan Thomas..	Heavy oil	Essentially below	"	One	Yes	0.4 to 0.5
Ash-Hep-Gray.	Light mineral oil	Below	Essentially	"	Yes	0.5 to 0.6
Wolf (type)....	Naphtha or gasolene	Below	None	2	Yes	0.6 to 1.0

(a) Now frequently provided with bonnets. (b) Candle power horizontally without reflector; simple and improved types. The great variation in candle power obtained by different investigators is due partly to non-standardization of photometric methods, but chiefly to differences in size of lamp, burner, height of flame, and kind of oil used.

Details of safety lamps. LOCKS should be on lamps in all gaseous mines; best type is the magnetic, which can be opened only in a special magnet holder. In Great Britain a lead seal is common; it passes through lugs to prevent unscrewing and can be stamped with a date. In " open-light mines," examiners often use a lamp locked with a key. BONNETS are advisable in rapid air currents, but in Germany, where air veloc is kept low, the bonnet is often omitted, so that gas flaming up in the lamp may be quickly seen, and condition of gauze easily noted. GAUZE mesh was formerly 28, now in Great Britain may be 20 wires per linear in. Two gauzes are best, one serving as reserve if there are holes in the other; also the space between tends to retain gaseous combustion products. An unbonneted single-gauze lamp is unsafe in a current of over 300 ft per min; at 450 ft, flame will pass through gauze in less than 2 min.

Permissible-flame safety lamps approved by U S Bur of Mines (1937) are the Koehler and the Wolf, each with flat or round wicks, magnetic lock, double gauze bonnet, and aluminum frame (or Koehler with steel and Wolf with brass frame).

Lamp house. As a rule, safety lamps are supplied and kept in order by the mining company. They should be systematically cared for in a fireproof building, well lighted by windows, and by protected incandescent lights. The house should be near the mine entrance, but at least 50 ft from it, to be safe from explosions. No one but lamp tenders should be permitted to enter lamp room. Miners, on coming from the mine, must deliver their lamps in this house, where they are taken apart, well cleaned (especially the gauze), the oil vessel filled, and new wicks, asbestos washers, and other parts supplied if needed. The lamps are reassembled, tested by breath or by a compressed-air blowing device, and hung up in order. Each man should be furnished the same numbered lamp each day. Lamps are delivered to men entering the mine by a checking system, which, in case of accident, insures identification by lamp or check number.

Relighting safety lamps. In a gaseous mine lamps should be magnetically locked and no one allowed to carry matches. Even in a so-called non-gaseous mine, lamps must not be opened and relighted with a match. Lamps are relighted in 3 ways: (a) INTERNAL IGNITER in the lamp itself (see Wolf lamp). Not favored in Great Britain, because an explosion inside the lamp while being relit might be communicated to explosive gases outside. (b) ELECTRIC RELIGHTER, consisting of a steel box into which the lamp may be

shut, with a lighting pin extending through the oil reservoir nearly to edge of wick tube; current from a secondary coil passes through the pin and causes sparks at top of wick tube, relighting the lamp. The coil is excited by storage battery, dry cells, or magneto with external crank, the whole being enclosed in the box. Batteries generating even minute amounts of hydrogen are objectionable, as an internal explosion has been known to rupture the box. (*c*) RELIGHTING STATIONS (in charge of "fireboss") located on intake air course. As they are few in number, men may have to go some distance for relighting.

Testing for firedamp (40). Firedamp (chiefly CH_4) increases height of a normal flame, and this increase, proportional to percentage of gas present, furnishes a quick indication known as testing with FULL FLAME; it is not reliable, as height of flame may vary with temp of oil and condition of wick, and wick may have been adjusted in air containing gas. In percentages from 1% to just below explosive limit (5.5% or slightly less, especially if mixed with ethane), CH_4 burns with pale blue flame, and if the wick is lowered until no yellow light shows, will form a faintly luminous pale blue cap over, but not separated from, the primary flame. The latter should be not over $^1/_8$ in high, if lamp is clean and the gasolene not too light. The cap takes some minutes to form, as the lamp must first fill with the mine gas. Nearby lights must be extinguished or screened; height of cap is then estimated by eye, with allowance for normal cap. Wolf lamp permits estimate of as little as 1% firedamp, the cap of which is about $^3/_{16}$ in high. As the proportion increases, the cap becomes more distinct in color.

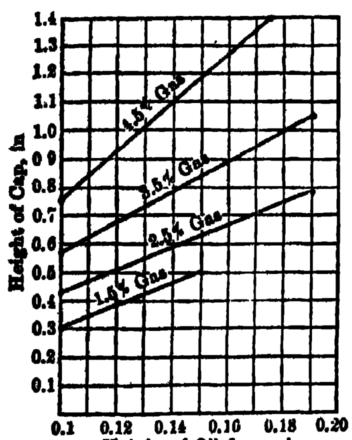

Fig 5. Increase in Height of Cap with Increase in Size of Testing Flame

In advancing rapidly through workings suspected of containing gas, length of full flame should be observed from time to time. If flame has not been adjusted for 0.5 hr prior to leaving on intake current, any increase in its height, or elongation of the normal flame into a high slender one (spiring), is due to CH_4, which should then be tested with flame drawn low. Natural gas, occasionally found in U S mines near gas or oil districts, behaves like CH_4 in a safety lamp.

Height of cap (Fig 5) ranges from about 0.20 in to more than 1 in, varying with different lamps and oils, and with height of test flame. As the latter is increased, Winstanley (87) found that height of cap increased faster when more than 3% firedamp was present. He believes that density or visibility of a cap is a more reliable indication than mere height, and that to estimate percentages correctly requires familiarity with variation in height and visibility for different percentages of gas and sizes of flame.

Tests of firebosses and examiners in a Scotch mine (42) showed: (*a*) that ordinary quick inspection did not detect less than 3.19% CH_4, in some cases much greater percentages; (*b*) careful testing detected minimum percentages varying, with the individual, from 1.06 to 4.42, aver 2.65%; (*c*) smallest percentage detected with a luminous flame, 2.11%; (*d*) max percentage escaping detection varied from 1.31 to 3.05, aver 2.16%.

Effect of deficiency of O and presence of CO_2 on safety-lamp flame is shown in Table 10, of tests run in a closed chamber until the atmos became extinctive. Since several per cent CO_2 may replace an equal percentage of N without appreciable effect on a flame, the resultant loss of illumination was due to deficiency of O, showing importance of keeping the O content of mine air above 20% to get good illumination from fuel-burning lamps.

Table 10. Effect of Deficiency of O and Presence of CO_2 on Safety Lamp Flame

Time	Light, in cp	Per cent of		Temp, deg F		Calculated % of moisture by vol
		O	CO_2	Dry bulb	Wet bulb	
11.50	0.405	20.90	0.05	65.3	56.3	1.15
12.13	0.370	20.66	0.25	69.0	59.2	1.25
12.28	0.315	20.34	0.52	70.7	65.3	1.80
12.43	0.270	19.88	0.88	72.5	67.1	1.80
1.3	0.170	19.34	1.26	74.3	69.0	2.08
1.23	0.11	18.92	1.71	75.6	70.2	2.20
1.45	0.045	18.28	2.17	77.0	73.2	2.50
2.3	0.00	18.01	2.40	77.0	75.2	2.80

Special lamps for testing firedamp, like the Clowes, Pieler and Chesneau, have been used by officials and investigators, but are of little value as compared with analytic methods, and are somewhat dangerous as working lamps. They have been superseded by gas detectors and indicators, as the Burrell, U C C and M S A (51); or by sampling and analysis.

10. ELECTRIC LAMPS AND LIGHTS

Miners' electric lamps for gaseous mines were introduced about 1895 in Belgium. They have been developed largely in conjunction with mine rescue work, but are replacing fuel-burning cap lamps for ordinary use.

In the U S, mine lamp makers report that there are in use (1938) 379 867 elec cap-lamps (about 80% with alkaline batteries), 756 hand elec lamps (used by officials), 4 000 elec signal or haulage trip lamps, and 1 500 animal haulage lamps. Of 616 857 safety lamps used in Great Britain in 1936, 66% were elec; of the latter, 13% were cap lamps.

Permissible electric lamps. Tests show that though there is no danger (at voltage and amperage used) of enough outside sparking in use to ignite firedamp, yet if a bulb is broken, the glowing filament may ignite. Hence lamps must be designed to break the elec circuit the instant the outer protecting glass is broken.

U S Bur of Mines now requires a 12-hr aver lighting intensity on 1 charge of at least 0.4 candle power (42, 43). Permissible cap-lamps now used are the Edison and Wheat, and there are 15 types of hand elec lamps on the permissible list, including a flood light and a pneumatic elec semi-portable lamp (91). Hand elec lamps are used in the U S for special service only, like rescue work. There are now permissible "trip" (car) lamps and one permissible flashlight.

Bur of Mines has recommended that: (*a*) in all coal mines portable lamps for illumination be permissible electric lamps; (*b*) where firedamp or blackdamp may occur, a permissible magnetically-locked flame safety lamp for gas detection, or equivalent permissible device, be supplied to at least one experienced employe in each such place; (*c*) any employe, before being supplied with a permissible flame safety lamp, be examined by a competent official to assure the man's ability to detect gas; (*d*) all coal mines, even if classed as non-gaseous in any part, be supplied with magnetically locked, permissible, flame safety lamps, in sufficient number for all inspection purposes.

Elec cap-lamps have in general been approved in Europe, except in thin and pitching deposits, where the battery hung at the miner's back is inconvenient in narrow workings. 804 Ceag elec lamps in an English colliery showed aver of 1.03 cp at beginning of shift and 0.76 at end (87); cost per lamp per week for 4 275 Ceag lamps in 1-yr period, 3.1¢. British requirement, effective Jan 1, 1916, is 1 cp at beginning and 0.6 cp at end of day.

Electric lamps with gas-indicator attachments. In Great Britain the Ringrose automatic alarm indicator and Thornton automatic elec indicator were approved by Mines Dept, but have not passed the trial stage.

Advantages of electric lamps compared with safety lamps: (*a*) Improved illumination. With cap lamps the illumination is where most needed, in direction towards which the person looks. (*b*) No danger of igniting firedamp through a defect or improper cleaning, or through breakage. (*c*) Using cap lamp, both hands are free for work. (*d*) No gases given off in burning. (*e*) In an atmos containing less than 20% O, the effic does not fall off as with safety lamps. DISADVANTAGE: no means of testing for firedamp. But this is rarely serious for a working lamp, as foremen and fire-bosses make tests periodically with flame safety lamps.

Flood lighting; especially applicable to collieries having concentrated mining systems, involving mechanical coal cutting and loading, and use of face conveyers. Two types of portable flood lights were approved by U S Bur of Mines in 1931, but have not yet been widely adopted.

Dry-cell electric lights (flash lights) except one special, do not meet requirements of permissibility for efficiency, or for safety in the matter of not opening out or cutting the circuit if the bull's eye be broken. But, this is unlikely to occur under conditions of use, and they are otherwise safe, except those having exposed metal parts of opposite potential, the use of which, where electric shot-firing is done, introduces the hazard of premature firing by accidental contact with the wires. This would not apply during rescue work, for which they are very useful. As they cost about 25¢ per day of 9 hr, they can not compete with storage-battery lamps for every-day use (87).

Electric lighting from circuits. Incandescent lights, from power or special circuits, are widely used in metal mines, open-light collieries, and to a limited extent in the intake gangways of gaseous mines. They are of greatest advantage along main haulage entries, slopes, in stables, at shaft bottoms, and on sidings; also for signaling purposes on electric trolley haulageways. They are unsafe on return airways of gaseous mines, since if a bulb is broken the filament will ignite firedamp; or, even if insulated, the feed lines may be short-circuited, due to wear, deterioration, or fall of roof, and an arc thus caused would ignite firedamp.

Where fixed elec lights are permitted by state regulations, they should be installed as prescribed in the National Electric Code, approved by the Amer Standard Assoc "for Class 1 hazardous locations" (in explosive atmospheres of dust or gas); the lamp has a heavy glass globe, sealed to the fixture, surrounding the bulb and protected by metal guards (46). For further protection the globe might be filled with an inert gas.

Electric lighting from compressed air lines is being widely introduced in European collieries, especially in Germany. The air, carried by a rubber hose, drives a tiny turbo-

generator, furnishing current for the lamps; one hose may serve 8 or 10 lamps. If the hose ruptures, the generator stops, as do the lights. The assemblage is easily moved as the face advances. One pneumatic elec light of British make has been approved by U S Bur of Mines. In 1936, 1 607 such lights were in use in Great Britain.

Reflector signs, lighted by headlights of oncoming vehicles and widely used on highways and automobiles, now find use in mines. Ordinary signs (as at switchstands and turnouts), which can not be seen far enough, may be made visible for sufficient distances by studding the letters with facet-cut reflector buttons. Also, a movable lighted stand is set up where repairing or timbering is being done (47). A man traveling haulage ways for switching or inspection might well wear a small reflector button on his belt in case his light goes out or can not be properly seen.

11. APPARATUS FOR DETECTION OF GASES, FOR USE WITHIN MINES

Safety lamps (fuel-burning) for detecting firedamp (see Art 9). Other appliances for detecting or analyzing mine gases are as follows.

Firedamp detectors, which are of a number of types:

(*a*) Those depending on diffusion of gases, or *osmosis*. Example. Webster firedamp indicator (52), consisting of a porous inverted pot, the bottom closed by a sensitive diaphragm, movement of which deflects a pointer. Pot is surrounded by porous, non-conducting and drying material; outside of this are gauzes between which is a material which will absorb CO_2. A tight cover surrounds the whole; put on in pure air, and taken off for making a test. Due to its lighter density CH_4, if present, diffuses through the porous material faster than the inclosed pure air, causing pressure which acts on the diaphragm and deflects the pointer.

(*b*) **Haber firedamp whistle,** brought out in Germany (1913), records presence of CH_4 by the difference in density of air and CH_4 mixtures, which causes a difference in sound waves. There are two whistles having the same note; one is in a pure-air container, the other is exposed to the entrance of the air to be tested. Both are blown simultaneously by mechanical means. If CH_4 is present the whistle exposed to it gives the higher note.

(*c*) **Shaw gas-testing machine** (52) is not portable, and must be used on the surface. It has 2 cylinders, one containing pure illuminating gas, the other the mine air to be tested. Measured quantities, obtainable from either cylinder by mechanical means, are mixed and passed into an exploding chamber, where the mixture is ignited. Force of the ignition causes a gong to strike. If the air contains some CH_4, less of the gas is needed to make the mixture explosive. It is a laboratory apparatus, is expensive, cumbersome and inefficient, compared with the more accurate quick-analysis apparatus.

(*d*) **Detectors employing catalytic agents,** as platinum and palladium. If these are brought into the presence of gases like CH_4, the so-called "catalytic" actions cause a slight rise of temp on their surfaces; this effect is made more noticeable with sponge platinum or palladium. It is utilized to heat adjacent substances which give indications in various ways. In the SUSSMAN ELECTRIC LAMP DETECTOR (50) by heating a mercurial thermometer the rising column of mercury touches sealed terminals, thus completing an electric circuit that lights a red bulb. In the HOLMES-ALDERSON FIREDAMP CUTOUT the heating of a compound strip of two metals, of different expansion coefficients, causes it to curve and complete an electric circuit. This energizes a magnetic solenoid which opens a switch cutting out the power circuit beyond. In the HOLMES-RALPH PORTABLE ELECTRIC LAMP ATTACHMENT (50), by the self-heating of a platinum wire in the presence of CH_4 a change in electric resistance is caused, indicated by a galvanometer needle. The amount of heating in these devices is so small that adjustments are very delicate; and as the degree of catalysis decreases with use, none of these detectors has yet been found practicable for everyday use.

(*e*) **Liveing's firedamp indicator** (49, 87) depends on increase of heat due to CH_4 burning on surface of a glowing coil. Two Pt coils carry current from a hand-operated magneto; one coil is in an air-tight tube the other exposed to atmos in a gauze cylinder; tube and cyl are on a common axis, their near ends enclosed in glass, with a photometric screen between. In a CH_4 mixture the exposed coil glows more brightly, and the screen is adjusted to obtain equal lighting; the extent of adjustment on a calibrated scale shows % of CH_4. The indicator is too delicate for ordinary use.

(*f*) **Léon and Ralph detectors** (50) use a hot wire for surface burning of CH_4, which raises temp of wire and increases its elec resistance. The resistance, measured with a Wheatstone bridge against that of a wire isolated from the mine air, indicates per cent CH_4.

(*g*) **Recent portable firedamp detectors and indicators.** None of the foregoing types has proved satisfactory, and new ones are being brought out, especially for attaching to miners' storage-battery lamps (50, 51).

A distinction has been made by U S Bur of Mines between a DETECTOR which merely shows presence of gas, and an INDICATING DETECTOR, which indicates with some precision varying percentages of CH_4 in the air. Many of these are not sufficiently precise or reliable for official approval. METHANE DETECTORS: 1. Wolf, for attachment to hand storage-battery lamps, is a very small flame safety lamp; 2. M. and K. (German) depends on difference in density of CH_4 and air (small and portable); 3. Martienssen (German) has a hot-wire loop, with a chemical catalyst adhering to parts of the wire. It has a dry cell, and is small enough to be carried in a coat pocket; 4. Gulliford

(British) (51), using the heated wire principle, is attached to storage-battery lamps. When current is switched on, the fine platinum wire is heated dull red; if fire-damp is present, the wire glows more brightly; if exposed to 3% CH_4, it fuses and breaks the circuit. A fresh fuse-wire is then inserted. It has been found safe for gaseous mines by the British testing station; 5. Burrell indicator (51) is a portable volumetric gas-analysis apparatus, carried like a safety lamp. CH_4 is drawn into it by suction, is burned off by a hot wire through a connection to a miner's electric lamp battery, and the contraction of volume is indicated by height of water in a tube, with a parallel scale for direct reading in tenths of 1% CH_4. It is accurate within 0.2 of 1%, has been approved by U S Bureau of Mines, but is less used than later permissible indicating-type detectors (51) as follows: U C C; M S A model 3, type AP with dry-cell battery; M S A model 5, type AP with Edison models H, J or K elec cap lamp; M S A type W-8 with Edison model K cap lamp.

(h) **Ringrose firedamp alarm and Ringrose detector** are connected to hand elec lights. The alarm uses a porous pot as combustion chamber, into which a continuous current of mine air passes through gauses, the CH_4 being burned off by a hot wire and leaving a partial vacuum in the pot. The vacuum, acting on a diaphragm, lights a red bulb as a warning when CH_4 exceeds a minimum previously fixed by adjustment. The detector uses the same principle, but warns by dimming the working lamp. Approved by British Mines Dept and is of limited use in Great Britain, but not approved by U S Bur of Mines.

Hot-wire, fixed, underground station indicator. A loop of current-carrying wire, inserted in a safety lamp, is heated by the turned-low flame of the lamp. The change in electrical resistance of the circuit may be indicated by a voltmeter at a distant point, as in the foreman's office. The objection to leaving an unattended light, even though a safety lamp, makes it unwise to use the device underground in this way. But such indicators are advantageous for laboratory testing of explosion-proof mining appliances.

Continuous methane recorders, enclosed to prevent ignition of CH_4 and with both remote and local signals to give warning of dangerous percentages of CH_4, are much needed; one American maker has produced trial types, but they require close attention and expert servicing, and are not yet officially approved.

Blackdamp detectors. The behavior of an ordinary lamp flame gives an approx idea of proportion of blackdamp present, up to extinction of the flame by a 3 to 4% deficiency of O, which may mean 15 to 18% blackdamp (Art 2). The Haldane flame-test apparatus (41) consists of a graduated glass tube, 7 in long, 0.75 in inside diam, into which is inserted a lighted wax taper, 1/16 in diam, in a thin slit brass holder. Held vertically, the taper induces an updraft, which becomes stronger as the taper is lowered in the tube, and if more than 1% blackdamp is present, will finally blow out the flame. As per cent of blackdamp increases, less draft is needed to extinguish and the taper is not lowered as far. The device does not detect CO dangerous to health, nor firedamp, nor show relative proportions of CO_2 and N, and is affected by humidity, but is valuable for daily use in open-light mines. The tube is graduated for an aver mine atmos condition of saturation at 64° F, at which water vapor is 1.2% of the wt of mixed air and vapor, or 2% by vol at 760 mm press.

Gas analysis. Ordinary devices for detecting one constituent may fail in the presence of other gases. Thus, a good safety lamp, capable in experienced hands of detecting as little as 1% CH_4 in otherwise good air, will have its indications masked or the flame extinguished if 3 or 4% of blackdamp is present, or 0 is deficient. MANY DANGEROUS CONDITIONS OF MINE AIR CAN BE DETERMINED ONLY BY ANALYSIS (55.56). Analyses of adjacent atmos are of particular value in fighting mine fires, especially when these are being sealed off; also in recovering fire areas, when it is not known whether the fire is out or only smouldering. Analyses of air from a fire area have sometimes indicated grave danger of explosion; so that the men were withdrawn from the mine or workings, to be out of danger, and the workings sealed to prevent entrance of air (Art 15, 19).

Control of ventilation in gaseous mines by daily analysis of the return currents from each ventilating area has been adopted by several large coal companies in the U S (56), and by the Ronchamp collieries, France, since 1891. Other French collieries constantly sample and analyze the air from the various working places. In German and Belgian collieries, control by analysis is widely employed. Great Britain, in 1911, established regulations requiring that CH_4 and CO_2 shall not exceed certain percentages, thus practically compelling analysis. Similar requirements are made from time to time in other countries (Art 6). U S Bur of Mines, in regulations for coal mining on the public domain (90), recommends systematic mine-air analysis.

Methods of gas analysis. For general methods, see books on chemistry (55, 56), but exact determinations require services of experienced chemists, and well-equipped laboratories. In recent years quick volumetric methods have been devised, by which determinations of ordinary gases can be made by men without chemical training after a little instruction, to within 0.2 or 0.3% of the exact percentage. This is sufficiently accurate in practice, except in case of CO. When CO is present there is always enough CO_2 accompanying it to be readily determined by field analysis, and to give warning of dangerous conditions. CO in dangerous amounts is never found in coal mines except in afterdamp of explosions and mine fires, when it is nearly always present in dangerous, if not fatal, quantities. In these conditions, particularly if there is much CO_2, the presence of CO would always be suspected, and a canary bird, which is very sensitive to CO, should be carried in a cage by men entering such atmos (54) (Art 14, 15, 17, 18, 19).

CO detector, a pocket-size instrument, is valuable for rescue and investigation crews. The tube is filled with Hoolamite (trade name for activated iodine pentoxide) by drawing air through it by an attached bulb (after breaking the sealing tip). If more CO is present than 7 parts in 10 000, color of the Hoolamite changes from gray-white to green, color intensity varying with % of CO. Comparison with a color chart shows approx % present. PYROTANNIC DETECTOR (portable), for finding the % of CO in blood of a person exposed to air containing CO, is also useful for rescue and first-aid crews.

Portable gas-analysis apparatus is of the volumetric-determination type. That first used for mines in the U S was the Orsat, widely employed for analyzing flue gases. Similar apparatus has been used in Europe. Burrell designed a modified Orsat (56); extensively used for mine rescue and fire-fighting.

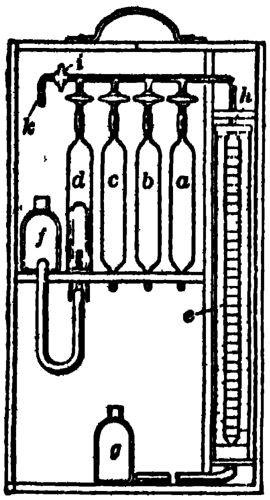

Fig 6. Modified Orsat Apparatus for Complete Analysis of Mine Air

Of the 4 pipettes in Fig 6, *a* contains KOH solution for absorbing CO_2; *b* contains alkaline pyrogallate solution for absorbing O; *c* contains ammoniacal cuprous chloride solution for absorbing CO; *a*, *b* and *c* contain glass rods to increase absorbent surface; *d* is a slow-combustion pipette for burning off CH_4, ignited by a Pt wire connected through sealed wires to a miner's elec light storage or dry-cell battery, the pipette being initially filled with distilled water slightly acidified with H_2SO_4; *e*, burette of 50 or 100 cc capac, graduated to 0.2 cc; *f* and *g*, leveling bottles; *h*, zero mark; *i*, stopcock; *k*, open end of glass tube leading to *e* and connected by branches to the pipettes. The apparatus is housed in a box 12 in high by 6.5 in wide and 6 in deep for carrying; front and back covers being removable.

Operation. By manipulating *f* and *g*, level the solution in each pipette in turn to a mark on its capillary tube connection, then close individual stopcock. By means of *g*, raise water level in *e* to zero mark *h*, stopcock *i* being open to the air. Connect a rubber tube at *k* and insert its free end in sample bottle, which has been inverted and uncorked under water By lowering *g*, draw a measured vol of mine air into *e*, usually all it will hold. Manipulating *g* and opening the proper stopcocks in turn, pass this sample successively into *a*, *b* and *c*, each time returning it to *e* for measurement of loss of vol by absorption. Then pass remaining gas to *d*, burn off CH_4, if any, and repass through *a* to determine CO_2 produced by the combustion (Table 11).

Table 11. Example of Results of Gas Analysis

	cc		cc		cc
Initial sample	50.0	After pass through *c*	40.4	After combustion	45.3
After pass through *a*	48.7	CO absorbed	0.4	Loss by combustion	4.1
CO_2 absorbed	1.3	Pass into *d*	40.4	After repass through *a*	43.4
After pass through *b*	40.8	Oxygen added	9.0	CO_2 by combustion	1.9
O_2 absorbed	7.9	Total vol in *d*	49.4	$H_2 = 2/3\ (4.1 - 2(1.9)) =$	0.2

Results: CO_2, 2.6%; O_2, 15.8%; CO, 0.8%; CH_4, 3.8%; H_2, 0.4%; N_2 by difference, 76.6%.

The small apparatus specified can be used within the mine, provided the work is done where the air is good and the safety lamp shows no dangerous amount of firedamp. A larger apparatus, of 100 cc capacity, is preferable for close determinations, but is more bulky to carry. The larger size is used in the U S Bur of Mines' rescue stations and cars. Haldane has a compact apparatus for determining only CO_2 and CH_4.

MINE ACCIDENTS AND THEIR PREVENTION

12. ACCIDENTS IN COAL MINES

Proper precautions greatly reduce accidents, as shown by comparing the rate of accidents in mines where special care is taken, with the aver rate in same district.

Comparisons may be based on: (*a*) number killed or injured annually per 1 000 employed; (*b*) number killed or injured annually per million tons coal produced. Basis *b* is sometimes preferred, but neglects the influence of local conditions on output per employe, and the question of compulsory mining out of all coal in thin and thick beds and back-filling excavations to prevent surface subsidence, as required in France and Belgium. Men engaged in back-filling operations are exposed to mining hazards, but produce no coal. Many authorities believe that, while basis *a* is not ideal, it affords a better means of comparison; moreover, basis *b* is not practicable for comparisons with metal mining (57).

U S Bur of Mines basis (until 1930) for its statistical comparisons is the number of accidents per yr per 1 000 300-day workers; thus assuming that the mining risk, which might be for only 100 or

200 days, was for 300 shifts in the year. This gives a truer comparison between different years, states or countries, and kinds of mining in which number of working days and kind of mineral mined might widely differ.

Table 12 shows a favorable reduction in accident rates, but more striking in the killed per ton produced, than in killed per hr of employment, chiefly due to greater productivity per man from increasing mechanization.

Table 12. Production, Number of Employes, Days worked, Man-hours, and Number Deaths per Million Hrs and Million Tons Produced, in U S Coal Mines (a)

Year	Production 1 000 tons	Employes	Active days	1 000 Man-shifts	1 000 Man-hours	Killed	Killed per million man-hr	Killed per million tons	Ton per man-hr
1921	506,395,401	823,253	173	142,358,691	1,145,738,000	1,995	1.74	3.94	0.442
1922	476,951,121	844,807	144	121,516,822	979,995,000	1,984	2.03	4.16	.487
1923	657,903,671	862,536	195	168,193,738	1,356,089,000	2,462	1.82	3.74	.485

(a) Compiled by Adams, Geyer and Parry. Bur Mines, *Bull* 409 (1938).

Non-fatal accidents in U S coal mines (Table 13). Until 1930, non-fatal statistics were unreliable due to variations in mode of gathering them in different states; but, from 1930, the Bureau obtained data directly from mine operators. Tables 12 and 13 show ratio of total injuries to fatalities in 1930 was about 50 to 1; in 1935, 53 to 1. The British Mines Dept, 1935 report, shows 155 injuries to 1 fatality, but allowance must be made for differences in defining minor injuries. Note.—A table of accidents in the different states of U S in 1914 is omitted here (see p 1542 of 2nd edn of this book).

Table 13. Number of Injuries and Accidents of Coal-mine Employes in U S (a)

Year	Number of injuries				Rate	
	Permanent total disability	Permanent partial disability	Temporary disability	Total	Per million man-hr	Per million ton
1930	122	2 606	101 093	103 831	103.5	193.4
1931	98	1 773	78 478	80 349	99.9	181.9
1932	79	1 448	57 445	58 972	92.7	164.0
1933	51	1 290	59 972	61 313	85.3	160.0
1934	94	1 610	66 304	68 008	88.4	163.3
1935	81	1 793	63 701	65 575	89.5	154.4

(a) Compiled by W. W. Adams, U S Bur of Mines.

Table 14 shows a higher fatality rate per 1 000 employes in U S than in Europe, but lower per ton, due to large amount of dead work done in the deep and pitching European coal beds, to meet requirements of extracting both thin and thick beds and back-filling excavations.

Prevention of coal mine accidents. Probably 90% are preventable; at least half are due to recklessness, absent-mindedness, or ignorance of the victim; the other half to careless acts of fellow workmen, and to deficiencies in equipment and organization. Following analysis, covering 1930 to 1935, is in the order given in Table 15.

(1) **Falls of roof** caused 461 to 905 deaths per year, or 47 to 51% of total underground fatalities. Most of them were due to insufficient propping near the face. The number would be greatly reduced by SYSTEMATIC, REGULAR AND CLOSE SPACING OF TIMBERS, regardless of apparently safe condition of roof. This is general practice in European col-

lieries, and the higher cost is justified by low accident rate from falls of roof, especially in France, Belgium and Germany (Table 16). Roof should be FREQUENTLY TESTED by VIBRATION METHOD (striking roof with bar or sledge with one hand and feeling with fingers of other hand to see if portion struck vibrates). This supersedes the more uncertain mode of judging by sound. Important factors for preventing falls: SYSTEMATIC DELIVERY OF

The classification of causes of accidents in Table 15 is complex, and varies in different countries, except as to major causes: (*a*) largest group in every coal district is due to falls of roof; (*b*) next are explosions of gas or dust; (*c*) major cause in the U S is haulage accidents.

TIMBERS at each working place; ENOUGH FOREMEN, to inspect and instruct miners, to see that orders to put up props are carried out, and to withdraw men when necessary.

(2) **Roof falls due to knocking out props** by car or machine. Similar in effect to "Falls of roof," but causes different. Fatalities, 4 to 34. In pitching beds (Penn anthracite mines) and where large mining and loading machines are used, cars and machines must be carefully blocked.

(3) **Falls of face or rib.** Fatalities, 77 to 146. Remedy, better side supports and spragging or blocking thick undercut beds, especially in pitching beds. In very thick seams all loose coal should be barred off, starting at top after blasting.

(4) **Rush of coal, rock or gob.** Fatalities, 13 to 27. This is a special hazard in pitching beds. Remedies, better layout of workings, and timbering or walling to support overhanging gob.

Above 4 causes accounted collectively in 1935 for 664 fatalities (59% underground and 53.4% of all), or 1.96 killed per 1 000 employes. The rates abroad are far below those of the U S.

Other causes of accidents in U S (1930-1935). Mine cars and locomotives caused from 179 to 325 deaths, or 16 to 21% of the underground fatalities. In level workings men may be run over or rolled between cars and walls on main haulage roads. These accidents are largely preventable by having GOOD MANWAYS and compelling their use; AMPLE CLEARANCE for a pathway along one side; WHITEWASHED REFUGE HOLES, always on same side of track, and at regular intervals not exceeding 50 ft.

Where haulageways are used as manways in a gaseous mine, only approved elec signal lamps should be used. In non-gaseous mines "protected" incandescent LIGHTS at regular intervals are advisable. Locomotives should have good HEADLIGHTS, and where possible a BLOCK-SIGNAL system (easily installed for elec haulage). Many accidents caused in "spragging" cars are preventable by providing BRAKES. Accidents often occur in mule haulage by riding in front and standing on the tail-chain, instead of on rear of train; if necessary to ride in front, have a MOVABLE SEAT hooking over the car end. Accidents while coupling cars, due to short bumpers, are frequent; bumpers should project at least 10 in, to provide 20 in clear space between car bodies. In pitching workings, in which cars are hauled to the face by mule, locomotive or rope, AUTOMATIC HINGED CAR-BLOCKS will prevent runaways. GOOD TRACKS and CLEAN ROADWAYS are important.

Gas explosions, burning gas and explosions of coal dust in 1918–25 caused 5 to 22% of total fatalities, and in 1930–35, 3.8 to 14.0% (Table 15). In 1935, 49 deaths (4.3% of underground or 0.15 per 1 000 employes) compare favorably with European statistics (Table 17), due principally to adoption of rock-dusting and permissible explosives and machinery.

Firedamp accidents are mostly preventable by care on the part of mine officials. The chief factors are: FREQUENT INSPECTION by competent firebosses and foremen and GOOD VENTILATING METHODS (including large capacity fans; good stoppings in room breakthroughs or crosscuts; use of line brattices, and of overcasts, where possible, in place of doors; use of double and triple doors; and keeping airways cleaned). Abandoned but open workings should be well ventilated, and regularly inspected, or else securely walled off. Walled areas giving off firedamp under pressure should be vented by drill-holes from surface. In gaseous mines, regular analysis of the separate splits is valuable in controlling ventilation. In mines where firedamp is often found (whether classified as gaseous or not) SAFETY LAMPS OR PERMISSIBLE MINER'S ELECTRIC LAMPS should be used (Art 9, 10). Mixed lights in the same mine or district are a menace to safety. PERMISSIBLE EXPLOSIVES (Sec 4, Art 9) should be used instead of long-flame explosives (black powder or dynamite). Machine-mining in gaseous collieries should be done by EXPLOSION-PROOF MOTORS. Electric-trolley locomotives are not

safe to use in working places or return ventilation entries of gaseous mines. Explosion-proof storage-battery locomotives have recently been introduced in the collieries of U S; also explosion-proof storage batteries on mine car trucks for feeding, undercutting, and other machines. This is not only safe, but, by preventing electric peak-loads, is economical. Ignition of gas has occurred from use of electric signalling wires in return air courses.

Accidents from explosives, other than those leading to gas or dust explosions, in 1930–35 caused 2.8 to 4.7% of total fatalities. They are chiefly produced by: (*a*) premature blasts, due to accidental ignition of black powder by open lights, cutting fuse too short to allow time to get out of danger, forgetting a lighted first fuse while lighting others, or getting tools out of the way; (*b*) use of metal tamping bar. Only wooden bars should be permitted. Even copper-tipped bars are unsafe; (*c*) returning too soon to investigate apparent misfires; (*d*) in electric firing, a lead wire may come in contact with a coal-cutting machine under power, or a power line, or with an unprotected dry cell or storage battery; (*e*) opening powder kegs with a steel wedge, or even a wood wedge, if there are sand grains embedded, may cause a frictional spark. PELLET BLACK BLASTING POWDER, made in cylindrical cartridges with central perforation, and wrapped in paraffin paper, is safer in handling and charging than granulated powder, but has a long flame and should not be used in gaseous or dusty mines. PERMISSIBLE EXPLOSIVES should always be used in coal mining, as required in Europe. In "shooting off the solid," they are not effic, being too quick in action, but that method is now barred in most states. Added cost of permissible blasting is insignificant per ton of coal.

Electric firing is safer than fuse, provided that, where electric coal cutters are employed, ends of the leads are kept in contact and covered with insulating tape until power is shut off the machine and its leads. If electric firing is by battery, the latter (if dry cell or storage) should be so constructed that the binding posts are not in circuit until a recessed spring-opening button or lever has been pressed to close the circuit. HAND-OPERATED MAGNETO BLASTING MACHINES are generally preferred. Use of power lines or connections to trolley lines is dangerous. For electric firing from the surface, there should be separate insulated circuits, and switch cutouts at mouth of every entry and working place, to prevent accidental stray currents entering firing circuit, and the switch should be kept open until closed by a foreman as the men leave the mine before blasting (59).

Stemming of explosives. For proper methods, see Sec 4, Art 8. Coal dust should never be used. Mechanical stemming devices have not yet been approved by the U S Bur of Mines, because of the flame hazard. Extensive tests in Great Britain showed that 3 parts sand with 1 part clay, and 3 to 5% $CaCl_2$ to retain moisture, make a good mixture.

Sheathing of explosives. The safety of permissible explosives is relative. Although their flame is short and of small duration, they have ignited firedamp in fractured coal, or in fractured roof when being "brushed" in a gaseous mine. Sheathing cartridges with an $^1/_8$-in layer of $NaHCO_3$, to cool the flame, has found favor in Great Britain; but not yet in the U S, due to increased cost of explosive, and necessity of drilling slightly larger holes.

Substitutes for explosives. "CARDOX" consists of a metal cylinder containing liquid CO_2 and a combustible to be ignited by an elec cap; the liquid vaporizes on heating, and the resultant gas, bursting a thin steel disk at the inner end of the cartridge, issues at high press, blasting the coal without flame. Efficient tamping is necessary to prevent the cartridge from being blown out of the hole. With approval of the U S Bur of Mines, certain types of Cardox find considerable use in mechanized mines, and in Great Britain the device is found well adapted to longwall mining. More recently "HYDROX" employs a steel tube with sealing disk, filled with a powder which, when detonated, generates nitrogen and water vapor. It was approved (1935) by the British Mines Dept. "AIRDOX," developed in the U S for coal mining, employs neither explosive nor combustible. Air under high press from a small compressor on a mine truck, is forced into a metal cylinder like that for "Cardox," and, bursting the inner disk, breaks the coal. HYDRAULIC BLASTING: the "hydraulic cartridge," or wedge, has been used in a few British longwall mines, where conditions are favorable and the coal well undercut. It is a steel tube containing a small hydraulic piston; water press is produced by a hand pump connected by hose to the cartridge. It requires a large borehole, is slow in breaking the coal and will not work in tight corners. A recent American device employs a rubber tube, instead of a steel cylinder. It is still in the experimental stage. Hydraulic cartridges, though safe, are too slow to compete with permissible explosives.

Hangfires and misfires are most prevalent in metal mining, where shots are fired in rounds and where fuse and caps are favored over electric firing (except in shaft sinking). Electric shot-firing failures are nearly always due to poor connections, rarely to imperfect detonators or to explosives impaired by age, heat, or wetting, causing non-ignition or, in extreme cases, burning of the explosive instead of detonation. Failures in use of fuse or delay-action detonators are due to: (*a*) sharp bending of fuse in handling; (*b*) wet fuse; (*c*) imperfect fuse (rare); (*d*) imperfect detonators; (*e*) fuse being cut or outer part of explosive charge cut and thrown off by previous shot in round; (*f*) sticks of explosive

left in stub-end of hole or loose sticks thrown into blasted material. **Remedies**: care in selecting and handling explosives; in using fuse, to count shots carefully, and if one fails or the count is in doubt, to wait at least 4 hr (better 8 hr) before entering the place. In blasting coal and brushing roof or floor, electric firing is much safer (unless firing is done from the surface), firing 1 shot at a time and inspecting before and between shots. In case of hangfire or misfire, disconnect battery leads, and wait 15 min before returning.

Fuse should not be used in blasting coal, as specified by Bur of Mines for "permissibility" of explosives.

Extracting misfires may be necessary in coal mining, because if a parallel hole is drilled close by, the first charge might be set off by concussion or flame and, having less burden, blow out and ignite coal dust. It requires care, especially if a cap is in outer end of charge. If another hole is drilled, everything for 100 ft outbye should be wet down or rock-dusted before shooting. Although careful extraction of tamping and charge is favored by many (especially if it can be wetted or washed out by a water jet), the usual practice is to drill a parallel hole 1 to 2 ft from the first. After firing, examine the broken coal for loose sticks of explosive.

Suffocation by gases from explosives in a well-ventilated colliery is rare, and unlikely to occur unless coal or a pocket of firedamp is ignited, thus adding afterdamp to powder smoke; or unless explosives are burned instead of detonated, by using too weak a cap (Sec 4, Art 8, and Sec 6, Art 10). REMEDY is to delay entering the working place until the smoke is cleared out.

Accidents by flying pieces of rock or coal from blasting are due to carelessness on part of victim in not getting to a place of safety, or firing a shot in adjacent working without notification, or not guarding entrances to working place after lighting a fuse, or while connecting the lead wires at another point. Where workings have several entrances it is well to furnish miners with PAINTED WARNING BOARDS, to be placed across or on floor of entrances not guarded by shot-firer.

Suffocation from mine gases caused 5 deaths in 1935. Except for explosions and fires, which are not included, there is little excuse for such accidents. They are generally due to entering dangerous places unnecessarily. To prevent this, such places should be properly ventilated or permanently walled off.

Accidents from electricity (shock or burns), not including ignitions of firedamp or coal dust, caused 51 to 88 deaths annually in 1930–35. Some were from touching bare conductors, trolley or power lines, some from improper insulation and installation of cables and motors.

Many of these accidents might be prevented by: trolley guardboards, when the wire is less than 6.5 ft above roadway, guarding by boards or props of bare power cables or preferably by rubber covering and sometimes armoring; good installations to prevent grounding of wires. In working places or traveling ways, trolley and powerline potentials should not exceed 275 or 300 volts. Electric coal cutters should be so designed and installed that a strong shock is not received on touching the frame. Cable leads should be of the single, concentric-cable type, the return wires being outermost to avoid shocks from grounding. RULES FOR INSTALLATION AND USE OF ELECTRIC EQUIPMENT in mines, as formulated by the Bur of Mines, should be observed. Animals killed have been fewer since the substitution of conveyers and gathering locomotives for animal haulage. Properly installed underground stables, with passageway in front of as well as behind the animal, would prevent some accidents; but above all, PROPER HANDLING and DRIVING WITHOUT ABUSE would prevent animals from becoming vicious.

Accidents from coal cutters, causing 22 to 46 deaths annually in 1930–35, are due to men falling on the moving parts of machines, or in handling them. Such accidents have increased with increasing mechanization at the face. The first-mentioned dangers are lessened by using inclosed machines; the latter are casual, to be guarded against by the individual.

Fatalities from mine fires (Art 15), by burning and suffocation, cost 26 lives in 1918, but were relatively few in later years; only 10 in 1935. Suffocation, rather than burns, is the primary cause, because fires progress slowly in restricted passages.

The smaller accidents occur near the face; generally due to recklessness or ignorance in entering the return current or afterdamp from fires. In colliery workings such fires are often caused by long-flame explosives, which may set fire to coal or gas feeders. Permissible explosives, properly used, rarely cause fires. In a large Illinois mine, 15 "fire-runners," formerly employed to extinguish fires after black-powder blasts, were dispensed with by introducing permissible explosives.

Falling down shafts or slopes caused 11 to 23 deaths annually in 1930–35. Man cages should have gates hinged to cage; also gates and fences around shaft mouths, and at landing places. Gates should be self-closing.

Surface accidents caused 62 to 95 deaths yearly in 1930–35. Of these 9 to 17 were by mine cars and locomotives in drift slope mines, and 5 to 17 by RR equipment. Practically all such accidents are preventable, either by the individual or by proper installation and safety guards.

Protective clothing for miners. HATS OR CAPS are common in both coal and metal mines. SAFETY SHOES or boots prevent injuries from falls of rock, coal or timbers, or being pinched by a car wheel. GOGGLES are advantageous for protection from particles of mineral in picking, drilling and loading. Some companies have goggles ground to fit eyes with defective vision. DUST MASKS should be worn in dust-making work, especially if dust is silicious; the finer the particle size, the more likely to cause silicosis or other lung troubles. LEATHER GLOVES prevent cuts and abrasions, which may lead to infection. KNEE PADS are needed only in low-roof workings, where crawling is necessary. Improvised pads are much used in thin coal seams in Great Britain. An American maker supplies sponge-rubber knee-cap protectors, which, by expansion and contraction of the cellular spaces, provide skin ventilation under the pad. SHIN GUARDS are useful when working around conveyers or other machinery. In Penna, use of hats or caps reduces compensation rates 14¢, use of safety shoes 8¢, and use of goggles 8¢ per $100 pay roll.

13. ACCIDENTS IN METAL MINES AND QUARRIES

Statistics in following tables are from reports of mine operators (except in a few states where they came from inspection departments). For equal periods of operation or exposure to risk, fatality rate at coal mines is usually higher than at metal mines. Metal mines ordinarily work more days per year, except Mississippi Valley lead and zinc mines, and gold placers. In metal mines single disasters, except fires, rarely kill large numbers, as in coal mine explosions. Tables 18 to 22 show fatalities and injuries for each kind of accident. Falls of roof, etc, caused the largest number of deaths, but the proportion of these to the total is greatest in coal mines. Fatalities in metal mines from explosives are much higher; those from handling and transportation are in far greater proportion in coal mining; and those from "falls of person" in metal mines are large enough to offset losses in coal mines from explosions.

Fatal and non-fatal accidents. Tables 21, 22 and 23 show wider variations in non-fatal than in fatal accidents. Apparent inconsistencies are probably due to variations in mode of reporting slight injuries. Death rates are reasonably consistent.

Table 21. Number of Employes, and Number Killed and Injured at All Mines (Except Coal) in U S (1926–35)

Open-cut, hand loading only	5	173	39 352	227	1	7	3.21	22.45
Total	311	251	7 818 227	31 104	77	4 936	1.24	79.38

(a) Underground and open-cut only. No reports used where less than 25 men were employed.

Falls of rock or ore from roof or wall caused nearly 30% of the deaths and 15% of the injuries; far more than any other source. Remedies: barring down loose pieces of ore or hanging wall after blasting, and timbering where necessary before work is resumed. Accidents from falls of ground are largely a question of method of mining. If deposit is extensive laterally, pillars must be properly proportioned to prevent falls of roof. Roofs of untimbered gangways should be arched.

Falls of rock or ore while loading at working face were a prolific source of injuries; evidently due to neglect of timbering or forepoling in weak ground, before mucking or drilling.

Timber or hand tools were an important source of injuries underground. Many such accidents are preventable by selecting careful timbermen. Hand tools on surface and in open-cuts caused over 2% of all injuries.

Explosives accidents, underground and in open-cuts, caused 14.8% of all deaths and 1.1% of all injuries; the proportion of fatal to non-fatal is high. Such accidents are commoner in metal than in coal mining; most of them are readily preventable by: care in storing and handling explosives and detonators on surface and underground; using wooden tamping bars only; use of electric firing in sinking; not returning to face too soon after firing; selection of explosives producing a minimum quantity of poisonous gases (5) (Art 3); proper thawing if necessary.

Haulage accidents, underground and in open-cuts, caused 6.7% of fatalities and 9.2% of injuries. Underground, best safeguards for mechanical and mule haulage, in drifts with small clearance, are: keeping refuge holes well whitewashed; having brakes on cars, and, on heavy grades, blocking wheels of standing cars; good lighting of traveling ways; and strong, not dazzling headlights on locomotives.

Falls down chute, winze, raise or stope are an important cause of both deaths and injuries. Safeguards: grizzlies over chutes, fences and gates around shafts, winzes and chutes, and proper warning boards.

Runs of ore from chute or pocket: accidents are difficult to prevent in steep veins, but well-designed chutes and gates are important.

Electrical accidents. Proportion of fatal to non-fatal is high. Carrying of trolley wires in constricted passages of metal mines is a special danger. Wires should be guarded by side boards, especially opposite chutes, where if possible wires should be placed on far side of drift, as a man in loosening the ore may strike the wire with his bar. Elec lights should be placed near chutes. Power cables should be insulated or thoroughly guarded, and voltage limited to 275 volts. Electrical rules by the American Eng'g Standards Comm and U S Bur of Mines should be followed. Storage-battery locomotives are being extensively substituted in metal mines to prevent accidents and fires caused by trolley wires. Electrical accidents underground, on surface and in open-cuts caused 6.1% of all deaths and 0.5% of all injuries.

Machinery accidents underground, on surface and in open-cuts caused 3.0% of the deaths and 4.2% of the injuries.

Mine fires in metal mines, though costly, rarely cause fatalities.

Suffocation from natural gases is rare, as inflows of noxious gases are infrequent in U S metal mines. Strong mechanical ventilation is the best preventive.

Inrush of water, a minor cause except in occasional disasters, such as flooding of the Milford mine in 1924, which caused 41 deaths.

Falling down shafts is prevented by good fences and automatic gates at every landing.

Objects falling down shafts. Accidents are largely preventable by: smooth-running cages or skips; not overloading cars or skips; dumping clear of shaft mouth; tight chutes, bins and floors in shaft and shaft house; tight or wire-mesh fences around landings; and placing fences and gates far enough back from shaft to prevent men standing dangerously near. Falling of objects on men on cages or buckets can be prevented by good bonnets on cages, and on crossheads over buckets or skips used for hoisting men. In inclined shafts, man cars or cages should have doors

Breakage of hoisting ropes is a minor cause, considering the great number of man hoists in use.

Table 23. Accidents in All Mines Except Coal, 1935 (W. W. Adams, U S Bur of Mines)

		No of accidents		% of total from all causes		Per cent fatalities in total from this cause

Overwinding accidents have been lessened by the growing use of elec hoists with automatic speed regulators (see Sec 12).

Cage and skip accidents, due to faulty construction, are entirely unnecessary. Absence of fences and gates at landings may allow men to be struck by passing cages or skips; or, when on the cage, some part of the body may extend beyond the edge. Excessive crowding on cages when changing shifts should be prohibited. Man cages should have strong bonnets, inclosed sides and proper end-gates and safety catches. It is notable that, though hoisting by bucket without guides is common in the Joplin zinc district, no deaths from this cause occurred in 1935.

Stepping on nail, underground and on surface, caused 2.1% of all injuries.

Handling materials other than rock or ore, underground, on surface and in open-cuts, caused 1.8% of the deaths and 13.1% of the injuries.

Surface accidents, distinct from those in open-cuts caused one fifth as many deaths and one fifth as many injuries as accidents underground. In open-cuts, proper methods of mining, care in examining ground and efficient supervision are of prime importance.

14. COLLIERY EXPLOSIONS

The number of deaths annually from coal mine explosions in the U S rose steadily until 1907, when 956 men were killed, including 361 in the disaster at Monongah, West Va, the worst that has occurred in this country. The most destructive of all explosions was in the Courrières colliery, France, in 1906, resulting in 1 100 deaths.

Classification of explosions into firedamp and coal-dust explosions and windy shots is attempted by different State Inspection departments. But there is no agreed basis in this classification; some inspectors attempt to classify an explosion by its originating cause, others by its means of propagation (usually coal dust). European statistics also do not usually distinguish between explosions of gas and dust, and both are often concerned. Only in the Penna anthracite district are explosions definitely from firedamp, because anthracite dust does not itself propagate an explosion. Though the logical basis of classification appears to be the mode of propagation, rather than the cause, no distinction is made in Tables 23a and 24, but the Bureau of Mines is now separating " cause ignition " from " means of propagation." Colliery explosion disasters from CH_4 and coal dust, acting together or alone, in which more than 100 men were killed in each, are listed in Table 24.

Table 23a. Killed in Gas and Dust Explosions in U S Coal Mines, Contrasted with Deaths from All Causes (W. W. Adams and L. E. Geyer, U S Bur Mines)

Year	Total killed					Rate per million man-hr	
	Explosions			All causes	% of total from explosions	Explosions	All causes

Causes of explosions can not always be determined, because of conflicting evidence of forces, direction of movements and heat effects. It is safe to assume that almost all major explosions were propagated by coal dust. Rock dusting, except at a very few mines, did not begin until 1924. In the years 1925 to 1934 inclusive there were 1 678 killed, or 168 per year. There was a slight decrease from 1925 to 1930, but more improvement after 1930, and in 1935–6–7 the aver was 48, due probably to wider adoption of rock dusting. Blown-out or overcharged blasts of long-flame explosives, or the discharge of these in the open, igniting gas or coal dust or both; electric flashes; open lights, or defective safety lamps; mine fires, which may ignite gas and in turn coal dust; and lastly, but rarely, CH_4 may possibly be ignited by sparks from flinty rocks falling from roof or running down steep breasts or chutes, striking on each other, or on iron. Some explosions have been attributed to electric ignition of coal dust stirred up into a cloud by derailment and wreckage of trains of cars; others to ignition of bodies of gas by mine fires, where ventilation has been cut off by falls of roof or erection of stoppings (Art 15).

Propagation of explosions. Firedamp was formerly believed to be the only cause of explosions, but bituminous and lignitic dust are now known to be more important means of propagation. CH_4 rarely exists in explosive proportions throughout large areas in mines, even in gaseous districts, because of the generally efficient ventilation. Therefore, though some Penna anthracite mines are among the most gaseous in the world, explosions are localized; while in some nearly non-gaseous bituminous mines explosions have swept through miles of entries.

Firedamp and coal dust make a dangerous combination, each aiding the other in starting and propagating explosions; but, BITUMINOUS AND LIGNITE DUSTS are highly dangerous in themselves, and if ignited when in suspension and in certain densities of dust cloud, will propagate an explosion as violent as a gas explosion; in fact, finely-divided coal dust (and other dry carbonaceous dusts, of sugar, soap, paper and cereal) when mixed with air, behave essentially like explosive gases (61,63,64). Pure coal dust has no definite upper limit of explosibility in air, like CH_4 (14%). Hence, it is more certain to propagate an explosion as far as it extends in sufficient density in air, where not treated with rock dust, or the passages are not well sprayed.

Ignition of firedamp. In still air, by side ignition, CH_4 is just explosive at $5^1/_2$%. In rapidly-moving currents the ignition limit is lowered, and at 1 000 lineal ft per min it is 0.5%. But, such high velocities with explosive proportions of CH_4 in strong ventilating currents are found only in great outbursts. If firedamp is detected in a ventilating current, men are usually withdrawn from that part of the mine. This should always be done (except in emergency work), when there is enough CH_4 to show a cap in a safety lamp in a moving current, or when by analysis there is over 2% CH_4, or, if open lights are used, when the current contains 0.5% CH_4 (Art 6).

CH_4 comes from blowers in the face, floor or roof, especially where there have been falls. In still air it is usually given off faster than it diffuses. Hence, it stratifies at roof level, or in a roof cavity. Then, if ignited, it burns rather slowly unless the body of gas has considerable lateral extension, when it flashes with increasing violence. Pressure theoretically generated by the max explosive percentage of pure CH_4 (9.4%) is about 125 lb per sq in. Through loss of heat, not over 70 or 80 lb press is actually obtained without pre-compression.

Prevention of firedamp explosions: (*a*) Strong air current carried to face by stoppings and line brattices; (*b*) prohibition of open lights and smoking of tobacco; (*c*) obligatory use of safety lamps or permissible electric lights; (*d*) use of permissible explosives only; (*e*) tests for CH_4 before and after blasting; (*f*) if undercutting is done by machine, the motor should be explosion-proof; (*g*) prohibition of trolley locomotives and bare power wires in gaseous parts of a mine; (*h*) daily analysis of return air, for control of ventilation; (*i*) rigid inspection of all parts of mine, by fire boss, inspector or foremen; (*j*) sealing off abandoned parts of mine, difficult to ventilate or inspect, and if these areas produce much CH_4, issuing under high press, a vent hole should be drilled from surface. If too deep for drilling a large enough hole, the gas may be piped into a return airway.

Auxiliary fans (Sec 14) and piping (metal or cloth) are used in both coal and metal mines for headings and rooms. Auxiliary fans are dangerous in gaseous mines. They tend to recirculate the air, so that a gaseous place accumulates CH_4. As they usually run only during working shifts, CH_4 collects between shifts. If driven by non-explosion-proof motors, they may spark and ignite gas. They should be used only for emergencies; and, in gaseous mines, should be driven by compressed-air or explosion-proof motors, for 24 hr per day, as in European coal mines.

Coal dust explosibility investigations, begun by Faraday in 1844, have been carried on in recent years at Liévin Gallery and the Pas de Calais coal field in France; at a testing gallery first at Altofts, later at Eskmeal and Buxton, Great Britain (12, 75); and by U S Bur of Mines at Pittsburgh and the Bruceton Experimental Mine (61, 62, 63). INTERNATIONAL COOPERATION ON MINE SAFETY RESEARCH, begun by an agreement with Great Britain (88, 75) referring especially to mine explosions, standardisation of samples and instruments, and interchange of information, was extended in 1931 to other European nations (88).

Definition of Terms Used in Explosion Experiments

Coal dust means particles which will pass a 20-mesh sieve (Bur of Mines empiric standard), produced in mining and handling coal, or artificially by grinding. To obtain dust of uniform composition and size at different testing stations, coarse coal is ground in ball or roller mills, or other pulverisers. As the inflammability of coal dust increases with fineness, samples are rated by the percentage passing a 200-mesh sieve, all having passed through 20-mesh.

Rock dust includes all inert dusts, from clay, shale or sand, found in mines. For electric haulage quartz sand is used to prevent slippage. While this dilutes the coal dust and gives some protection, since siliceous dust is injurious to breathe, it should not be used as a substitute for shale or limestone dust for general rock-dusting.

Ignition of gas or coal dust (as the term is employed by Bur of Mines) is the starting of inflammation by some initial source of heat. In case of CH_4 the inflammation will pass rapidly into an explosion if there is enough CH_4 in proportion to the adjacent mine spaces. In case of coal dust, premixed with air which has been ignited, combustion may not produce sufficient pressure or concussion to raise more dust, beyond the influence of the agency that brought the ignited dust into suspension; hence the flame will die away and it is not considered a propagation or explosion.

Propagation is the continued inflammation of gas or dust through the mine passages, as far as the gas or dust zone extends.

Explosion, while practically synonymous with propagation, usually connotes considerable dynamic force, advancing as a moving zone of combustion.

Inflammation in gas mixtures is transmitted from point to point by transference of heat by radiation and convection, and by such rapid increase in temp and press of expanding gases that each layer in succession of unburned gas ahead is compressed adiabatically and raised to ignition temp. When this stage is reached, the propagation attains high velocity. This phenomenon was discovered by Berthelot (1881), who termed it "l'onde explosive" (explosion-wave).

Detonation-wave is the term given by Dixon to the explosion-wave of Bertholet. He states "the rate of the explosion-wave is a definite physical constant for each gaseous mixture; the wave travels with the velocity of sound in the burning gas, which itself is moving rapidly *en masse* in the same direction."

Retonation-wave (Dixon), "l'onde retrograde" (Le Chatelier), is a wave of compression traveling backward through the spent gases.

Reflection-wave (Dixon), "l'onde reflechie" (Le Chatelier), is a compression-wave reflected from a closed end or other contraction or reflecting surface of a tube. In irregular galleries these waves are numerous, and travel forward or backward through the spent gases.

Collision-waves (Dixon), "l'onde prolongie" (Le Chatelier), are compression-waves produced when 2 explosion-waves, generated simultaneously in different parts of a gaseous mixture, meet and extinguish each other, each compression-wave continuing in the direction of its originating explosion-wave.

Secondary waves, like the last three named, do not depend on chemical action to sustain them, and therefore gradually die away; they pass through one another, or are so merged as to be unrecognizable. Their velocities approximate those of sound waves, varying with densities of the gases traversed and the movement *en masse* of these gases relative to the walls of the passageways.

Dixon states, if CH_4 and air are ignited at the closed end of an open tube, the speed of flame increases rapidly to 1 000 meters per sec, without great fluctuations, but does not approach the rapidity of a detonation-wave.

Coal-dust explosion-waves resemble those from gas inflammations, and retonation and reflection-waves are probably identical with those in gas mixtures; but, since uniform dust clouds can not be obtained, laboratory experiments, like those for determining gas explosion-wave velocities, are not possible. In the large testing galleries and Bruceton experimental mine, dust clouds have not yet been made sufficiently uniform to obtain constant acceleration of an explosion flame; while velocities of 2 000 to 4 000 ft per sec have been recorded, it may be as low as 50 ft per sec.

Table 25. Velocities of Explosion-Waves (Le Chatelier)

Kind of wave	Velocity, meters per sec		
	$C_2H_2 + O_2$	$2\,CO + O_2$	$C_2H_2 + 2\,NO$
Detonation-wave...	2 990	1 900	2 850
Retonation-wave...	2 300	....	1 140
Reflection-wave....	2 250	1 000	1 350
Collision-wave.....	2 050	....	....

Shock-wave is a wave of compression which travels in gas as fast as sound, the velocity varying with density of the gas and character of the passage traversed. It may be produced by any violent concussion, as from a blast, and hence is important in raising ignitible dust. Successive shock-waves may advance ahead of the slower-moving explosion. At the Bruceton mine a shock-wave set up in still air by a blown-out shot inside the mine, started at about 1 200 ft per sec, its velocity gradually decreasing to less than 1 100 ft per sec in a distance of 1 300 ft.

Advance air-wave (British, "pioneering-wave") is a compression-wave or a series of them, pushed ahead of the flaming zone of an explosion. It makes possible the propagation of a coal-dust explosion by bringing the dust into suspension.

Return-wave, or wave of depression, is the flow of air at atmos press to fill the partial vacuum produced when the expanded after-gases of an explosion cool. Depressions of 6 to 7 lb per sq in have been recorded in the Bruceton tests (63), and in a larger mine greater depressions might occur. Return-waves, being thus limited in press, are much less violent than primary or secondary waves, but are prolonged. It is possible that in an explosion in a large mine an inward rush may begin in one entry before the heated gases cease discharging from another, provided the two entries are not connected, except in the interior of the mine.

Present (1938) knowledge of coal-dust explosions, based on many investigations of disasters and at testing stations, is summarized as follows:

(*a*) **Coal dust** with a ratio of volatile to total combustible of more than 10 is EXPLOSIVE in air if the percentage of ash in the coal is not too high.

(*b*) **Character and fineness of dust.** Other things being equal: the higher the percentage of volatile-combustible the more explosive is the dust; the finer the dust the more explosive; but, in presence of much fine dust, say less than 200-mesh size, dust coarser even than 20-mesh may enter into the explosion; the higher the ash and moisture the less explosive the dust. Pittsburgh coal dust, 70% passing through a 200-mesh sieve, if mixed with 60% of inert or non-combustible dust, will not ignite from a blast of 4 lb black powder; the stronger the source of ignition the more readily will the dust ignite; thus, if a 50-ft zone of pure coal dust is ignited by a blast, it will in turn ignite an adjacent dust zone mixture of 40% Pittsburgh coal and 60% inert dust, which will then propagate the explosion. Under the above conditions, it requires 75% inert dust to prevent propagation. With low-volatile coal dusts less of the inert mixture will prevent ignition and propagation.

(*c*) **Low-volatile Penn anthracite dust** containing less than 6% volatile combustible is not explosive, either alone or in presence of CH_4 below the explosive limit of the latter. This conclusion is supported by immunity of the Penn anthracite district to widespread explosions. A certain variety of anthracite, of softer structure and volatile-combustible ratio of about 10%, would not alone propagate an explosion, but would do so in presence of 1% or more CH_4.

(*d*) **Presence of CH_4** in the air, in percentage below its own explosive limit, INCREASES EXPLOSIBILITY OF COAL DUST (except low-volatile anthracites). An increase of each 1% CH_4 seems to offset 3 to 5% or more increase in inert matter; hence the increased danger of dust explosions in gaseous workings.

(*e*) **High humidity of the atmosphere**, even to saturation, or wet walls and floor DO NOT PREVENT IGNITION OR PROPAGATION of a dry dust explosion, for, while presence of moisture is retardant, the quantity present even at saturation is insignificant as compared with the heat energy of sufficient coal dust to propagate an explosion. Moreover, the specific heat of water vapor is little more than that of the inert nitrogen of the air, which must also be raised to ignition temp.

(*f*) **High moisture content** of the dust IS FAR MORE IMPORTANT than HIGH HUMIDITY OF THE AIR. Moisture must be converted into vapor or steam, and then raised to ignition temp, replacing some of the air and O present. Moisture content of dust is thus more influential than ash content. But, pure inflammable dust is ignitible by a violent source of ignition, unless mixed with enough moisture to prevent the mechanical raising of a dust cloud. In tests, pure fine Pittsburgh dust, with about 20% moisture, propagated an explosion; to be safe required 30% moisture. Normal moisture of Pittsburgh dust is about 2%. Roughly it requires an amount of water equal to about 1/3 of the weight of dust, to prevent mechanical raising of dust into a cloud (1).

(*g*) **The quantity of Pittsburgh dust that will consume all the O present if completely burned,** is 0.123 oz per cu ft of air at atmos press; but, in a violent explosion, when the press reaches say 120 lb, if the additional dust is present it would require 8 × 0.123 = 0.984 oz, to consume all the O, with corresponding increase in energy. But, since coarse unburned particles are always present, more than the theoretical weight is necessary to obtain max explosive violence.

(*h*) **Excess dust in the air retards explosion,** but this is not of practical importance, for, even if the explosive wave is retarded, the excess dust drops to the floor and the explosion flame, though momentarily continuing at a lower velocity, is equally destructive of life.

(*i*) **Minimum quantity of pure fine (200-mesh) dust that will propagate an explosion.** A test reported by Taffanel, on the most inflammable dust from Courrières, showed 0.023 oz per cu ft of air, and in tests by Rice, on Pittsburgh dust, 0.032 oz per cu ft. These are merely indications for particular cases; 0.12 oz of Pittsburgh dust will theoretically consume all the O in 1 cu ft of air at atmos press. It will make a strong explosion, although not all the dust is actually burned. In a heading 6 by 9 ft (54 sq ft), containing 0.12 oz dust per cu ft, there would be 54 × 0.12 = 6.5 oz of dust per linear ft. If spread evenly on ribs, roof and floor, the thickness of the dust film would be only 0.003 in. There is usually much more than this in the cleanest colliery.

(*j*) **Velocity of a coal-dust explosion.** It starts with comparative slowness, taking 0.5 to 1 sec to traverse the first 100 ft, or possibly several sec with impure or high-ash dusts. With pure dusts the second 100 ft may be traversed at 500 ft per sec, and the third 100 ft at over 1 000 ft per sec. Beyond this the veloc may exceed 3 000 ft per sec. Velocities are usually higher when there is CH_4 in the dust-air mixture. There is not a max flame veloc. Flame passes through the moving air, and coal dust is forced ahead of combustion zone.

(*k*) **Pressures of explosions** are to some extent functions of the velocities. If the origin is a blown-out shot (of say 4 lb black powder), the shock-wave may give a momentary local press of 10 to 15 lb per sq in, falling to less than 5 lb at 150 ft from origin; then succeeds a slight depression, followed by slowly increasing press, which may be only 5 lb at end of first sec. In a pure-coal dust explosion, there is then a rapid rise in press. At the Bruceton mine, 350 ft from the origin, 63 lb per sq in has been registered, at 550 ft, 73 lb and at 750 ft, 119 lb. Higher pressures have been reported in the Altofts and Liévin gallery tests. Press does not rise steadily, but by violent pulsations. When it rises, retonation-waves move backward through the spent gases toward the origin, and beyond it if the passageway provides a continuous circuit into another part of the mine. Such waves may be very violent, throwing loaded cars and other objects toward the origin. Then follows a period when the gases cool and produce a depression, causing inflow of air from distant points. This is a slow wave of low press, probably rarely over 8 lb per sq in, which may also move light objects toward the origin or beyond it, following the main explosion (61).

(*l*) **Coked coal dust.** An explosion of bituminous dust of a coking coal usually leaves much coked material in its path. This is loose near the origin, and is thrown against the faces of timbers or projecting surfaces of walls. As the explosion gains headway coke may be found both facing and on opposite side of salients; at very high veloc but little is deposited, and then only on surfaces facing outward, or in recesses. Variations occur, due to retonation-waves and subsequent scouring action of the inrush of dust-laden air. Globular coke is produced by the coking of particles in transit; usually found only in a *cul de sac*, or stub heading. Coke *in situ* is produced when the flame has lingered in gassy workings. Thin layers of coal on roof or ribs are also coked.

(*m*) **Tracing origin and course of an explosion.** No one feature or piece of evidence is infallible. In extensive explosions, all data must be plotted. When gas ignition is the prime cause it is difficult to determine the precise origin; for if the gas is stratified along the roof, as in still air or a very slow current, it may burn several hundred feet along the roof before mixing with the air sufficiently to come within the explosive limits of CH_4 in air.

(*n*) **Afterdamp from an explosion.** Explosion of gas or dust is the rapid combustion of complex hydrocarbons, under complicated and varying conditions of press, with deficiency or excess of carbonaceous matter. In violent explosions there is some pre-distillation of gas by radiant heat or adiabatic compression. The former is more likely to occur in slow-moving explosions; in rapid ones the fine dust probably burns as a whole, though coarser particles continue to burn until the O is exhausted, after the fore-front of the explosion has passed.

Table 26. Typical Analyses of Gases Taken by Automatic Samplers at the Bruceton Mine, 350 Ft from Origin of Explosion (63)

Test No	No of bottle	Time interval, sec	CO_2	CO	O_2	CH_4	C_2H_4	H_2	N
89	1	0.00*	8.15	5.30	6.51	1.10	0.60	3.15	75.19
	2	0.31	4.44	3.23	12.43	1.01	0.10	1.62	77.17

* With operating foil opposite sampler, the first sampler took 0.03 to 0.04 sec to close from burning of foil. The second and third samplers operated by clockwork started by the foil burning and thus breaking an electric circuit.

Prevention of coal-dust explosions. All the rules for prevention of firedamp explosions (Art 14) are equally applicable to coal-dust explosions, because many of them are caused by ignition of a pocket of CH_4, or more generally by presence of a small percentage of CH_4 in the air. The bad practice of stopping the fan at shot-firing time is no longer employed, as CH_4 may accumulate in the interval before firing. If a mine makes any CH_4, even less than can be detected by casual safety-lamp inspection, the danger of igniting dust is increased; tests at the Bruceton mine show no difference in originating an explosion in still air or in a current. Most experiments have been in practically still air.

In absence of other treatment, very little dry pure dust is required to propagate an explosion, and gangways can not be sufficiently cleaned of dust to insure safety. It is advisable to remove frequently from haulageways both coarse and fine coal, to prevent the traffic making more dust. There are two methods of treatment: wetting and rock-dusting.

Wetting method consists in laying dust by watering, so that it will not be raised by a concussion (*Trans* A I M E, Vol 71, p 1185).

Generalised watering has proved to be a failure. Many explosions have occurred in mines considered to be well-watered; similar disasters took place in Great Britain prior to 1924, and in Germany until 1926. Water dries too quickly in a well-ventilated mine, and, unless coal dust is wet enough to be muddy, watering is of little use. But rock-dusting, now approved in all countries, where efficiently done, has not yet failed.

Rock-dusting method (66, 67) is to spread 3 parts shale or preferably limestone dust for each 1 part of coal dust, as checked by analysis. Haulageways are cleaned thoroughly and the rock dust thrown on roof, ribs, and floor, about 5 lb per lineal ft being required for first treatment in entries about 9 ft wide by 6.5 ft high. Advantages: rock dust is visible, does not change from day to day, and degree of protection afforded is readily checked by rough analysis. It is best applied by dusting machines, which blow off any coal dust remaining in high places where most dangerous, as on roof, timbers and ribs, and replace it with coating of rock dust.

In recent years rock-dusting has been widely adopted. Sir William Garforth in 1907 conducted tests with rock dust at Altofts. Following the Courrières disaster, France established a coal-dust gallery at Liévin, in 1907. The U S Gov't began coal-dust gallery testing (conducted by G. S. Rice in 1908) at Pittsburgh and the Experimental Mine (Bruceton) in 1910. Results of all tests were favorable. In 1913, rock-dusting was recommended in preference to watering by U S Bur of Mines. In 1920, the British Gov't made it mandatory in all dry bituminous mines, and in 1924 in all coal mines (except anthracite) not having 30% water in the coal dust; the rock dust to be so spread that the mixed dust on floor, roof, and sides of workings shall nowhere contain over 50% combustible (66). In 1919, at a mine in Illinois, rock-dust barriers were adopted to limit explosions. In 1924 many U S mines began generalized rock-dusting, the U S Bur of Mines issued specifications therefor, and by 1925, it became widely adopted. Many explosions starting in gas at mine faces are said to have been prevented from propagation by the dust. France, after the World War, officially approved the method. In Germany, Apl 1, 1926, rock-dusting in the Ruhr mines was made obligatory (66, 67).

Specifications for rock-dusting, sponsored by A I M E, and concurred in by U S Bur of Mines, were adopted in 1925 by the Amer Eng'g Standards Comm (66). Essential points: all coal mines except anthracite shall be dusted throughout active entries and workings; entries without tracks and old workings shall have at their entrance ROCK-DUST BARRIERS (see below), of types approved by U S Bur Mines; road, rib, and roof dusts systematically sampled; and, if the incombustible anywhere falls below 55%, that part shall be re-dusted. It was expected that the aver dust mixture will then have over 65% incombustible (68).

Character of rock dust. It should be light colored, like limestone or gypsum, should all pass through a 20-mesh sieve and at least 50% through 200-mesh, and must contain less than 5% free SiO_2, so as not to affect health of miners. To prevent accumulation of coal dust, water sprays should be used on the cutter-bars of machines, and loaded cars sprayed in transit.

Distributing rock dust. In European mines the dust is generally applied by hand, though compressed-air funnels or injectors are used in France, and sometimes in England, where, also, mechanical dust-distributing cars operated by hand or from an axle drive are employed in some mines. In the U S, mechanical distributers are usual. Distributers use permissible elec motors for air-blowers and stirrers or mixers, for obtaining large capacity. One common type with a movable pipe for discharging in any direction has advantages for dusting roof and sides of passages; another has a discharge tilted from side to side of an entry or room; a third has a fixed fan-shaped discharge. Certain distributers have a large-diam air hose on the discharge, to extend through holes in stoppings to the parallel entry, for dusting the latter when it has no track or is the return airway.

Road, roof, and rib-dust sampling should be systematic, a certain number of samples being taken weekly, to determine condition of the dust present as to its explosibility in air.

Samples should be taken separately of: (*a*) road dust; (*b*) rib dust; (*c*) roof dust (including that on timbers). In absence of overhead timber, (*b*) and (*c*) may be combined. In sampling, weigh and sise the dust and analyse separately for (*a*), (*b*) and (*c*). Bur of Mines tests demonstrate that (*a*) is the most dangerous, because of position and fineness, (*b*) next in danger, and (*c*) least of the three, as to ignition and propagation in initial stages of an explosion. Samples may be gathered by a Bur of Mines dust-sampling scoop, with lower receptacle covered by a 10-mesh screen. Oversize is rejected; that through 10-mesh placed in sampling cans, and on reaching the laboratory it is screened on 20-mesh, that passing 20-mesh constituting the sample. Sampling strips should not be over 50 ft apart, if the dust along entry or room appears to be approaching the danger limit (35% combustible). If light-colored rock dust is used, the color as darkened by coal dust is an important indication. ANALYSIS OF SAMPLES need be made only for moisture and ash, except in case of limestone or other dust giving off CO_2. When a mine has no chemist, and always for speed in determining noncombustible material, the Taffanel volumeter should be used; it can be handled by a non-technical man. For a modified form, by Bur of Mines, see (66). Results are entered in a record book, and on a skeleton map of the mine, showing dusted and redusted zones duly dated.

Quantity of rock dust required. For first dusting after cleaning an aver entry, use 2–4 lb of dust; for a room, 4 lb or over. Subsequent amounts depend upon rapidity of deposition of coal dust. In some mines 0.5 ton rock dust to 1 000 ton coal produced may suffice; in old, extensive mines, twice as much may be needed for safety. COST of dusting varies, if done thoroughly, from 0.5¢ to 2¢ per ton of coal produced. It is cheaper than systematic watering, and for rock-dusted mines there is now a deduction in the liability insurance premium. Limestone or gypsum dusting improves illumination and thus tends to lessen accidents along roadways. As gypsum cakes rapidly in moist air, it will not be dispersed in the air by the advance waves of an explosion.

Rock-dust barriers are used to extinguish a coal-dust explosion started in unprotected workings. They consist of pockets of rock dust, arranged to be dispersed by an explosion wave directly in the path of the wave (61, 63, 64, 68). The original TAFFANEL BARRIER, consisting of 10 to 15 overhead shelves, placed across the gangway and piled with rock dust, has proved effective in almost all tests. The RICE BARRIER may be inclosed to prevent contamination by drifting coal dust and to keep rock dust dry; it is operated by wind vanes set for certain air velocities (too low to blow dust from open shelves) and discharges 2 to 3 tons of rock dust in a dense cloud. MODIFIED FORMS OF BARRIER have been developed at various mines, but most of them failed in tests, either because they were too sluggish for fast explosions, or dump the dust in masses instead of dispersing it, or hold too little rock dust, or have no covering to prevent contamination by coal dust or to protect rock dust from humidity, or no guard to prevent personal injury by accidental tripping.

Bur of Mines does not advocate barriers as a substitute for generalised rock-dusting, but recommends that mines be sectionalised and barriers placed at entrances to panels, or inaccessible workings, and at other strategic points. When not supplemented by general rock-dusting, a barrier should contain about 100 lb of dust per sq ft of cross-sec of the passageway; less in large passages, more in small (Rice). Taffanel barriers are used in some French mines as supplemental devices at critical points, and at entrances to separate ventilating splits.

Water barriers, consisting of easily overturned water troughs and tanks, have been tried; but, if tripped by an advance air wave, may discharge the water uselessly before the flame reaches them.

Salts for explosion prevention. $CaCl_2$, a deliquescent salt, when strewn on roadways in granulated form assists in packing the dust. It helps in a naturally dry mine, but is not sufficient in itself to allay the dust. Common salt is not effective, as pure NaCl is not deliquescent. Neither salt prevents ignition or propagation of explosions. Fresh coal dust collects on the crusted salt surfaces faster than it becomes wetted.

15. MINE FIRES

Fires in mines containing much timbering are, as disasters, next in importance to mine explosions. Though few mines are entirely free from danger of fire, risk is minimised by care, good design of plant, and fireproof construction at exposed points (70, 71). In coal and metal mines, where only a few or no lives were lost, the aggregate damages have reached millions of dollars. In the Lake Superior iron district, from 1890 to 1913, 31 fires caused 22 deaths.

Causes of fires: OPEN LIGHTS, igniting timbers, cloth brattices, wood stoppings, hay in stables or en route, lubricating or other oils and saturated cotton waste. Ignition of oil refuse, sawdust or chips, or oil-soaked boards, by MATCHES, CIGARETTES, AND BURNING TOBACCO. Ignition of timbers by DEFECTIVE ELECTRIC WIRING; incandescent lamps in contact with timber. BUILDING SMALL FIRES UNDERGROUND for heating lubricating oil or dinner buckets. Explosion or flame of KEROSENE OR

GASOLENE TORCH igniting timbers, floor, or débris. DUMPING HOT ASHES in open pits connected with underground workings, which may contain carbonaceous material or timber. Fires from this cause in the Penn anthracite region have cost vast sums. It is a source of danger in outcrops of coal beds, and where the caving system is used in metal mines. LIVE-STEAM PIPES in contact with dry timber or carbonaceous material. EXPLOSIVES ignited in handling, or by weak detonators. FRICTION OF WIRE ROPES on timbers, or on wood rollers that have stuck. OVERHEATED BEARINGS of continuously-running machinery like underground fans. Fans should have fireproof settings. LIGHTNING causing fire in wood structures at top of shaft, in timber lining, or at bottom of shaft. SPARKS FROM LOCOMOTIVES passing near shaft mouth. INCENDIARISM. COAL-DUST EXPLOSION throwing hot coked dust on timber or loose coal so that, on reëstablishing air current, fires start up. SPONTANEOUS FIRES are likely to occur in underground rooms containing oily waste. In coal mines they may be caused by slow oxidation in gobs and working places; in metal mines, where there are rich sulphide ores, fires may originate by the sliding of ore in steep stopes; friction on footwall, grinding together of the ore aided by slow oxidation, may heat the sulphides to temp of rapid oxidation. A prolific cause of fires in collieries is ignition of CH_4 by longflame explosives; or coal may take fire from flame of overcharged shots. In metal mines, fires were formerly caused by lighted CANDLE ENDS dropping onto timbers or inflammable material; particularly dangerous at shaft landings or chutes. DROPPING LIGHTED PAPER into ore chutes, to ascertain amount of ore, sometimes ignites the wood lining.

Fire prevention. Most fires are preventable. Irresponsible persons are a constant menace. Table 27 shows the commonest causes are CARELESSNESS IN HANDLING LIGHTS, or in throwing away lighted candle ends or smoldering lamp wicks; preventable by using electric lights, or inclosed lamps or lanterns, at landings, stables, and sidings. At the working face, portable electric miners' lamps in coal mines and acetylene lamps in metal

Table 27. Colliery Fires Causing Loss of 10 or More Lives, and Some Metal Mine Fires

	Date		Name of mine	Place	Lives lost	Origin of fire

	1917	June 8	Granite Mountain	Butte, Mont	163	Carbide light ignited insulation of cable in shaft
	1922	Aug 27	Argonaut	Jackson, Calif	47	Probably elec short circuit igniting shaft timber

mines are safer than oil lamps or candles. Permissible elec miners' cap-lamps are safest and give best illumination.

Lubricate cars on the surface, where feasible; if underground, keep oil in a fireproof room, with cement floor and steel fire door. To heat oil, use hot-water coils. Keep a supply of dry sand in buckets. In metal mines, candles or other combustibles should not be stored on shaft landings, but in metal containers at a distance.

Underground pump, engine, and transformer rooms, in all mines, should be arched, and floored with non-combustible material. There should be fire doors opening outward, for quick closing, and sand or rock dust kept in the room and close outside, for extinguishing electrical fires.

Underground stables (Sec 11, Art 11), should be built of non-combustible material. Straw and hay should be dampened or covered with wet tarpaulin, if handled by men using open lights.

Explosives. Only a day's supply should be STORED UNDERGROUND; and while such explosives should be kept in wood-lined magazines, the exterior walls and doors should be of non-combustible material. No OPEN LIGHTS permitted IN MAGAZINES. Thawing of explosives should be done at a distance from shaft, protected by an offset.

Incandescent electric lighting, properly installed and insulated, at shaft landings or bottoms and in stables, is a great measure of protection. Lamp sockets should be fixed, not hung loose from cords, and the bulbs have wire-guards. Elec lights (except permissible portable lamps) and wiring should not be used in coal mines where the air current may contain as much as 0.25% CH_4.

Fireproof construction. Fires often start in colliery tipples, and in the headframes or shaft houses of metal mines, the burning embers dropping down the shaft. Such structures should be of all-steel or concrete. Where wood is used the members should be massive and the space between shaft collar and landing floor not inclosed. Mine entrances should never be covered with inflammable structures. Shaft collars should be concreted where possible. Permanent shafts less than 1 000 ft deep can at reasonable cost be lined throughout with gunite or concrete; it is even more important to fireproof shaft bottoms, and landings. When the escape shaft is near the hoisting, or main shaft, there should be triplicate ventilating doors in connecting passageways, one of which opens in a direction opposed to the other two, and all close automatically by counterweights. This prevents a fire from short-circuiting, and burning out both shafts.

Power lines. Steam pipes in shafts are now obsolete. ELECTRIC LINES must be insulated or armored, and not in contact with coal or timber; bare lines in a passageway should be strung on side opposite to that along which men travel; in levels of pitching veins, on side opposite the chutes. Guard boards are necessary at all crossings where lines are less than 7 ft above track or floor. Lines passing through wooden door frames or brattices must be insulated. Fixed power lines are best put in buried conduits; when in gaseous collieries, should always be installed in intake airways. In collieries, stationary electric machinery should be only in intake airways; portable electric machinery, of permissible type, with approved trailing cable and junction boxes when at working faces, in return airways, or where there may be inflammable gas. See "Safety Rules for Elec Equipment in Coal Mines," adopted, 1926, by Amer Eng'g Standards Comm.

Fires in caved workings of metal mines are sometimes caused by blasting adjacent to broken timbers with dynamite, which has a flame of sufficient length and duration to ignite wood, especially if imperfectly detonated by weak caps. For such work permissible explosives, as for coal mining, lessen danger of ignition.

Spontaneous fires in goaves, rooms, or chambers of COLLIERIES are preventable by hydraulic filling with sand or culm. In METAL MINES having large bodies of heavy sulphide ores, spontaneous fires may occur and are difficult to cope with; where possible, apply hydraulic filling. Means of dealing with such fires is by use of fire stoppings, and pressure ventilation in adjacent live workings.

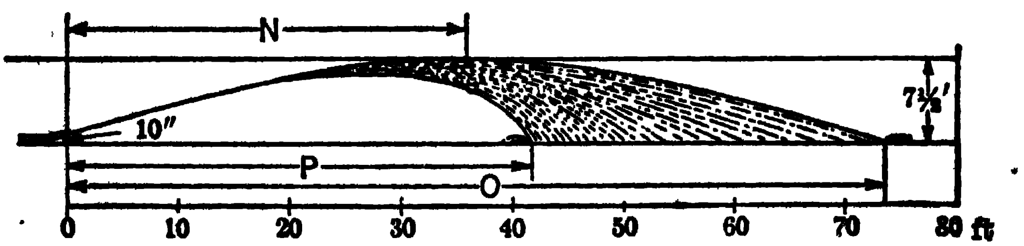

Fig 7. Max Trajectory of Water Jet in an Entry 7.5 ft high. Press at hydrant, 40 lb; length of hose, 50 ft; diam of hose, 1.5 in (71)

Fire-fighting equipment. All mines containing timber should have ample water supply and pipe lines laid around mine openings and surface plant, and to shaft landings. In some cases pipe lines extend throughout the mine, as in many collieries, for both fire protection and wetting down coal dust at the face. Small CO_2 and water fire extinguishers are useful. Hydrants should be not over 100 ft apart; all hose taps uniform in size, with standard threaded connections. FIRE HOSE in 50-ft lengths, on portable reels, and with nozzles attached, should be kept in boxes along entries, timbered drifts or levels, at intervals of 600 to 1 000 ft. For underground handling by one man in emergencies, 1.5-in hose is best size, with 0.5 to 0.75-in cone nozzle; best operating pressure, 30 to 40 lb per sq in.

Fig 7 and Table 28 give results of tests in the Bruceton mine (71) and indicate limitations of stream trajectories in entries or drifts of ordinary height.

	9/16	29 1/2	38	58 1/2	48						

(a) N = horiz distance from orifice of nozzle to point where curve of stream is tangent to roof; P = horiz distance from orifice to point where lower part of stream strikes the floor; O = horiz distance from orifice to point where upper part of stream strikes floor (Fig 7) (71).

Water pressure may be regulated in deep mines by automatic differential pressure valves; or by water tanks in offsets from shaft at different levels, with float-operated filling valves. Ample water supply should be kept in elevated reservoirs or tanks, to be independent of fire pumps in case of emergency. To PREVENT FREEZING, carry pipe-lines down the upcast and through return airways, or heat the water in a circuit connected with the water column.

Automatic sprinklers are sometimes used for surface plants and in shafts and underground stables. They are too expensive for use throughout the mine. Where fire-lines are not used, water-filled FIRE BUCKETS and WATER BARRELS painted red should be placed at intervals, particularly at shaft landings.

Emergency fire-doors at critical points are effective for shutting off fire areas. Manipulation of ventilating fans and air currents is of great importance in fighting fires; colliery fans should always be reversible (71).

Fire-fighting organization. Trained crews on each working shift should have monthly practice at assumed points of fire. Copies of SPECIAL FIRE MAPS, showing plan of ventilation, all water lines and taps, and position of pumps, hose, and other apparatus, should be placed in each fire-hose box throughout the mine and on surface. Where pipe lines do not run, FIRE EXTINGUISHERS should be placed at such intervals that no more than 5 min will be required to reach any point in the tributary district. In some collieries large CHEMICAL FIRE EXTINGUISHERS are placed on mine trucks for rapid transport. Underground TELEPHONE SYSTEM is valuable in fighting fires. SMOKE HELMETS, in which the air is renewed by pumping, are good in fighting fire, but as the user can not go more than about 200 ft from the base, they are not well adapted for emergency work. OXYGEN BREATHING APPARATUS (Art 16, 19) is used more for fighting fires than for rescue work after explosions. CO gas masks, approved for use where safety lamps will burn, are now widely used; but where O is deficient, oxygen breathing apparatus is necessary (77).

Fighting colliery fires. It is best to attack directly by streams of water, but if the air current is toward the point of attack and coming past the fire, water may turn to steam and make it difficult for the firefighters. In this case, throw on large quantities of limestone dust or sand to blanket the fire; the former is best if it is possible to approach close enough. In bituminous mines bags of limestone dust are stored at convenient points (66). The dust checks the flames, but, if there is a large mass of burning coal and timber, water

must be applied to cool and extinguish it. If the fire still makes headway or, in case of a gob fire, is not approachable because of roof falls, it must be inclosed by stoppings.

In presence of gas, as closing by stoppings is dangerous, the last stopping which shuts off intake air should be a door, with weights and pulleys for automatic closing. A counterweight is also attached, consisting of a bucket of water which is allowed to trickle away, and when empty the main weight shuts the door. Or, the door can be held open by cords, which are broken by the discharge of caps or a few ounces of permissible explosive covered with clay or rock dust to prevent ignition of possible gas. The danger caused by shutting off the air current is from the backing up to the fire of CH_4 from blowers, or distilled gases from the coal. Explosive gases may be generated by fires in metal mines having shale walls. Generally, gases from timber fires are not explosive. In collieries, if after the temporary stoppings or brattices have been erected for some hours, no explosion results, permanent stoppings should be begun. A pneumatic dam (Art 17) may help as an emergency stopping. A practically air-tight emergency stopping is a light steel or wood frame across the passage, covered with wiring or burlap, thickly coated with gunite. This was used in a Butte mine, to enclose a pyritic fire in a stoped area, and prevent air reaching the fire through joints in the walls.

Direction and volume of ventilating current. The current should not pass over the fire, but a line brattice should be brought up the entry, with a cross-brattice so erected as to prevent air from feeding the fire. The question may arise whether it is better to shut off the air by a stopping on the intake or the return side. Where stoppings can not be erected simultaneously, due to gas and smoke, it is best to place the first stopping on intake side, so the men can work in fresh air. Placing it on the return side may be dangerous, as it backs up distilled and other inflammable gases over the live fire and may result in explosion. Hence, the first stopping should be on the intake side; then, by carrying in air by deflecting brattices, build the stopping on the return side, completing with an automatically closing door. Before erecting fire stoppings in bituminous mines, the vicinity is rock-dusted to prevent a coal-dust explosion from gas.

Reversing ventilation promptly is important. At one disastrous mine fire, which started at foot of intake shaft, when the fan was finally reversed (after lapse of about half an hour), the fire had reached the other shaft and many lives were lost. A fan should never be reversed without knowledge and approval of the underground foreman; hence the importance of an underground telephone system, connected with the surface.

Sealing fire area. Stoppings should be as close to the fire as possible. If the sealing is perfect, flame is soon extinguished in the inclosed area by depletion of O, also in collieries by absorption of O by the coal (Art 3); then slow combustion continues until the O is practically exhausted; with tight fire stoppings and a small inclosed area, this may take from 1 week to several months. Where CH_4 evolves rapidly in the area of a blazing fire, do not place the seals too close to the fire, but 500–1 000 ft away, so an explosive mixture will not occur before the seals are built. In such case CO_2, liberated from tanks on the intake side of the fire, lessens danger of gas explosion (71).

Perfect sealing is impossible. Though the stoppings be airtight, air percolates through fractured strata, or along bedding planes, and most rocks are porous. A change in barom press of 0.5 in above or below normal is equivalent to a difference of 1.3 in of water-gage on one side or other of the inclosing pillars and stoppings. It is then a question whether the O is consumed faster than it is renewed by leakage. This is tested by taking samples of air through pipes with valves, placed in each stopping. Where the nature of strata or thinness of pillars permits rapid leakage, INJECTION OF INERT GAS (CO_2 or SO_2) is useful, not because these gases have materially greater extinctive effect than excess N, but to reduce the proportion of O below the 10 or 12% which permits active combustion. If the area is small LIVE STEAM may be used with advantage (71), serving to keep fresh air from entering, by maintaining higher press than atmospheric in the fire area. If the area is large, as of an entire mine, injection of gases or of steam is of little value; steam is rapidly condensed, and the inert gases are absorbed by the water. Moreover the volume of gas available for injection is usually insignificant as compared with the spaces to be filled. SO_2 GAS, made by burning sulphur, has been tried; results, inconclusive. In burning sulphur, it is difficult to keep the O in the gaseous products down to 10 or 12%. CARBON DIOXODE, produced by action of H_2SO_4 on limestone, was tried at a large fire in a Colo mine, which had been surrounded by fire walls, but failed due to roof breaks admitting air (71). If properly controlled, PRODUCTS FROM BURNING NATURAL GAS, or PRODUCER GAS, might be suitable for injection. But, a fire furnishes its own extinctive gases, and it rarely pays to inject artificial gases. Liquid CO_2 was recently successfully used in a German colliery to extinguish a persistent gob fire in steep-dipping workings, when other means had failed due to leakage of air. After covering the gob with sand, the CO_2 was forced through pipes into the burning mass, cooling it by expanding and also excluding O (71). After combustion stops, the HEAT OF A LARGE FIRE, surrounded by its own ashes, DISSIPATES VERY SLOWLY. The Monarch mine fire, Ill (1910), was sealed for 2 months, and when the area was explored by men with oxygen breathing apparatus, no excessive heat was observed; but, on admitting a ventilating current, smouldering fires under heavy roof falls immediately revived and had to be dug out.

Flooding the mine with water is usually the last resort in fighting fires, since it is slow and costly, first to flood, then to pump out and repair damage. In collieries damage may be considerable, owing to falls of roof, or to squeezes where the bottom is soft shale or

clay. An UNDERGROUND CONTOUR MAP of the mine is of utmost importance in deciding for or against flooding. To LIMIT THE FIRE AREA dams may be necessary, and must be strongly built to resist water press, if on steep dips. Preparatory to flooding, plans must be made to liberate entrapped air or gas above the fire level by drill holes; otherwise, the water level may not reach high points of the fire. In one mine, after attempting to extinguish fire by sealing, water was run into the shafts until it rose above the main working level, but when pumped out, hot coals were said to have been found in an upper portion of the workings, not reached by water on account of entrapped gases.

16. INUNDATIONS AND COLLAPSE OF MINES

Mine inundations in foreign countries, where collieries are sometimes worked under the sea, have been diastrous. In a Japanese colliery, water from the sea broke through a fault plane in sandstone extending up 155 ft to the sea bottom, which consisted of 82 ft of sands and clays; 237 men were drowned. Inundations with large loss of life have been rare in American mines. Except in the Lake Superior district, little mining is done near large bodies of water. In coal mining, of which the records are more complete than for metal mining, to 1915, 7 inundations caused 149 deaths. Four of the 7 inundations were due to inrushes of water from old workings. Sept 25, 1923, the Redding Colliery, Scotland, tapped old water-filled workings, and 40 men were drowned. In metal mining, the loss of life has been light. Feb 5, 1924, an inrush killed 41 men in the Milford iron mine, Crosby, Minn. Nov 3, 1926, an inrush from a swamp killed 51 men in the Barnes-Hecker iron mine, Ishpeming, Mich.

Prevention of inundations. Surface flooding is prevented by proper location of shafts and proper grading. To prevent future flooding from abandoned workings, plans and cross sections of excavations that are to be abandoned must be made. In approaching old workings long holes must be drilled in advance (by diamond drill or equivalent) through which the water is drained. In working large deposits, where the width of orebody prevents adequate solid support of the water-bearing ground, the latter must be kept well drained, or completely excavated down to the rock or ore. Water and sand inrushes in shaft-sinking through water-bearing ground, or driving headings under stream beds in loose formation, is sometimes a problem (Sec 8). For effects of caisson disease, see Sec 15, Art 28, also Bib 83. BARRIER PILLARS left around old workings must be carefully calculated to carry the load due to overlying strata. This is a more important factor in estimating the required strength of barrier pillars than the hydraulic head, for, if the pillar begins to crush, water will percolate through the pillar, and cause its failure. (For data on barrier and other pillars, see Sec 10). This problem has been important in the anthracite district of Penn, where upper workings have filled with water; also in the bituminous field, wherein steep-dipping beds there is different ownership of workings to the rise and those to the dip. The question of required strength of barrier pillars is so important that a state commission was appointed. They reported that a barrier pillar strong enough to resist crushing by the overburden was sufficient to act as a dam (74).

Collapse of mines. "Squeezes" in coal mines, causing the "top" and "bottom" to come together, are usually gradual enough to permit the men to escape; but, in 1914, the Adamson No 1 mine, Okla, collapsed so suddenly that 13 men were killed. Cavings may occur when ore or coal has been too completely extracted, leaving insufficient pillars for roof support. Timbering, also, at considerable depth below surface, may be inadequate to support the superincumbent weight. In coal mining, squeezes are especially apt to occur when the clay underlying the seam is softer than the pillar of coal, which is then forced downward, with side flow and heaving of the clay. PREVENTION OF CAVING in coal mining: (*a*) in room and pillar work, take out in advance or first mining 20% to not over 60%, depending on depth of seam below surface; (*b*) pack excavations with rock débris, or fill by sand flushing; (*c*) or, work the seam by longwall, with stowing (Sec 10). Similarly in metal mining, size of pillars must be proportionate to the strength of rock or ore composing them, and the weight to be supported. In deep metal mining, besides leaving strong pillars, empty stopes should be filled with waste or sand, or with rock blasted from hanging- or foot-wall. Sand from tailing piles is often used for filling. Back-filling with crushed mine waste, blown through a large pipe to a hose at the face, has recently begun in European coal mines, for level workings or even those to the rise, but is less efficient than sand-filling.

"Bumps" in coal mines are primarily due to wt of overlying strata. They throw slabs of coal violently from ribs or sides, break down roof, or burst up the floor with a loud report that sounds like the word "bump." A violent bump will smash down or dislodge timbers and may cause an air-blast.

Tremors, like a local earthquake, caused by a severe bump in 1916 at Coal Creek mine, B C, were felt over 5 miles away (12). Gas is sometimes given off simultaneously. Rice (12) suggests 2 kinds: PRESSURE-BUMPS, in which a pillar or adjacent stratum is overloaded and bursts, like a rock in a crushing machine, and SHOCK-BUMPS, where sudden breakage of a rigid stratum above and spanning a subsidence cavity, produces a hammer-blow on mine roof. Conditions causing pressure-bumps: (a) wt of overlying strata too great for unit strength of coal acting as a pillar; (b) strong roof over the coal bed; (c) fairly strong floor, not flowing or squeezing under press. Then, a weak pillar spalls off violently; or the floor may burst upward and scatter the props. To cause shock-bumps, besides conditions named above, there must be: (a) strong, rigid rocks above the coal seam and immediate roof; (b) subsidence of some kind under these rigid rocks; (c) excessive roof span, so that overlying rock breaks and falls, striking on the immediate roof and causing a shock-wave, imparted to pillars and floor. In certain mines, the roof is so elastic that, after bending a few inches, it springs back, leaving a wedge-shaped space over the edge of pillar. This may displace timbers. Bumps occur only in deep mines (say, 1 500 ft or more), and under strong strata. Severe bumps have occurred in Springhill No 2 mine, Nova Scotia, which Rice believes were pressure-bumps, and those in Coal Creek mine, 1916, shock-bumps. Bumps have been noted in England and elsewhere in Europe (11, 12).

Remedies. Since the chief cause of danger to men is overloaded pillars, or, in case of shock-bumps, false or loose top, and as bumps are rarely dangerous in longwall mining, longwall should obviously be used under conditions causing bumps, and, where suitable, retreating longwall. This refers to severe cases; lesser pressure-bumps are usually preventable by leaving large, evenly spaced pillars on the advance, and drawing them systematically to prevent concentration of wt on weak blocks. Tests on strength of coal in pillars, made for Penna Anthracite Mine Cave Commission, 1912–13, on small blocks taken from the mine, may not give true results owing to effect of cleat, or face joints (74). Coal is semi-plastic when pressure at right angles to bed exceeds 2 000 or 3 000 lb per sq in or more, depending on character of coal (74). The British Safety in Mines Research Board has recently made tests of convergence of roof and floor in various mines, both on longwall faces, and in narrow headings into the face. One example cited (1936) was in a 4 1/2 ft bed, 2 100 ft deep, where slow descent of roof extended 68 ft ahead of the face, and forward slanting breaks in the roof shale were observed 50 ft in advance (88).

Rock-bursts and air-blasts in metal mines resemble bumps in coal mines, being marked by sudden bursting off of masses of hanging wall or pillars. Sometimes individual rock blocks are under strain and easily fly apart (termed "explosive rock"). Since vein matter and walls of metal mines are usually stronger than in coal mines, rock-bursts are not serious until greater depths are reached than where bumps occur in coal mines; rarely giving trouble at depths less than 4 000 ft.

Rock-bursts might be classified like bumps into PRESSURE-BURSTS, SHOCK-DISTURBANCES and, with very local effects, EXPLOSIVE-ROCKS. Pressure-bursts have caused anxiety in the Lake Superior copper conglomerate vein, at vert depths of 5 000 ft or more; especially in drawing pillars between stopes, when the diagonal line of extraction approaches shaft or level pillars, and sometimes have caused air-blasts. Shock-waves also have been caused by ground movements in hanging wall, producing severe tremors felt more on the surface than underground. Previous to 1924, the Calumet & Hecla mine adopted retreating longwall without leaving pillars, at depths of 3 500 to 4 900 ft. Only trouble from bursts was in approaching shaft pillars, which are in the vein (72 *a*, *b*).

In the Kolar mine, India, below the 5 000-ft level, rock bursts began when 60% of vein was extracted; granite blocks quarried on surface, placed in packs to support 40% of hanging wall, gave favorable results, as they compress 10%, compared to 23% compression of packed pigstyes (72*c*). A later study (1937) of the Kolar outbursts illustrates doming and effect of different supports. Pigstyes, pronounced unsuccessful in the Rand mines, are valuable if filled with granite blocks, after the initial squeeze, whereas waste filling is apt to displace the timbers (72*h*).

As mining becomes deeper, rock-bursts have been increasingly numerous on the Rand, with many earth tremors, and in 1924 a commission, appointed to study them, reported that from 1918 to 1924 rock-bursts had killed 193 and injured 498 men.

Remedies. Sand filling of stopes was formerly considered the best remedy; but at great depths though preventing large movements and collapse of walls, it may fail to check small movement and merely lessens but does not prevent bursts. Longwall mining is regarded favorably (72*d*, *e*). In deep iron mining in the U S, and in the Lake Superior copper district, the problem will be of increasing importance. On the Rand, the danger has been stressed (72*e*) of leaving pillars and remnants, as between approaching faces. The Assoc of Mine Managers, 1933 (72*f*), studied rock-bursts, reporting on use of the "sag meter" to record convergence of hanging and footwalls and give warning of impending bursts, and on relative effic of pigstyes, wood cribs filled and unfilled, circular concrete blocks and circular steel supports filled with sand. For a study of ground failure in deep metal mines, formation and shape of pressure arches and invert arches, effect of pillars and dip of strata, see Bib 72*g* (1937).

RESCUE AND RECOVERY WORK

17. MINE RESCUE APPARATUS AND RESCUE STATIONS

Mine rescue apparatus (76–79) may be classified as: oxygen or air-breathing portable apparatus; resuscitation apparatus, for reviving men overcome by gas or smoke; communication appliances, as telephones, signals and guide ropes; lighting apparatus, portable electric lights, safety lamps; gas indicators, canaries for testing, safety lamps, gas analysis apparatus; first-aid-to-the-injured appliances, as stretchers, medical supplies, underground refuge and first-aid chambers; bratticing materials for restoring ventilation; fire-fighting appliances, as smoke helmets, portable extinguishers chemical engines, hose, water buckets and limestone dust (77, 83, 84). A rescue apparatus room should be adjacent to the mine entrance, with a room equipped with first-aid supplies and medicines.

Portable breathing apparatus for rescue work has long been used. In it the contained air is resupplied with fresh oxygen, and the CO_2 fixated by a chemical substance.

In the U S (1908), after the Marianna mine explosion, Pa, the only living man was saved by a party equipped with Draeger outfits. In 1909, at the Cherry mine fire, exploration with breathing apparatus through a sealed shaft led to reopening the mine, and recovery of 21 men 7 days later. Lives have sometimes been lost due to defects in apparatus, or insufficient training. Though breathing apparatus is far from perfect, it has in general been successful in preventing losses of life. Helmets attached by hose to air pumps, though good for distances to about 200 ft, are useless for general rescue work. They are properly fire-fighting equipment, and are called SMOKE-HELMETS. Self-contained breathing apparatus for rescue and exploration should have at least 2 hr working capac. SELF-RESCUE apparatus, that may be carried in the pocket, is sometimes used (79); they are good for 0.5 hr, against CO_2 and small percentages of CO, but do not supply O.

Gas masks, developed during the World War, led the Bur of Mines to devise masks for mining and other industries. They are now part of the equipment of all well equipped mine rescue and fire fighting stations. The usual gases from explosions, blasting, or mine fires, are CO_2 and CO; sometimes nitrous fumes and H_2S. For chemical works in which special poisonous gases or dusts may occur, particular kinds of gas or dust masks must be used (78, 29).

The most difficult gas to break up or render harmless is CO; finally done by making a chemical compound called HOPCALITE, which catalyzes CO to CO_2. Mask designs differ for various gases. Military masks are unsafe in concentrated poisonous gases, and useless against CO; hence, should never be used in mines during fires or after explosions. For this service, certain masks are approved if used only where an oil lamp, or in coal mines a safety lamp, will burn (requiring presence of 17% O); as they do not supply O, they must be regarded as auxiliaries in mine rescue and fire-fighting work (78).

Characteristics of portable oxygen-breathing apparatus:

(*a*) Apparatus employing O compressed to 120 atmos and in some recent apparatus 135 atmos; CO_2 absorption chemicals (chiefly caustic soda for European apparatus; in U S, soda-lime or cardoxide) in can or box, loose, or on wire trays; a rubber breathing bag, with automatic relief valve, to provide for fluctuations in breathing needs; and forced, circulatory system. The DRAEGER and WESTFALIA apparatus, widely used in different countries, are of this type. Both use either helmet or mouth-breather. Wt, about 40 lb, when charged. The WEG outfit, made in England, is of the same type, but has a mouth breather only and oxygen feed is controlled by an automatic valve, controlled in turn by lung movement, whereas all other kinds of compressed oxygen apparatus have fixed feeds of 2 or 2.5 liters of O per min at atmos pressure.

(*b*) Employing compressed oxygen, with CO_2 absorption chemicals in loose or stick form in a flexible breathing bag, which must be shaken from time to time for better absorption of CO_2; emergency valve on by-pass for O flush-out. The FLEUSS or PROTO outfit (Fig 8), made in England, has a mouth breather only; wt, about 40 lb, fully charged. It has a by-pass for extra supply of O, if needed by wearer. Its parts are: *a*, reducing valve; *b*, by-pass; *c*, main valve; *d*, skull cap; *e*, smoke goggles; *f*, nose clip; *g*, mouth piece; *h*, inhaling valve; *i*, pressure gage; *j*, saliva trap; *k*, relief valve; *l*, exhaling valve; *m*, pressure-gage tube; *n*, pressure-gage valve; *o*, oxygen-supply tube; *p*, caustic-soda spaces; *q*, breathing bag, with inhaling and exhaling compartments; *r*, oxygen containers.

(*c*) Employing compressed O, with CO_2 absorber in liquid form. It is represented by Tissot apparatus, made in France, unique in having in combination with the mouth breather a device for insertion in nostrils, to permit breathing either way. Breathing bag and other parts are contained in a wood-covered knapsack. Wt, 14 kg (31 lb).

(*d*) Employing O liberated from $KNaO_3$, through reaction produced by absorption of moisture and CO_2 of the breath. Not having the heavy oxygen bottles of (*a*), (*b*), and (*c*), it is the lightest and promises success, though a difficulty not yet solved is the high temp of the air supplied and the irregular oxygen feed. Represented by the Pneumatogen, made in Austria; used also in England; mouth breather is employed, 1911 type weighs 22 lb. Reactions for liberation of O and fixation of

CO_2: $KNaO_3 + H_2O = NaOH + KOH + O_2$; $KOH + NaOH + CO_2 = KNaCO_3 + H_2O$; $KNaO_3 + CO_2 = KNaCO_3 + O_2$

Self-contained oxygen breathing apparatus had considerable development during and after the World War. General principles have not changed, but the helmet has been abandoned because of the spaces that may fill with exhaled air and danger of leakage. In the U S the Draeger, Fleuss and other foreign apparatus fell into disuse, and in general have been supplanted by American apparatus like the Gibbs and the Paul; which, with the Fleuss-Davis Proto (British) and the Draeger, 1924 type, are on the Bur of Mines permissible list. The Gibbs and the Paul have automatic oxygen feed-regulating valves, instead of a fixed rate of feed, like the Draeger and Fleuss-Proto, and have a slight outward or positive press throughout the air-circulatory system. This protects against slight leaks when using in poisonous gases or those containing insufficient O. GIBBS APPARATUS (Fig 9): O from bottle passes through a tube with closing and reducing valves to cooler; thence, by admission valve and tube to exhalation side of cooler. Mixture of O and exhaled air passes to regenerator, and up into inhalation side; thence into breathing bag through spaces around admission valve; thence by inhalation tube to lungs; thence through valve to exhalation side of cooler. By-pass valve furnishes O to user independently of main closing valve. The McCaa and Paul outfits are similar to the Gibbs, with minor changes. The McCaa has a 2-hr capac; some are made for 1 hr and 1/2 hr, weigh less and permit quick inspection. For details of these types, see Bur of Mines handbook on "Self-contained Oxygen Breathing Apparatus" (revised 1933), which also describes equipment of rescue stations and trucks (77). In France, the present leading oxygen breathing apparatus is the Fenzy, which also has automatic oxygen-feed regulation (77).

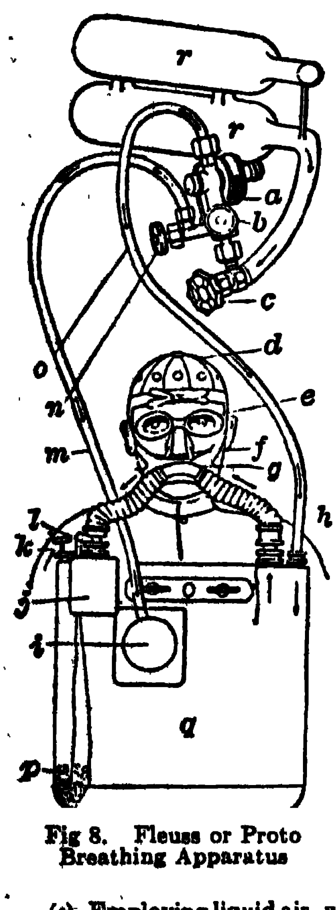

Fig 8. Fleuss or Proto Breathing Apparatus

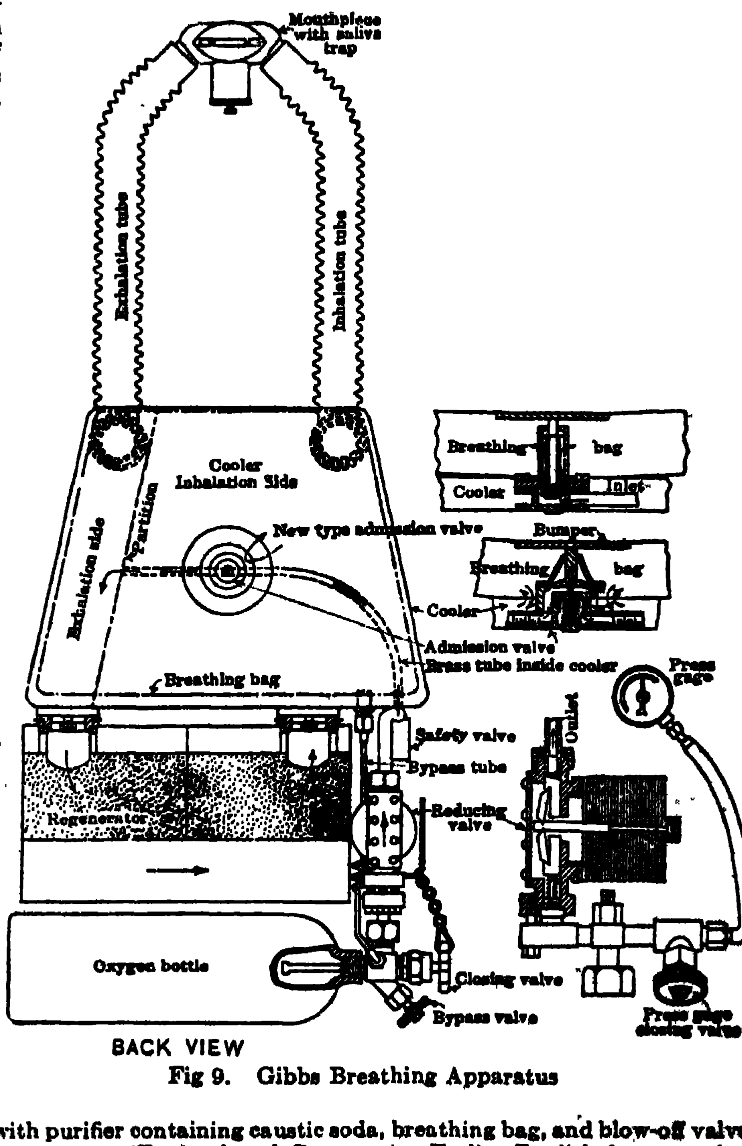

BACK VIEW

Fig 9. Gibbs Breathing Apparatus

(e) Employing liquid air, with purifier containing caustic soda, breathing bag, and blow-off valve. Represented by the Aerolith apparatus (England and Germany). Earlier English form, used at Newcastle Fire and Rescue Station, weighs 40 lb, fully charged with 8.5 lb liquid air. It is contained in a nickel knapsack. Liquid air supply must be constantly renewed by the plant of the rescue station. Air is liquefied at $-191°$ C, and occupies about 0.08 of its vol at sea-level press. The difficulty of having constantly to renew the supply of liquid air, which evaporates whether the instrument is in use or not, prevents general application of this apparatus. IMPROVED LIQUID O APPARATUS. The Brown and Mills, and the Rotherham, have regenerative features (essentially an absorbent for CO_2); have not yet been introduced into the U S.

Portable breathing apparatus used in the U S in 1938 comprise 1130 Gibbs, 869 McCaa and about 300 Paul, Fleuss-Davis, Proto and Draeger, all on Bur of Mines permissible list.

In recent years the number of available sets has not increased: due to concentration of rescue apparatus at central stations in mining districts and greater use of gas masks for supply and construction parties, following rescue and fire-fighting crews wearing oxygen-breathing apparatus.

Care and use of apparatus (77). It must be kept in perfect condition. Every station should have at least 5 sets, better 10. A rescue party should consist of at least 5 men, so if one becomes unconscious there will be 4 to take him out. Men should be thoroughly trained for not less than 6 days, 2 hr per day, and be able to take apart and put together the apparatus. There should be a leader, paid to care for apparatus and train men.

Crews should practice in apparatus 2 hr per week, and be examined periodically by a physician as to their fitness. No one should be permitted to use apparatus under dangerous conditions, without a certificate of training from the Bur of Mines, State training station, or joint or private rescue station giving equivalent training. Apparatus should be kept in a room by itself, dust-free, dry, well ventilated, and not overheated, so the rubber parts will not be injured. It should be cleaned immediately after use, and hung in its proper place ready for emergency calls (77, 80).

Tests of rescue apparatus at high altitudes made (1915) by Bur of Mines on Pike's Peak, Colo, at from 7 000 to 14 000 ft above sea-level, show that standard types of apparatus are efficient, without reference to altitude and at the higher levels more work can be done by wearing apparatus than without it, owing to the liberal oxygen supply.

Resuscitation apparatus. Besides first-aid methods (Art 20), there is special apparatus for reviving rescued persons, by mechanical movement to assist restoration of respiration, and flush bad air out of the lungs by means of oxygen.

Bratt's Resuscitator draws the air and gases from the lungs by suction caused by an ejector, in conjunction with the compressed O, and alternately forces in by light pressure, pure O, or a mixture of O and air. The change from suction to forcing movement is made by a hand lever. PULMOTOR, made by the Draeger Co, accomplishes this movement automatically by pressure of the oxygen. In both of these, the movement may be made by hand, the O being carried in an iron tank or bottle (like those used in rescue apparatus). When the Pulmotor acts automatically it furnishes a mixture of O and air, the proportions of which may be varied to about 35% O. A committee on resuscitation from mine gases, appointed by Bureau of Mines (82), reported adversely on automatic apparatus; on the grounds that, if improperly used, the suction may cause collapse of the air passages in upper part of lungs; and that, in forcing O into the lungs, injury may be caused by the press rising too high. The Committee favored manual methods of artificial respiration, supplemented, in case of gas poisoning, by giving O by an "inhalator," in conjunction with the "prone" manual method (Art 20); or, in exceptional cases, by the Sylvester manual method. Some physiologists favor using 7% CO_2 with 93% O while administering the manual method, as CO_2 stimulates breathing.

Communication apparatus in rescue work. Portable telephones are helpful, for communication between the temporary underground base and the surface, and between base and party using breathing apparatus. The former can employ ordinary telephones, though preferably of iron-clad mine type. They should be placed in intake air; in return air of a gaseous mine, magneto sparks might ignite CH_4. To keep the advancing rescue crew in touch with the base is more difficult. When helmets were used with breathing apparatus, a satisfactory telephone attachment to the helmet was employed; but, since mouth-breathers are now required, a special phone is necessary, requiring no lip movement.

The Western Electric Co make a phone to be strapped to the head, so that it presses against the throat of man using the breathing apparatus. He "talks" while the breather is inserted in his mouth. This takes practice, but sounds transmitted by an experienced man are readily intelligible to a trained man at the base. Field receiver is of ordinary type, held to the ear by a spring. The wires are made into a light-weight, comparatively cheap, cable, to be abandoned in case of retreat. It is on a special reel, to maintain a circuit when paying out or winding up. The chief at the base is therefore constantly in touch with the advance party. This apparatus has been rarely used. Wireless has been tried with little success. Geophones have some value in shallow mines for locating imprisoned men who may rap signals.

Pneumatic horns are good for signaling, especially in descending shafts on cages or buckets. Gongs are inconvenient. The leader of the crew should have a horn, and the chief at base one of different note, or a bell, a code of signals being agreed upon. The first 3 regular hoisting signals should be employed: 1 bell, go ahead, or lower, or stop when in motion; 2 bells, retreat, or hoist; 3 bells, man to be hoisted; on return signal he will get on cage or bucket, and signal 1 bell. Special signals can be arranged.

Guide ropes. When a rescue party is to enter a smoky atmosphere, so that the mine walls are indistinct (especially in crooked passages of an unfamiliar mine), a light manila rope should always be dragged by advancing party, and a code of signals by numbers of tugs on rope is arranged.

Lighting apparatus for rescue work should consist of portable electric lights of permissible type (Art 10).

If these are not available, charged ready for use, ordinary electric flash lights, with dry cell batteries, must be employed. Outside sparking will not ignite firedamp, but if the outer glass and

bulb are broken so as to expose the glowing filament, firedamp will be ignited; hence they must be carefully handled and regarded only as emergency lights, unless of the types free from this objection and approved by the Bur of Mines. SAFETY LAMPS (Art 9) should be carried by at least 2 in each party, to test the air.

Gas indicators. In recovering a mine the rescue party should have safety lamps, Burrell gas indicators, CO detectors; also canaries (Art 5), carried separately in small cages. The Haldane cage is a light aluminum box with mica windows, tight closing door at one end, a bird perch within, a small oxygen bottle above, which serves as a handle, with valve for oxygen admission. Canaries, though more sensitive to CO poisoning than men (Art 5), are less used than formerly, but the Bur of Mines rescue crews often carry them (54). Their advantage over CO detector is that they can be easily watched as the party advances; if one falls it is quickly noted, whereas the CO detector causes a stop to make tests.

Gas-analysis apparatus (Art 11) should be kept in every rescue station. In case of a mine fire, it is important to know if the atmosphere near it approaches explosive limits, so that men can be withdrawn. Also, in fighting fires, the presence of CO in the return air indicates an active fire, as otherwise CO is rapidly diffused and absorbed by moisture.

First-aid-to-the-injured packets and boxes, including simple medical supplies, stretchers, etc, should be in every rescue station and field party (Art 20) (77). A few mines have been equipped with an underground ambulance car, hand pushed or drawn by mine locomotive.

Bratticing material for restoring ventilation. It is impossible to keep enough bratticing at any rescue station to be of importance in recovery work after an explosion, but every mine should have an ample supply; and a joint rescue station, if in the neighborhood, should keep a reserve of brattice cloth.

Smoke helmets are similar to those for diving, being connected by rubber hose to a hand pump; or, if the mine has compressed-air plant, to an air-pipe line, with an automatic pressure-reduction valve and a relief valve between pipe and helmet, set to give not over 6 or 8 oz press per sq in in the helmet.

Return hose to pump is unnecessary, as air escapes around edge of helmet, thus preventing entrance of bad air, and helping to keep helmet cool. If the wearer has a special coat with flaps at neck for fastening around edge of helmet, the escaping air circulates under the clothing and keeps the body cool; important in fighting fire. Haldane found that a man with smoke helmet could do 4 000 ft lb work per min in an atmos at 93 to 94° F, with wet bulb at 84°, and continue for an hour without discomfort.

Two smoke helmets can be connected to a single air hose by using a "Y"; not advisable unless hose is large, and there are other helmets and ample compressed air to effect a rescue if one man be overcome. For safety, work with helmets should not be carried on farther than 200–300 ft from a point where air is pure. Their use is therefore limited to building fire stoppings, or handling hose and directing the stream on the fire. Many helmets are on the market, differing but little. They have been used advantageously at Anaconda mine, Mont, in fighting stope fires. Masks and O apparatus have supplanted smoke helmets, except for erecting fire stoppings or other construction near a fresh-air base, in which case gas masks or airhose masks are less fatiguing to workers (29).

Portable fire extinguishers should be in every rescue station, for dealing with incipient fires after explosions, even in mines having fire-fighting water lines, as these may be damaged by the explosion.

There are numerous good extinguishers, including those requiring simple overturning to empty a vial of H_2SO_4 or other acid to act on Na_2CO_3 for generation of CO_2, thus producing pressure for throwing a stream of water. Not all are adapted to mine use. As such apparatus will be used by trained men, it is better to have a positive and protected means of breaking an H_2SO_4 bottle, and a strong outfit to stand rough handling. Chemical fire engines on mine trucks would rarely be useful for rescue work after explosions, as mine tracks are apt to be temporarily impassable. SPECIAL CHEMICAL EXTINGUISHERS giving off gases are not good for fires in overhead timbers, which require a stream of water. Carbon tetrachloride extinguishers are effic in fires where there is electric arcing, as this liquid is a non-conductor; but are applicable only where air current is strong and all the men are on the intake side, since phosgene and other toxic gases may be produced. Sand or rock-dust are generally best in electrical fires in confined places; water should not be used until elec current in the vicinity has been cut off, to avoid shocks to men handling the hose.

Fire buckets should be a part of rescue station equipment; painted red and labeled "For fire-fighting only."

Water hose. 1.5-in rubber-lined cotton hose, in 50-ft lengths, with standard pipe threading and hand couplers, should be kept at stations. Even if such hose is maintained for use in the mine, it may not be in condition for an emergency. It should be on light reels, easily carried by hand and have special tees of several sizes, with gate valves attached, for clamping on water pipes, a hole being drilled in pipe by a ratchet drill, extending through the open valve. This permits quick connection, without interrupting flow of water.

Pneumatic fire-dam is a German fire-fighting device, of rubber with iron braces, and when filled with air is shaped like a mattress. It has a mica window to permit inspection of the fire, and is intended for quick erection in mine passages, pending building a permanent fire wall. Used with breathing apparatus it has merit for inclosing a fire area quickly, but is not used in U S.

Mine rescue organization and stations. A mine management should not merely purchase apparatus, and hang it up in a dusty, poorly ventilated room. Organized crews and suitably prepared stations are necessary. A man without training is a hindrance, not a help. Apparatus must be properly assembled and charged. Rescue crew unit consists of 5 men. The number of units should be proportioned to number of employes, preferably a certain percentage of each shift. At least 5% of employes should be trained (70, 84).

Five sets of apparatus are recommended for a station, with a spare set for a single crew of 5 men. The station should be near the mine entrance, but not in line with a slope or drift, nor near enough to be destroyed in a fire or explosion. It should comprise a cool, fire-proof, well-ventilated apparatus room; a repair room, with small tools; and a training gallery, which should be tight, to permit testing of apparatus in irrespirable gases; showers or bathroom, a toilet, and a room for lectures and first-aid training.

Joint rescue stations, of which there are several hundred in the U S, are best where mines to be served are near enough for any one to be reached in 30 min by auto or wagon. Advantage of a central station, aside from the larger stock of equipment, is that it permits employment of a foreman living at or near the station and subject to instant call, who is responsible for upkeep of apparatus, and shall train and lead rescue crews. He should therefore be a high type of man. Besides the stated apparatus, the station should contain copies of the mine maps, prepared with reference to possibility of explosions or fires, and showing direction of ventilating currents, hose connections, etc.

State and Federal rescue stations. A few states, as W Va and Ill, have them, and conduct training work. U S Bur of Mines (1938) has 11 stations, 11 rescue RR cars, with equipment for training and rescue; but recently appropriations have been too small to maintain most of them.

Auxiliary equipment for joint rescue stations may include an AUTO RESCUE TRUCK, equipped with 5 sets breathing apparatus, oxygen charging-pump driven by auto motor. 2 folding stretchers, 2 large oxygen tanks, 6 safety lamps, and 10 permissible electric lights; also, masks and other appliances; all on the truck ready for instant departure. If distances to farthest mines are considerable, an auto bus and additional supplies are desirable. For shaft mines, an emergency or collapsible cage, like that designed by Rice, rendered important service in 3 disasters which had wrecked the regular cages. A light hoisting cable should also be provided, long enough for the deepest shaft in the district, also a disk fan driven by an explosion-proof motor, taking current from a storage-battery locomotive, may be useful.

Refuge chambers in collieries are rare in the U S. Cases of men bratticing themselves off after explosions, or when escape was prevented by smoke from fires, indicate that chambers of simple form are best; that is, marking off a finished room, or unused entry in each division of a mine, erecting stoppings in breakthroughs, and providing doors in mouth of the working. Doors need not be strong, merely tight fitting. Prospect holes, if any, may be cased and refuge chambers placed under them, thus securing ventilation and communication. Men should be instructed to go to such chambers in emergencies; to accustom them to this, drinking water, first-aid, and other supplies, may be kept in the chamber, which might also serve as asst foreman's office. Their location should be indicated by signs, and entrances whitewashed, for ready recognition. In case of disaster, rescue parties would search the chambers successively.

Barricades. At the Cherry mine fire, Ill, 1909, 20 men saved their lives by erecting barricades and were rescued after 7 days. In many other similar cases, including metal and coal mine fires and explosions, several hundred men have thus saved themselves (79).

18. RESCUE AND RECOVERY WORK AFTER EXPLOSIONS

Most collieries are exempt from explosions, but explosions are always unexpected; their possibility should be realized, and all means of prevention adopted. The foreman of a rescue station should know instantly what to do, in case of explosion.

First steps after an explosion. Action must often be immediate. Fan should not be reversed, if there is possibility of escape of men through intake. If fan is seriously damaged: (*a*) repair it if possible; (*b*) borrow or buy a small fan, if it can be erected within 48 hr; (*c*) lower a steam jet into the upcast, or, if intake is a slope or drift, erect a wooden chimney say 18 ft high, close to entrance, box it in, with steam jet in its base; (*d*) in extreme emergency, hang a fire-basket in upcast, or at mouth of slope or drift erect a chimney, with fire grate at base. Unless a mine is unusually gaseous the return air at mouth will not be inflammable. It can be tested by a man on guard with a safety lamp, who can admit fresh air to dilute return gases.

Rescue-work organization. State laws are not definite as to who shall be in charge in times of disaster. Generally the state mine inspector takes charge, as a matter of expediency, not legal right, though he has authority to stop underground work, if he sees fit. In other cases, operators' representative assumes control.

Occasionally both sides have disclaimed responsibility, with unfortunate confusion. The Bur of Mines has no legal authority, and its rescue car and station men can be regarded as volunteers only. In any event, SOME ONE PERSON MUST HAVE COMPLETE AUTHORITY, if the work is to be done systematically. An efficient member of the mine staff is usually the best. If question is raised as to his legal authority, he should confer with the state inspector. Notices, signed by state and company officials, should then be posted, naming the person in authority, who may be entitled GENERAL MANAGER OF RESCUE WORK. He at once appoints GUARDS, to prevent entrance into the mine of any except authorized persons, to keep back crowds from mine openings, and to guide and keep volunteers from interfering with the work before they have been assigned places. Guards are marked in some way, as by a colored band pinned around the arm. Ropes are immediately strung about the mine entrances and working yard. The following CHIEF ASSISTANTS are also appointed, each responsible day and night for his part of the work:

(*A*) Chief of surface guards.

(*B*) Man to engage volunteers and assign their duties.

(*C*) Chief of rescue work, with 7 sub-assistants in charge: (*a*) of breathing apparatus and their crews; (*b*) of rescue men without apparatus; (*c*) of bratticing crews. (Usually, *a*, *b*, and *c* work under general direction of state inspectors); (*d*) of keeping safety lamps in order and giving them out; (*e*) of checking men in and out of mine. Each man entering should have a numbered metal tag, to be given up when he comes out, and is checked off. If metal tags are not available, use pasteboard or paper tag put into an upper pocket); (*f*) of stretcher gangs, for removing the injured and dead; (*g*) of marking location of every dead body, with description of how it lay (generally best done by one of the mine surveyors).

(*D*) Doctor in charge of temporary hospital at mine mouth, transport of patients to main hospital, and main hospital itself, in absence of regular organization. If there are enough physicians and surgeons, they are assigned to underground bases.

(*E*) Doctor in general charge of morgue; bodies are taken in charge by coroner.

(*F*) Manager of supplies for rescue apparatus, brattice materials, timber and lumber.

(*G*) Commissary manager, to keep mine village supplied with food, and rescue crews supplied with hot food and coffee at all hours of day and night.

(*H*) Manager of temporary sleeping and living accommodations for the volunteers, such as tents, cots, and bedding near mine mouth and necessary sanitary arrangements, including water for bathing and drinking. The hard-worked and strained rescue and recovery men must have comfortable resting places, at least after the first day. Completely to explore mines after large disasters often requires 1 to 2 weeks or more.

(*I*) Information man, charged with giving out non-sensational, but satisfactory accounts to the press, and to relatives and friends of entombed miners, thus preventing circulation of sensational stories. He should be familiar with mining, and firm but courteous.

Supplies. In great disasters, food and brattice cloth must generally be ordered by telegraph or telephone. A severe explosion may wreck hundreds of stoppings, which must be replaced quickly by temporary stoppings, each requiring 4 yd of brattice cloth, of a width a little more than aver height of seam up to 6 or 8 ft. Each stopping requires at least 3 props and 2 boards.

Manager *F* (above) must immediately estimate supplies on hand, and then order from neighboring mines or supply houses what is needed. UNDERGROUND TELEPHONE supplies are also necessary for communicating with underground bases. Iron-clad box phones are best, but ordinary wall receivers will do temporarily (Art 17, Communication apparatus). Say 100 to 200 suits of miner's overalls should be ordered; also supply of rubber boots, if mine is wet or flooded.

Safety and electric lamps. Even a safety-lamp mine rarely has enough extra lamps (unissued to those entombed) to supply the rescue parties. These must be ordered by wire, with extra glasses, wicks, repair parts, cleaning tools, and gasolene-charging tank. Permissible portable electric miner's cap lamps, with charging board, should be ordered if the mine has electric power for charging; also, electric flash lights, each with 12 extra dry-cell batteries and 2 extra bulbs, are useful in searching for bodies and for general use.

Disinfectants. Chloride of lime, carbolic acid, and other disinfectants should be obtained; if many mules have been killed large quantities will be needed, their bodies being covered with disinfectant and brattice cloth.

Fresh cloth gloves should be supplied on each shift to the men handling bodies, and these and the clothing of the dead should be burned. If bodies are badly decomposed, rubber gloves should be used and disinfected at end of each shift. Outer clothing of men handling bodies should be daily disinfected; if in bad condition, burned and replaced by new clothing.

Underground rescue work should be begun as soon as the parties are organized, but not sooner. Manager of rescue work should secure blue-print copies of the mine maps for the chief of each crew and each state inspector. An engineer, if at hand, should prepare an outline map of entries, slopes, gang-ways, and shafts, with outline scheme of former ventilation. Persons must not be allowed to enter mine singly, but only in groups of 5, under competent mining men. If trained breathing-apparatus crews are at hand they should lead; at least one of the party being acquainted with the mine. Parties without apparatus should proceed cautiously, testing for firedamp with safety lamps (76).

If possible each party should have CH_4 and CO detectors, and for quick indication a canary, to determine presence of CO; if the canary falls (Table 7, Art 5) the party should return to the point where the air was good. Rescue parties should follow the intake air. It may be necessary to wait until the fan or air connections have been repaired, or until temporary hoisting arrangements are made at intake shaft. Such delays are unavoidable, to prevent foolish sacrifice of life due to entering undiluted afterdamp. Sometimes natural ventilation will start by differences in temp and elevation (Sec 14), and thus permit entrance without waiting for fan repairs. Brattice crews should replace temporarily each successive stopping, giving time after each has been set up to clear the gases ahead. The FIRST PARTS OF MINE TO BE SEARCHED ARE NOT THOSE SHOWING MOST VIOLENCE, BUT WHERE THE EXPLOSION HAS WEAKENED OR DIED AWAY, SINCE IN SUCH PLACES THERE MAY BE LIVE MEN. As the U S Bur of Mines has established rescue stations with trucks and there are private rescue stations in different places, trained crews with breathing apparatus will probably arrive within a few hours. These crews should proceed as follows: a crew goes ahead to next open crosscut, if not over say 100 ft; through this and back on the return for some distance, and back to temporary base, examining for smouldering fires, extinguishing them, and noting location of bodies. Then the open crosscut in front of base should be bratticed, and intake air forced ahead for advancing the base. On branch and butt entries, rooms should be successively examined by the crews, to determine when necessary to carry brattices into them. As soon as the bodies are removed from any pair of entries these should be bratticed off. With rare exceptions, BREATHING-APPARATUS CREWS SHOULD NOT HANDLE BODIES; THEY SHOULD RESERVE THEIR STRENGTH AND TIME FOR THEIR SPECIAL FUNCTION OF SEARCHING FOR THE LIVING, EXTINGUISHING FIRES AND LOCATING BODIES They should not work more than 2 hr at a time. Thus, let crew *A* be relieved by crew *B* for 2 hr, while *A* waits at base; then *B* rests while *A* again works 2 hr; *A* then goes out of the mine. As it may take say 0.5 hr to come and go to headquarters outside, each crew, on finishing its second 2 hr and going outside, will have been on duty 7 hr. Allowing 0.5 hr at beginning and end of shift for eating and 8 hr for sleep, the crew will be able to resume its round, being thus 14 hr out of 24 on duty, of which 8 hr will be under oxygen. This is about the maximum, and more rest should be allowed in recovering a large mine. On above basis, continuous advancing exploration would take a *minimum* of 4 crews of 5 men each, but 6 or even 8 crews of apparatus men would be far better. Bodies are labeled by a number tag, and location and condition recorded in a notebook. On rib or roof close to the body its number is marked in a circle. Knowledge of the position and condition of the bodies is often vital in determining the origin of an explosion.

Investigation of explosion. State inspectors are required to make an inspection and report, which is usually done after most of the bodies have been recovered, and ventilation restored. Inspectors often forbid other examinations until they have made their own.

Operators generally make an independent inspection. Bur of Mines engineers also investigate the cause and mode of propagation of the explosion from point to point; their report is not published, but information is furnished to the manager with a view to remedying dangerous conditions. The Bureau publishes data on the various explosions in a district, but, to avoid legal responsibility, without naming the mines.

19. RECOVERY WORK AFTER MINE FIRES

Preliminary procedure (71) in reopening mines or mine areas which have been sealed (Art 15, 17). Before disturbing the seals it is well to obtain mine air samples from behind the fire stoppings, through pipes left in the stoppings, or by drilling holes through them or at one side, and inserting pipe with valve.

In collieries giving off CH_4 freely in the sealed area, its presence is usually indicated by leakage through or around the stoppings, and men engaged in sampling, drilling or reopening must have no open lights. Also, the hole, if through concrete or brick, is drilled slightly downward, and kept filled with water, to avoid sparks struck at moment of finishing.

Absence of CO in fire-area atmosphere indicates that active FIRE IS OUT; but it is not conclusive, for, if the point of sampling is far from a smouldering fire, the CO actually produced may be absorbed by moisture on the walls. Mine-air samples from a hole drilled to or over the seat of the fire give truer results. They must be taken when the movement is outward, as when barometer is falling, though if sampled through a drill hole the air can be pumped out. If the movement is not outward, the sample will be defective, due to air leakage through or around stoppings. If the sample shows any CO, the fire is probably alive, and unless time is vital it is wise to defer reopening, meantime recoating all firewalls.

Reopening a mine or fire area, after a small fire, especially if near the working face, rarely presents difficulty. But if the fire is nearer the entrances, and, from its duration before sealing, was known to be extensive, especially if the whole mine was sealed, the problem is more serious, above all in a gaseous colliery, but also in any mine in which there is extensive timbering or rich sulphide ores. In this case, it is almost certain there are hot coals buried under ashes and roof falls, and if fresh air is admitted it is likely to revive the fire.

Reopening a gaseous mine, in which there is smouldering fire, is always dangerous, since, if air is admitted, it may make an explosive mixture with CH_4 and distilled hydro-

carbons. Men with hose and wearing oxygen or smoke helmets should first enter behind stoppings to extinguish the fire. Build airlocks of flooring material, with 2 doors and space between, in front of the fire wall which seals the drift entrance, or over shaft, if top of shaft is sealed off. Then have seal broken by men using breathing apparatus (Art 17). If seal is of concrete, certain preliminaries are necessary before erecting the airlocks, so that heavy work will not have to be done by men in apparatus.

This preliminary work consists in cutting a groove around the seal with chisels (preferably pneumatic chisels), as nearly through the concrete as possible without bringing it down, having tarpaulin ready to throw over in case a hole is knocked through. Sometimes, at drift or slope entrances, it may be best to tunnel around the stopping, but the airlock is built before breaking through. Because of the difficulty of reopening, temporary firewalls are best made of brick laid in lime mortar, and coated with cement.

Blasting down firewalls in the presence of firedamp must be done with care; only quick-acting permissible explosives should be used, tamped with fine rock dust or dry cement. This will make an inert dust cloud that will prevent ignition of CH_4 or coal dust. A battering ram, of a heavy timber suspended by wires or ropes from temporary framing, is efficient for knocking down brick walls. In shafts, provision is necessary for lowering and hoisting men and supplies through the airlock. If regular cages can not be used, buckets, or an emergency cage (Art 17) is required. After building an airlock a trained rescue crew wearing apparatus begins investigation.

In critical cases a relief crew in apparatus should be in waiting. If water collects on the shaft bottom to a depth preventing exploration, it may be best to fill the shaft with cinders or gravel to a point above the roof level of the entries, to permit taking off the shaft seal and ventilating to bottom. Then pump out the water. Finally, construct an airlock at bottom, and explore the mine with aid of oxygen apparatus. The investigation should extend as far as it is safe to travel, but not exceeding 45 min (1.5 hr round trip) from base, so that if all goes well there would be on returning 0.5-hr oxygen and soda supply available. This provides little enough margin if difficulties are met, and 1 hr round trip from base is a safer limit. Thus, if mine passages are clear and not hot, a distance of 1 mile from base can be traversed; but under adverse conditions, as extensive roof falls or accumulation of water, it is unsafe to advance more than 1 200 ft from base. If seat of fire is beyond these limits, the party should merely take samples of the air, and study where new stoppings can be erected nearer the fire zone (71).

After conditions within the sealed-off area have been determined by one or more trips of the apparatus crews, the problem is: (*a*) whether stoppings are to be removed and ventilation restored; (*b*) if fire is too distant or extensive to be inspected with breathing apparatus, to make new stoppings nearer to fire zone, to permit part of the mine to be recovered for operation, and carry ventilation to the new stoppings, which will serve as a base for further inspection.

Advance fire stoppings, put in by apparatus crews, are usually of brattice cloth and boards nailed to props. These are generally sufficient to prevent serious escape of extinctive gases, while more substantial stoppings are being erected in their rear. Pneumatic stoppings (Art 17) are suitable for temporary use, when the passageway is of uniform section.

Restoring ventilation in a fire area where there may be a smouldering fire or hot buried coals is dangerous in a gaseous colliery. Mine-air samples should be taken and analyzed to determine that the atmosphere on being diluted will not be explosive. If it is likely to be explosive at one stage of dilution it is safer to withdraw all men from the mine as soon as the stoppings have been opened, which, under serious conditions should be opened automatically, or by blasting by electric circuit from surface. Men should be kept out until, by making frequent analyses of the return air, danger is judged to be over. When men can enter, inspection of the fire area is made by a party carrying a canary. If the fire is found to be reviving, water lines are brought in quickly, and placed on the fire. Fallen rock, under which there may be coals hot enough to flame in presence of fresh air, should be drenched before removal.

20. FIRST AID TO THE INJURED. MINE HOSPITALS

"First aid," is the giving of immediate assistance to an injured person with the means at hand, that may prevent injury from becoming permanent, may save his life, tend to prevent dangerous infection of an open wound, and to lessen pain. It is especially important in mining, since a severely injured man at a distant point of a large mine may not be immediately found, and by the time an empty car can be secured, hauled to the shaft and hoisted, an hour or more may elapse, and perhaps another hour before a surgeon can be brought to the mine receiving room or the miner's home. First aid was first taught to miners in the Penn anthracite district, and afterward extended to many mining districts by the Bur of Mines and Red Cross Soc. It has been a marked success; much suffering has been prevented, and many lives saved. It has taught miners the importance of

hygiene in their daily lives, disciplined them by the necessity of team work, and by inter-mine, state, and national first-aid contests, has given incentive for young miners to advance themselves.

First-aid directions for injuries are given in Bur of Mines circular 8 and "Manual of First-aid Instruction," 1935 (82, 83).

First-aid organization should be formed at every mine, to train men and for social betterment and improved living conditions. Officers of the organization should include a medical director. For practice, membership should be divided into teams of 6 men: 1 captain, 1 patient bearer, and 4 stretcher bearers. Joseph A. Holmes Safety Assn has now (1938) 472 Safety Chapters in 28 states, which cooperate with the Bur of Mines in promoting first-aid and rescue training in all branches of the mineral industry.

Equipment needed for practice. Each squad should have: 12 triangular bandages; 12 medium-size safety pins; 6 packages gauze (plain or picric); 6 first-aid outfits; 6 light wood or yucca splints, 3.5 in wide by 18 in long; 12 roller bandages, assorted sizes; 2 tourniquets; 2 rolls cotton, plain or absorbent; 2 blankets (U S army preferable); 1 stretcher (U S army regulation); 6 wooden splints for legs and back fractures; 1 or 2 sets of first-aid charts.

Organizing teams (76). Men working in same part of mine, and on same shift, should be grouped. Each team should have a first-aid cabinet at a convenient point in their part of the mine, and each member always carry at least one first-aid packet, containing a triangular bandage and sterile compress.

In case someone has been hurt, a first-aid man should hasten to the scene, and quickly and carefully examine the victim. If the injury is serious, other members of the team should be collected, and the mine physician notified (by phone, when the mine is equipped with phones) so he may know the nature of the injury. For gathering the team, each member might have a policeman's whistle, a code of whistles being prearranged to signal the locality of an injured person. If there is a flow of blood, it should be stopped by pressure on the right spot. Place patient in as comfortable position as possible, keep him warm, and cheer him up.

Necessity of antiseptic conditions. Bacteria or germs are minute vegetable cells, found in air, water, the ground, clothing, and on and in the body. The mouth and sputum are filled with germs, some harmless, some more or less harmful, besides those which produce specific diseases. For propagation, each requires a certain food, temperature, and environment. Having found a suitable breeding place, which may be in the human body, they multiply rapidly and give off poisonous substances (TOXINS). These may simply be irritants, or may destroy tissue. Under some conditions harmful bacteria may produce blood-poisoning. Bacteria gain entrance to the body through wounds, or the digestive system; first-aid deals with the former source of infection.

Sepsis arises from entrance of harmful bacteria into a wound, causing inflammation; poisonous substances are produced, destroying tissue, forming pus and preventing healing. To avoid sepsis, prevent germs from entering a wound by keeping unclean things from contact with it. Destroy or prevent growth of germs that may have entered at the time of injury.

Antisepsis is the treatment of wounds by DISINFECTION. Disinfectant, or germicide, kills bacteria, and their spores or eggs. Destruction of disease germs in clothing and excreta is called STERILIZATION.

Hemorrhage. Loss of one-third of the blood in the body usually causes death. Compression and position are methods of first-aid treatment. Compression is applied by fingers, compresses, tourniquets, or constricting bands (handkerchief, belt strap, suspenders, or other means). In ARTERIAL HEMORRHAGE, the most dangerous, blood gushes in a bright red stream. Pressure must be applied between the wound and heart. In CAPILLARY HEMORRHAGE, bright red blood oozes slowly; easily controlled by applying a clean compress of gauze. In VENOUS HEMORRHAGE the blood is dark red or blue, and discharges steadily. The compression should be on the side of wound away from the heart. Usually, bleeding can be controlled by applying a compress of sterile gauze directly over the place. Elevating the bleeding part aids in controlling flow of blood. After stopping bleeding, the patient should be treated for shock.

Shock is a sudden depression of vital powers, arising from injury or profound emotion, inducing exhaustion. Symptons are sub-normal temp; irregular, weak, rapid pulse; cold, pale, profusely-perspiring skin; irregular breathing; patient usually conscious, but stupid and indifferent, lying with partly-closed eyelids. Be sure there is no concealed hemorrhage, needing immediate attention. TREATMENT: Lower patient's head, wrap him in blankets, or whatever clothing is available. If possible give an ordinary stimulant like black coffee, to be sipped hot; or, half-teaspoonful doses of aromatic spirits of ammonia every 20 or 30 min. Inhalation of oxygen is often useful; artificial respiration is necessary in some cases. Hot applications over heart and spine should be made.

Contusion, or bruise. Skin is unbroken, or merely injured. Symptoms: tenderness, swelling and numbness, followed by aching pain. Discoloration occurs quickly in surface contusions. TREATMENT: elevate injured part, bandage tightly to arrest bleeding and control swelling; apply icebag or towels wet with cold water.

Wounds are classified as: INCISED wounds, made by a sharp instrument; CONTUSED, by a blunt object, like a fall of rock; LACERATED, by tearing or dragging, as by machinery. Symptoms: Pain, bleeding, and gaping or retracted edges. TREATMENT: Remove clothing from wound at once; arrest bleeding (see above) and put on sterile dressing. Never wash wounds; leave this to physician. If done in the mine, the wound may be infected by washing unclean substances into it.

Fractures are the most important injuries for treatment in mines by first-aid, because the victim is temporarily crippled, and if neglected or ignorantly handled there may be permanent crippling. Kinds of fracture: INCOMPLETE, bone not entirely broken; COMPLETE, bone is broken; SIMPLE, broken bone does not protrude through the flesh; in COMPOUND FRACTURE, one broken end protrudes, or has cut or torn the flesh down to the bone. Compound fracture is nearly always accompanied by loss of blood and severe shock. Symptoms of fracture: pain, swelling, discoloration, abnormal motion of bone, loss of power, and grating together of bone ends. TREATMENT: Examine with gentleness; handle limb as little as possible; draw it into natural position and fix by splints. If nature of injury is in doubt, await the doctor; a sufferer from broken limb should never be moved until the part is properly supported by splints.

Dislocation is displacement of surfaces of a joint. In simple dislocation, articular ends are separated without injury to surrounding tissue; in compound dislocation, the ligaments around joint are torn. In complicated dislocations, muscles, vessels, and nerves are injured. Symptoms: Pain, swelling, discoloration, rigidity, natural position of limb is changed and length altered. TREATMENT: Restore bone to normal position and hold it in place. First-aid men should never try to reduce dislocations, except those of jaw and fingers; some surgical skill is generally needed.

Sprain is twisting or wrenching of a joint, producing a tearing of ligaments and sometimes of surrounding soft parts. It is followed by severe pains, and marked swelling and discoloration. TREATMENT: Let injured person rest. Elevate injured part and fix it in place by splints, or wrapping joint tightly with a roller bandage or adhesive plaster. Give hot or cold applications by placing injured part in hot or cold water, or by towels wrung out of hot water or ice water.

Strain is wrenching or tearing of a muscle or tendon; usually caused by violent exertion, or sudden movement. It causes sharp pain. TREATMENT: Let injured person rest; bandage injured part tightly, or apply adhesive plaster; splinting sometimes necessary.

Burns and scalds. FIRST DEGREE burn is simply a scorching or reddening of outer skin; SECOND DEGREE destroys entire thickness of skin; THIRD DEGREE destroys skin and tissue beneath. Shock caused by severe burns. TREATMENT: Carefully remove clothing from burned surface, from which exclude air at once with clean covering. Best covering is picric-acid gauze (sterile gauze, saturated with 1% solution of picric acid, or 0.5 teaspoonful to 1 pt water). Moisten the gauze with clean water and apply it to burned surface. Place absorbent cotton over the gauze, and apply bandage to hold it in place. Vaseline, sweet oil, olive oil, and balsam oil are all good dressings. If nothing better is at hand, dissolve bicarbonate of soda in sterilised water. Gauze dipped in this and spread over the burn gives relief. Carron oil (a mixture of equal parts of lime water and linseed oil) has been used, but is not recommended.

Electric shock. Electrical contact with a live wire causes dangerous shocks, burns, and sometimes death. Symptoms: sudden loss of consciousness; absence of, or very light, respiration; weak pulse, and burns at points of contact. If victim is in contact with wire, do not touch him without first short-circuiting the current. Do not search for a switch, as time is too important, but lean a drill or iron bar from one rail to the trolley line, preferably at a point between victim and power station. If no bar is at hand, stand on a dry board or piece of paper, and pull him off with a gloved hand; or having no glove, use cap or other article of clothing, so as not to receive a shock. Or, drag victim from the wire with a rope, belt, or bandana, looped over his feet. TREATMENT: As soon as patient has been freed, begin artificial respiration (see below).

Suffocation or asphyxiation may be caused by an object blocking the windpipe, by drowning, or by inhalation of gas and air mixtures, which fill the lungs without supplying sufficient oxygen; or by inhalation of poisonous gas, like CO (Art 5), causing unconsciousness, and possibly suspension of breathing by poisoning rather than absence of oxygen. TREATMENT: Quickly remove patient to good air; apply artificial respiration, and if he has been in poisonous gas give him oxygen treatment.

Artificial respiration. There are 2 principal methods, the Schaefer, or prone, and the Sylvester, in which the patient is placed on his back. The Schaefer is generally approved by physicians.

Directions for its use (82). Quickly feel with finger in patient's mouth and throat, to remove any foreign body (tobacco, false teeth, etc); then begin artificial respiration. Do not stop to loosen patient's clothing; every moment's delay is serious. Lay the subject on his belly, with arms extended straight forward, with face to one side so that nose and mouth are free for breathing (Fig 10). Let an assistant draw forward subject's tongue. Avoid so laying subject down that any injured places are pressed upon. Do not permit bystanders to crowd about and shut off fresh air. Kneel, straddling the subject's thighs, and facing his head; rest the palms of your hands on victim's loins (or muscles of small of back), with thumbs nearly touching each other and with fingers spread over the lowest ribs (Fig 10a). With arms straight, swing forward slowly so that that the weight of your body is gradually brought to bear on the subject (Fig 10b). This operation should take 2 or 3 sec, and must not be violent, lest internal organs be injured. Lower part of chest, and also the abdomen, are thus compressed, and air is forced out of the lungs. Then swing backward, to remove pressure, but leave your hands in place, returning to first position. By their elasticity, the chest walls expand and the lungs are supplied with fresh air. After 2 sec, swing forward again, and repeat the 2 movements 12 to 15 times a min, making a complete respiration in 4 or 5 sec. Having no watch or clock, follow natural rate of your own breathing, swinging forward with each expiration and backward with each inspiration.

While this is being done, an assistant should loosen any tight clothing about the patient's neck, chest, or waist. Continue treatment, if necessary, 2 hr or longer, without interruption, until natural breathing is restored, or until a physician arrives. After natural breathing begins see that it continues; if it stops, resume artificial respiration. During the operation keep subject warm by

proper covering, and by laying beside his body bottles or rubber bags of warm (not hot) water. Keeping subject warm should be done by an assistant. Do not give any liquids whatever by mouth until subject is fully conscious.

It is considered unnecessary to give oxygen in addition to manual treatment unless patient had been "gassed." Mechanically-forced respiration is not approved, because of possible injury to lung cells, and when oxygen is advisable it should be by hand manipulation, keeping time with normal respiration. Inhalation apparatus can be utilized in unison with the manual treatment, as by the Schaefer method, a mask being fastened over the nose and mouth, and the apparatus (Art 17) operated by an assistant.

Bandages are to keep dressings in place, retain splints on broken limbs, stop bleeding by pressure, and as slings. Kinds: triangular, roller, and special bandage of U S army. TRIANGULAR BANDAGE is useful in first-aid work; easy to make and apply. It should be of unbleached cotton, linen or muslin; cheese cloth is too soft and difficult to fold properly; bed sheeting or pillow cases are good. The cloth should be 34 to 40 in sq, and by cutting diagonally 2 bandages are made. Use safety pins and knots for fastening. ROLLER BANDAGE is of muslin, flannel, gauze, or cheese cloth, wound on itself to form a tight roll; requires practice to apply properly.

Tourniquet, to stop profuse bleeding from arteries or veins, consists of a strap around the limb, and a pad under the strap, to press on artery or vein. Many first-aid cabinets contain U S army regulation tourniquet: a strap of webbing, with buckle and catch. An improvised tourniquet may be made of a handkerchief, towel, triangular bandage, pair of suspenders, or belt strap. Tie around the limb, with a pad over artery or vein, pass a stick through the loop, and twist until blood barely oozes, or is stopped.

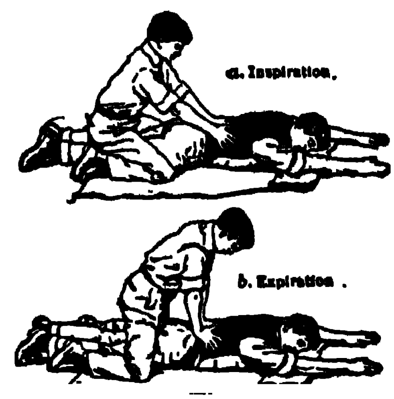

Fig 10. Schaefer Method of Artificial Respiration

Transportation of the injured. In a mine it is often impossible to bring an empty car near the point where the victim lies; he must sometimes be carried long distances. If done in a clumsy manner, much of the benefit of first-aid may be undone. Carry serious cases on a stretcher, sometimes improvised, by using mining drills passed through the sleeves of 3 or 4 coats, the coats being buttoned. These are established first-aid methods of carrying a patient by 1, 2, 3, or 4 men, with and without stretchers.

Ambulance car should be maintained by large mines. It saves much suffering if arranged with springs and suspension supports for a stretcher.

Underground hospital. In extensive mines, the car containing the injured man may be delayed at bottom of a cold downcast shaft. On this account, and to maintain medical and first-aid supplies, some mines have underground hospitals where injured persons can receive supplemental treatment. They should be well-lighted, painted white, and kept clean; have an operating table for first-aid treatment, first-aid equipment, drinking and washing water, etc.

Surface hospital near the mine entrance is advisable, as most mines are distant from a town hospital, and a patient might have to wait in heat, or cold, or a dusty building, for ambulance. A small well-lighted room is sufficient, painted white, with smooth floor, and equipped with first-aid supplies, cot, table, water supply, and disinfectants. Surface and underground hospitals may be inexpensive, but should be absolutely clean.

MINE SAFETY

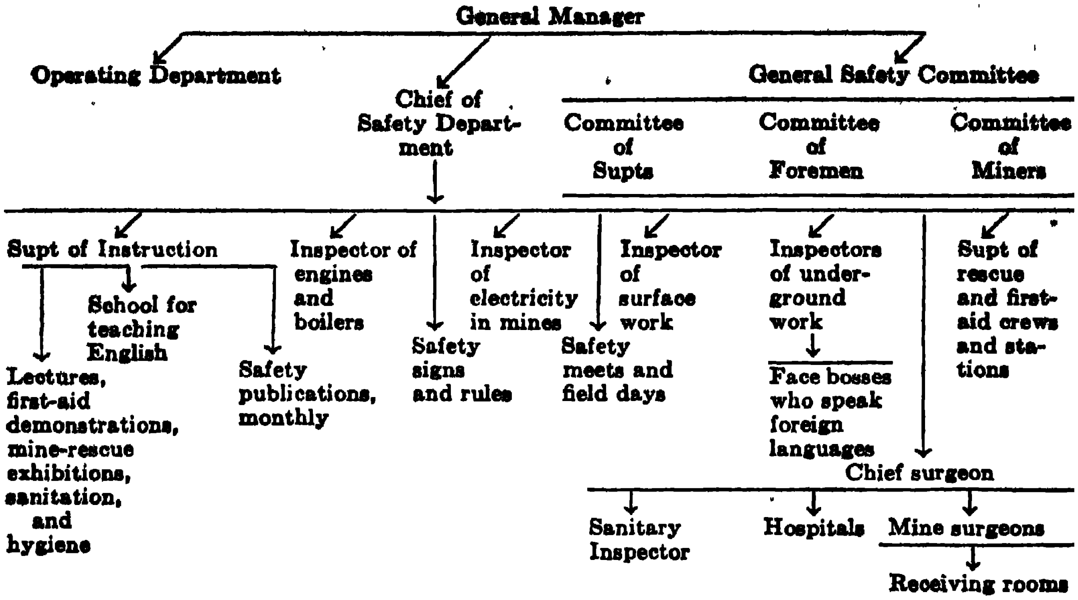
21. SAFETY ORGANIZATION FOR MINING COMPANIES

Safety organization is essential to sound business policy, and rests on humanitarian grounds.

Compensation acts of many states have greatly increased cost of settling death and injury claims; in some states this cost, in percentage of payroll, is 2 to 4 times that which prevailed up to 1910 (Art 24). But compensation now goes more fully to injured persons or needy heirs, and is not as formerly so largely consumed in litigation. Mining companies should care for widows, orphans, and injured, resulting from accidents, instead of depending on public charity. The industry also is benefited by safety improvements, since the cost of accidents must ultimately be added to selling price of product. See Sec 22, Art 8.

Avoidable accidents in U S mines form 60 to 75% of the total. They can be lessened by inspection, education, discipline, safety appliances, and proper organization. Best kind of organization is parallel to, but independent of, the operating department.

Plan of Safety Organization for Large Companies, Suggested by Rice



An energetic manager, in the effort to economise in mining, transport, and loading ore or other product, may overlook questions of safety, and for economy or speed continue to use machinery that should be scrapped. On the other hand, an overcareful, timid manager, constantly fearing accident, becomes inefficient. But, if the organisation includes a competent inspector, responsible to a higher authority than the operating manager, and reports a certain practice unsafe or recommends a change, the manager is relieved that he is not responsible for the cost incurred.

22. MINE SUPERVISION AND INSPECTION

Supervision. Mine accidents are often due to isolation of the miners, one or two in a working place, rendering supervision difficult. While there is usually a foreman, with shift-, timber-, and other special bosses, many miners may be scattered in remote workings, with only a single shift-boss to supervise a large area; especially true under the contract system. As the shift-boss may not be able to visit each working every day, proper timbering and other safety precautions are apt to be neglected. There should be enough assistant foremen or shift-bosses to inspect every working at least twice a day; 4 times a day is the practice in the Yorkshire longwall mines. The best practice is to have one boss to 20 to 25 miners.

Face-boss. Where many underground workers can not speak English, it is important to have a "face-boss," who is a good miner and able to speak several languages, to direct foreigners as to their duties; or, if a written order has been given by the foreman, to translate and explain it. Accidents often happen because the foreman, in giving instructions to foreigners, has supposed they understood when they said "yes, yes," while knowing no English.

Inspection by general company officers every 2 or 3 months, by general supts 2 or 3 times a month, and by mine supt and foreman each day, is vitally important. There must also be detailed inspection by special inspectors. In collieries, especially when gaseous, a FIRE-BOSS must, under some state laws, visit all workings and abandoned places which are not walled off, within 2 hours before entrance of day shift, to test for gas or firedamp, fence off places making gas, and mark dangerous places in the roof for setting timber. On returning to the mine entrance, and before the men are allowed to enter, he shall post information concerning dangerous or gassy places, and enter notes regarding the inspection in a book kept for the purpose. Large mines may require several fire-bosses.

Private mine inspectors, as distinguished from state inspectors, are employed by large companies to report on observed conditions to a higher official of the company, in some cases to the General Manager, in others to the President. This system has resulted in improvement in safety and hygienic conditions; also, through information secured from the miners, it corrects injustice to individuals, and produces better relations between company and employes.

Checking men in and out of mines. At large mines, especially collieries, there should be a complete record of every one underground at any time.

The simplest mode of doing this is to number every employe, keeping his name and place of working either in the pay-roll ledger or in a special book in an office near the mine entrance. Before entering the mine, each man must pass by the office window (the shaft or mine entry being fenced in), and receive a metal check bearing his number, preferably arranged with a safety-pin, for fastening to his clothing, or with a small chain passed through a button hole. Before distribution, as each shift goes on duty, the checks hang on nails on a frame, with a number over each nail. As the number of employes changes, unused numbers are covered by hanging pieces of cardboard over them, the corresponding checks being kept in a drawer or box. As each man comes to the surface and passes by the checking office, he leaves his check, which is hung on the board. Examination of the board at any time shows how many men are underground, and a review of the book, in which each man's working place is recorded, indicates where the men are; an important matter in case of fire or explosion.

Inspection of men and equipment entering a gaseous colliery should be regularly made by a responsible man at the mine opening. He examines lamps, tests safety lamps, and examines clothing of an occasional man and all new employes to see that no one carries matches, smoking tobacco, or pipes. It is possible to light tobacco by heating a wire inserted through safety lamp gauze, or by producing an electric spark through manipulation of an electric lamp or battery; hence possession of smoking material indicates dangerous practices.

23. SAFETY MEETINGS AND PUBLICATIONS

Safety meetings, as an aid to increased care in preventing mine accidents, educate miners and foremen alike, and foster harmonious relations between employer and employe. State and national contests attract attention of miners to the movement and its importance to themselves. SAFETY PUBLICATIONS, issued by mining companies from time to time, do great good, because employes who can read English learn how a certain accident occurred, and how it might have been prevented.

Joseph A. Holmes Safety Assn (see Art 20).

Danger signs and direction signs are useful in preventing accidents, and by adopting uniform symbols, especially the red ball for danger, and the arrow pointing the direction in which to go, non-English speaking miners can understand what to avoid and where to go safely.

Bonus for workmen, as a reward for safety records and suggestions, has distinct value. A large coal Co in W Va, with a very low accident rate, gives a substantial sum monthly to foremen in its half dozen mines. As the mines are sectionalized, the results indicate how large a factor leadership and characteristics of different foremen is in attaining max safety possible under the natural hazards in mining. Other companies have similar practice.

24. MINE-ACCIDENT LIABILITY INSURANCE

Workmen's compensation acts. Until mining states began the enactment of these Acts, the cost of death and injury cases was generally small as compared with payroll cost; widows, orphans, and injured were generously treated by some companies (Sec 22).

To about 1910, coal-mine accident insurance ranged in different states from \$1.50 to \$3.00, and limited insurance was given by one cooperative company in a central state on preferred rates at 75¢ per \$100 of payroll; in the same state rates now range from \$3.50 to \$5 per \$100, and are quoted at \$7 on coal mines in a western state that has had many disasters. Metal-mine compensation costs have been similarly increased by compensation acts of the respective states.

Insurance for meeting liability arising from mine accidents has been of questionable value to operators when flat rates were given in each state by standard insurance companies, regardless of whether safety precautions were observed or not (Sec 22).

Rating of coal-mine hazards to determine premiums has been adopted by some accident insurance companies. They have used a system of credits or discounts for rating organization and for different accident-prevention methods and devices, and employ mine inspectors who not only inspect but give advice. Some states, notably Penna, have accident-liability insurance dep'ts, employing inspectors for rating mines, based on specific valuation of each hazard. They use essentially the plan of certain private Ins Cos, of marking demerits for deficiencies and awarding bonuses for meritorious precautions in each item of hazard rating (86). Placing a money value on safety precautions is important in introducing proper measures and lowering accident rates.

25. STATE AUTHORITY, REGULATIONS AND INSPECTION

Jurisdiction. Each state has police power over the mines within its borders and makes its own regulations, which unfortunately differ widely, instead of being uniform for the same class of mines and mining conditions. Best mode of formulation and administration of mining regulations in each state is probably through a permanent non-partisan industrial commission, to which inspection bureaus and the workmen's liability accident insur-

ance bureau report. Before altering a mining code, public hearings are held, to which interested parties are invited as in N Y, Penna, Wis, Calif, Utah and other states.

Coal-mine regulations have long been on the statute books in the leading coal mining states; one of the best codes is that of the Penna bituminous district.

Operating regulations for coal mining on the public domain (Bur of Mines, 1920), are the most comprehensive of any coal mining codes, in defining mining methods for safety and coal conservation. Respecting mine-fire prevention, the Illinois regulations are the most explicit and stringent, though some features are impracticable if taken literally.

State metal-mining regulations are neither complete nor satisfactory; among the most complete codes are those of Calif, N Y and Utah. A committee of metal-mining men has also formulated a code which has been published as a model by the Bur of Mines (85).

State colliery inspection. Practically every coal-mining state, 25 in number, has a mine inspection bureau. In some states, as Penna and W Va, the head is called Chief of the Department of Mines; in Ohio, the Safety Commissioner of the Industrial Commission is in general charge; in most states, the head of inspection is called Chief Inspector of Mines; in others, simply Mine Inspector.

In the important coal-producing states, as Penna, W Va, and Ill, there are many mine inspectors, each having a specified district, roughly proportioned according to tonnage produced. There is no definite unit, but, in states with large production, there is an inspector for every 2 million to 8 million tons, produced in say 10 to 60 RR shipping mines and many wagon coal banks. Good service requires thorough inspection of every mine in a district 4 times a year; which means, even if mines are close together, that not over 30 large mines can be thoroughly inspected by 1 man. The inspection unit in point of production should not be more than 4 million tons per annum, and, with widely scattered small mines, not over half this. Quality of inspection varies widely. Most important coal-mining states require candidates for inspectorship to take an examination, the inspectors being chosen by the governor from those that pass.

State metal-mine inspection. Latterly, increased attention has been given to this service by many western states, and several have passed regulations for safety; but as yet most state regulations for metal mining are lax as compared with those for coal mining.

County mine inspectors. In some states, the counties have appointed inspectors who may or may not cooperate with state inspectors. Generally, county inspectors have little authority, and are regarded as filling purely political jobs. Occasionally, a strong, energetic inspector has been able to introduce reforms by force of personality.

26. FEDERAL SAFETY INVESTIGATIONS AND PUBLICATIONS

Origin and scope. In 1908, Congress appropriated funds for investigating mine accidents and explosions, and placed the work under the Technologic Branch of U S Geol Surv. In 1910, Congress established the Bur of Mines, transferring to it mine accident and fuel investigations. In 1913, the powers of the Bureau were widened by establishing "in the Department of the Interior a Bureau of Mining, Metallurgy, and Mineral Technology . . . to conduct inquiries . . . concerning mining, and the preparation, treatment, and utilization of mineral substances, with a view to improving health conditions, safety, efficiency, and economic development. . . ."

July 1, 1925, the Bureau was transferred to U S Dept of Commerce; leasing supervision remained under the U S Geol Surv, but the Mineral Statistics division was transferred to Bur of Mines. In Apl, 1934, the Bureau was returned to Dept of the Interior.

Restrictions. Bureau representatives have no right of entrance into mines, except as permission is voluntarily given by mine operators. The Bureau's reports on individual mine accidents are not published, as these might conflict with state inspector's reports, and lead to legal difficulties, but information is given to the mine operator, with recommendations, so that similar accidents may be avoided in future.

Rescue and first-aid equipment. To educate and train miners in first-aid and the use of oxygen-breathing apparatus, there are 11 fully-equipped safety or rescue cars (reconditioned Pullmans, with berths for crews and injured). Crews: foreman miner, first-aid miner, and cook, and, for a fully manned car, a mining engineer, mine physician, and clerk. Recent appropriations permit but few cars to remain in commission.

These cars circulate through different mining districts, giving instruction, and in case of a disaster the nearest car or cars are rushed to the scene. Besides the R R cars, 11 stations are equipped for giving training, at Pittsburgh, Birmingham, McAlister, and elsewhere, the foreman and field mining engineers going immediately to any disaster to assist and investigate the cause.

Testing appliances and conditions for safety in mines. The Bureau conducts, chiefly at the Pittsburgh Experiment Station, testing of explosives, electric appliances, safety lamps, breathing apparatus, mechanical safety appliances, and at the Bruceton Experimental Mine (12 miles from Pittsburgh), tests on gas and coal-dust explosions, strength of mine pillars and timbers.

Federal inspection of mines is conducted only in Alaska, on the segregated Indian lands in Oklahoma, where the Department of the Interior acts as agent for the lessees (Indian nations), and in a few mines on government lands and in the National Parks in western states. This inspection, formerly under the Bur of Mines, has been done since 1925 by the U S Geol Surv.

Publications of the U S Bureau of Mines on mine safety and health comprise: (*a*) BULLETINS of definite data on general subjects, of permanent reference value, also annual accident statistics; (*b*) TECHNICAL PAPERS on specific subjects, of more or less continuing value; (*c*) REPORTS OF INVESTIGATIONS (mimeographed) on special subjects and tests, not always final; (*d*) INFORMATION CIRCULARS (mimeographed) of data from general observation or foreign literature, not from Bureau investigations; (*e*) SCHEDULES OF TESTS FOR PERMISSIBILITY of specific machines and devices; (*f*) HANDBOOKS of rescue apparatus and first-aid methods; (*g*) MINERS' CIRCULARS for foremen and miners on mine explosions, falls of roof, miners' diseases, etc. Subjects treated: character and use of explosives; limits of inflammability and explosibility of gases, coal and other mineral dusts, and metallic dusts; prevention of coal-mine explosions; mine ventilation and air conditioning; allaying dusts harmful to health; miners' occupational diseases; safer mining and shaft-sinking methods; causes of fall of roof or ore and better timbering; hazards in mechanization and use of electricity; fire prevention; mine lighting; inspection methods; safety organizations; permissibility of safety equipment; bursts of gas, bumps and rock bursts in deep mining; safety and health statistics.

SECTION 24

MINING LAWS

WRITTEN FOR THE FIRST EDITION BY THE LATE

HORACE V. WINCHELL

OF THE CALIFORNIA BAR

REVISED FOR THE SECOND AND LARGELY REWRITTEN FOR THE THIRD EDITION

BY

ARCHIBALD DOUGLAS

OF DOUGLAS & ARMITAGE, COUNSELLORS AT LAW, NEW YORK

MINING LAWS

This Section has particular reference to Federal Mining Laws, and those of the western mining states, largely based upon the text written by the late Horace V. Winchell, of the California Bar. Articles 1–6, on the historical development of the U S Mining Laws, also much of Art 11–13 and 16–20, are changed but little from Winchell's text.

The present edition includes a discussion of extralateral rights by Judge Clayberg; Art 27–32, on Federal Mining Taxes, by Paul Armitage, of the New York Bar; Art 33–42, on the Mining Laws of Canada, by Gordon McMillan, K C, of the Toronto Bar; and Art 43–46, on the Mining Laws of Mexico, by Robert T. Brinsmade, an associate of the law firm of Basham & Ringe, of Mexico City.

The more important Apex cases have been checked by Professor William Edward Colby, of the California Bar. Respecting the Apex Law, the text of the U S Code has been used, rather than referring back to the original statutes. As lack of space prevented verbatim inclusion of the Mining Statutes of the Western Mining States and of Alaska; and because it was necessary to give a summary of the Mining and Depletion provisions of the Federal Revenue Acts, now in force; also the Canadian and Mexican Mining Laws, and forms of perpendicular side-line agreements, with examples of surface mining deeds; it was decided to set forth in some detail the Mining Statutes of California, as illustrative, and to refer briefly to the Mining Laws of the other states subject to the Federal Mining Acts. No reference is made to Mining Laws of states not containing public mining lands.

The U S Code includes a chapter on the Bureau of Mines and one on "Lands Containing Coal, Phosphorus," etc. Parts of the entire Code, and references to other parts by Title, for the information of the mining profession, are presented. The articles on problems of the Apex Law, by Judge Clayberg, are taken from the first editions of this handbook, with brief references to some later decisions.

It must be impressed upon all those who read this Section that its object is only to summarize the mining laws, which, with the statutes, change from year to year. While it is hoped that this cursory review will be generally informative, the writers urge upon all who have legal problems to solve, to consult an able mining lawyer practicing in the State or Country in question.

NOTE.—The reader is particularly cautioned that the information contained in this section of the book is as of Dec 31, 1938, and that, as stated above, changes are frequently made in the mining laws of the several states of the United States and in the other countries cited.

1. INTRODUCTION

Character of mining laws. These laws define the status of the prospector for mineral deposits, establish his methods of procedure, protect him in possession while searching for mines, and give him assurance of title when all required conditions have been fulfilled and valuable minerals discovered. Regulations for the operation of mines, and for the safety and health of employes are also subjects of Federal and State legislation, but are rather in the nature of police and sanitation rules for the daily guidance of mine workers; they are subject to frequent change, and are not considered here. (See Sec 22, 23.)

Importance of an understanding of mining laws is indicated by three considerations:

1. There is always a prescribed course of procedure to be followed in acquiring and perpetuating such title as is granted by the laws, both while a property is in the exploratory stages and after ores have been discovered; and without strict compliance with these statutory provisions there is danger of losing the mines after they have proved of value.

2. The peculiar apex provisions of the U S mining law and the decisions of the Supreme Court are of vital importance to the mine owner in those states where the laws apply. The titles to many mines have been seriously affected or entirely forfeited by inattention to the obvious and unmistakable wording of the statutes.

3. A mining engineer, called upon to place a valuation upon mines in districts where the apex laws are in force, must be familiar with those laws. Possibility of apex litigation hangs over many mining investments, and no engineer can safely recommend the purchase of a quartz (vein) mine without taking it into consideration.

2. THEORIES RELATING TO ACQUISITION OF MINING CLAIMS

Principles of construction of mining laws of the world may be grouped in two classes: 1. That in which the State or a private owner of mining property has the right to grant concessions or leases to individuals or corporations at discretion, or under certain general

restrictions. This is the "Concession" system. 2. That in which any individual, under specified restrictions, generally as to nationality or color, has the right to locate on discovery or otherwise certain limited areas of ground, and under certain conditions to hold, work, or dispose of the same. This is the "Claim" system (Alford, p 1).

Concession system had its origin in the rights of kings and feudatory lords to the mineral products of the ground, and it prevails today in modified forms in all the ancient civilizations. Its advantage is that the State or other owner of mining rights may select its concessionaires, and thus place the mines only in the hands of those who are able to operate them and to pay the required rents, taxes, or royalties. There is incidental economy in the maintenance of order, collection of dues, and the greater stability of mining operations. The system is criticized for placing unduly large powers of property control in the hands of a few men, and for taking away from the poor prospector the chance of sudden wealth; it is also said to destroy competition in the sale of mines, placing inordinately large profits in the hands of a few; and that it conduces to the holding of mining ground unworked, thus reducing mineral production and restricting opportunity for labor. These objections may perhaps be over-balanced by the facts that the terms of concession may and usually do require a certain amount of development; that they reserve to the Government some control of the financial transactions and capitalization of the concession holders, and that the operations of large corporations are generally conducted with greater efficiency and economy, in both prospecting and mining stages, than those of smaller concerns or of individuals.

Claim system originated in the early days of mining in the U S. Prospectors rushed to the newly discovered gold districts of California, later to those of Australia; and to preserve public order, some arrangement became necessary for determining on the spot the area of ground that each man was allowed to work, and the conditions under which he could hold and deal with it. Hence arose the right of the discoverer to a "claim," a term now in general use in legal parlance. Where consolidation of claims is prohibited, the result is waste and many failures; where claims are permitted to be held without systematic development, no good results to the country at large, nor to the claim holder; and it is criticized as being a system which, although it may appear at first sight to encourage individual enterprise, in reality leads to great waste of capital and unorganized energy.

Two fundamental principles form the basis of all mining laws: 1. The right of mine operators to a secure and indefeasible title to their property so long as they fulfil certain specified conditions, compliance with which is absolutely within their own power; 2. The right of the state or other landlord to certain rents, royalties, or taxes on the profits of the mines, and to reasonably constant performance of effective work on the mines, so that capital, represented by property and labor, shall not be unduly idle. These principles are essentially common to the laws of all countries, though in individual cases modified to suit climatic, ethnological, and physical conditions, as well as the history and theories of land tenure of the particular mining region (Alford, p 7).

UNITED STATES MINING LAWS

3. SOURCES OF THE LAWS

Public mineral domain. Since nearly all of the domain in the states and territories subject to the federal mining laws was originally acquired by treaty or purchase from France and Mexico, wherein the civil law was the basis of jurisprudence, and at the time of session both of these nations had well established and defined codes of mining law, it is natural to expect to find the influence of French and Spanish laws in the growth and development of our own system (Lindley, p 6). Traces of the principles of the common law, under which, in general, minerals were the landlord's property and went with the surface, are also found in the old ante-revolution British grants. Some customs and rules adopted in the West are traceable to Cornwall, and from there to Germany. The principles of common law prevail in the U S, and establish in the owner of the surface the *prima facie* title to minerals beneath it, until rebutted by evidence that ownership of the mines and minerals had, from some special cause, become severed from that of the soil and surface. Such separate and distinct title to minerals may arise through legislative acts of Congress or of any state, or through voluntary act of transfer by the individual who once owned both surface and minerals.

Colonial grants. In almost all crown grants to the colonies, there was reserved to the sovereign a certain fixed proportion of the "royal metals" (gold and silver) discovered. Thus the charter of N C (1584), granted to Sir Walter Raleigh by Elizabeth, contained the

following: " Reserving always to us, our heirs and successors, for all services, duties and demands, the fifth part of all the ore of gold and silver that may from time to time and at all times after such discovery, subduing, and possessing, be there gotten and obtained." This form of reservation occurs, with few exceptions, in all succeeding grants.

The U S, in first dealing with its public lands, followed these precedents and made similar reservations, suggested by precedent rather than considerations of public policy. The general policy of the U S, as expressed in the statutes, executive acts, and proclamations prior to 1845, was to reserve mineral lands from sale absolutely. These lands, so far as then known, contained lead, iron, copper and zinc, in the part of the U S territory then called the Northwest or Indian Territory, and comprised the area now embraced by Mich, Wis, Ill, Ia, Mo, and Minn.

Federal leasing system. Within the territory of the Louisiana purchase, acquired from France in 1803, lead mining began about 1720, under patent to Law's Mississippi colony, while that region still belonged to France. On March 3, 1807, Congress passed a law providing: " that the several lead mines in the Indiana territory . . . shall be reserved for the future disposal of the United States; and any grant which may hereafter be made for a tract of land containing a lead mine which had been discovered previous to the purchase of such tract from the United States shall be considered fraudulent and null, and the President of the United States shall be and is hereby authorized to lease any lead mine which has been or may be hereafter discovered in the Indiana territory for a term not exceeding five years."

This legislation inaugurated the policy of the U S of leasing mineral lands. Leases were given under supervision of the War Department, covering tracts at first 3 miles, afterward 1 mile square, and bound the lessees to work the mines with due diligence and return to the U S 6% of all ores raised (Lindley, p 64). No leases were issued under the law until 1822, and but a small quantity of lead was raised previous to 1826, from which time production increased rapidly. For a few years the rents were paid with some regularity; but after 1834, because of the immense number of illegal entries of mineral land at the Wis land office, smelters and miners refused to make further payments, and the government was unable to collect them. After much trouble and expense, it was, in 1847, finally decided that the only way was to sell the mineral land, and do away with all reserves of lead or any other metal, since they had been only a source of embarrassment to the department. Meanwhile, by a forced construction of the same act (afterward declared invalid), hundreds of leases were granted to speculators in the Lake Superior copper region, which from 1843 to 1846 was the scene of wild and baseless excitement. The bubble burst during 1846; the issue of permits and leases was suspended as illegal, and the act of 1847, authorizing sale of mineral lands and a geological survey of the district, laid the foundation of a more substantial prosperity (Hewitt, *Trans* A I M E, vol V, p 180).

Mexican grants. The treaty of Guadalupe Hidalgo, concluding peace with Mexico, was signed Feb 2, exchanged May 30, and proclaimed July 4, 1848.

This treaty added to the national domain more than 500 000 sq miles, embracing Cal, Nev, Utah, Ariz (except Gadsden purchase of 1853), N Mex west of the Rio Grande and north of Gadsden purchase, Colo west of the Rocky Mts, and SW part of Wyo. Gadsden purchase added to the public domain 45 532 sq miles, forming part of the present States of Ariz and N Mex. By the treaty, all property theretofore belonging to Mexico within the limits defined by the compact between the two nations passed to the U S, upon which government was imposed the obligation to protect titles acquired under Mexican rule. A valid right before the cession was equally valid afterward.

Registration of Mexican grants. As to those in Cal, Congress provided for the appointment of a board of land commissioners, to whom all persons claiming lands by virtue of any right or title derived from the Spanish or Mexican government were required to present their claims. Appeals could be taken from decisions of this board to federal courts, even the highest. By acts of July 22, 1854, Feb 28, 1861, and Feb 24, 1863, the surveyors-general of N Mex, Col, and Ariz, respectively, were instructed to report to the Interior Department upon the status of private land claims in their jurisdictions. At present, it is presumed that all rights and claims of every nature to lands arising out of Mexican grants have been finally adjudicated (Lindley, par 117, *et seq*).

4. SOURCE OF THE PUBLIC DOMAIN

The national government acquired no property rights within the present boundaries of the 13 original states, nor in the states of Vt, Ky, Me and W Va; hence, no question of apex rights or other questions of federal procedure or titles arise therein. The first acquisition of national domain which became subject to disposal of Congress was by cessions of territory claimed by 7 of the original states.

These cessions, beginning with that by N Y (March 1, 1781) and ending with that of Ga (April 24, 1802), brought within the jurisdiction of the federal government all that portion of the present

area of the U S now comprising Tenn, Ill, Ind, Ohio, Mich, Wis, those portions of Ala and Miss lying north of the 31st parallel, and all that portion of Minn lying East of the Mississippi River. In 1803, the territory acquired by purchase from France, commonly called the "Louisiana purchase," added over 1 000 000 sq miles to the national domain, embracing parts of Ala and Miss, the states of La, Ark, Mo, Iowa, Kas (except a portion in the southwest corner), Neb, all of Col east of the Rocky Mts and north of the Arkansas River, both Dakotas, the greater part of Mont, part of Wyo, and the Indian Terr. The acquisition of land from Mexico has already been mentioned. Alaska was purchased from Russia in 1867. By treaty of cession between the U S and Hawaii, adopted by Congress July 7, 1898, all lands within the Hawaiian Islands, covered by the treaty, which belonged to the republic as distinguished from private lands, passed to the U S, and became subject to the disposal of Congress the same as other public lands.

As yet, the public-land laws of the U S have not been extended to the new territory of Hawaii, and, until further action by Congress, the land laws of the republic existing at the time of the treaty of cession are continued in force. These laws do not provide for sale or other disposition of lands classified as mineral. By the treaty of Paris, Porto Rico was ceded to the U S by Spain, and all crown lands passed to the U S. By act of Congress, July 1, 1902, all such lands were ceded by the U S to the territory of Porto Rico for the use and benefit of its people, and are subject to sale and disposal under territorial laws of that island. Treaty of Paris also transferred ownership of the Philippine Islands from Spain to the U S. On July 1, 1902, was approved an act containing a code of laws governing disposal of public lands valuable for minerals. This law was amended in 1905 (33 Stats at Large, 692; Comp Stats, Supp 1911, 527; 10 Fed Stats Ann 267). It will be seen later that federal statues regarding the public domain do not apply to all territory controlled by the U S. As to one portion, there was no congressional jurisdiction for lack of title, and as to still other portions there has been specific exception by act of Congress.

5. THEORY OF UNITED STATES MINING LAWS

Character of mining property. Mines in the U S are not ranked as public property, to be worked by the federal government. Mining with us is not a " public utility," but a private industry, to be fostered and regulated like all other economic industries (Lindley, p 120). The regalian doctrine of the crown's ownership of the royal metals, wheresoever found, based upon the theory that these metals were a prerogative of the crown, which prevailed in England, France, Spain, and Mexico, was never recognized in this country. A grant or conveyance by the U S carries all minerals, unless reserved expressly or by implication in the law or instrument purporting to pass the title (Lindley, *loc cit*). The government of the U S does not concern itself with mining lands nor the mining industry after it parts with the title. This title vests in the patentee absolutely. No royalties are reserved, nor is any governmental supervision attempted. Upon issuance of the deed of the government, mining land becomes private property, subject to the same rules of law as other real property (Lindley, par 22). Although quite within its sovereign power, the U S government has never engaged in mining operations.

Minerals in private lands. No provision is made in the U S laws for location of mining claims upon or within privately owned lands. Laws of many countries in Europe and South America reserve this right under the theory that mining is a public utility. But in the U S public mineral lands only may be located and entered under the mining laws.

Reservation of mining rights. Authority to administer public lands was given to the Department of the Interior under act of Congress passed Mar 3, 1849. Prior to 1866 it was the settled policy of the U S government to reserve the minerals in all lands sold or granted to individuals, states, or railways, and other corporations.

The first sale of mineral lands by the government was that of the reserved lead and zinc mines in Mo at $2.50 per acre under act of Mar 3, 1829. By act of July 11, 1846, sales of similar lands were authorised in Ill, Ark, Wis, and Iowa. Under act of Mar 1, 1847, lands in the Lake Superior district containing lead, copper, or other valuable ores, were offered at public sale at $5 per acre; and by act of Mar 3, 1847, the sale of lands in the Chippewa district, Wis, was authorized on similar terms. Excepting these special sales of mineral lands, it was the uniform policy of the government to reserve mineral lands from sale or grant in all cases. Thus, in grants for educational purposes and for internal improvements within the states, there was often a reservation of lands known to be mineral at the time of grant. If, however, minerals were discovered after completion of the transaction, the state's title thereto would not be affected. The same is true in general of railroad grants. Non-mineral lands only were to be granted; but discovery of mineral character after title has legally passed does not invalidate title, because issuance of patent to the land implies that it has been examined by the land department and found to be non-mineral in character, and establishes vested rights which can not be attacked. The important features of the law are presented briefly, in the following pages. For fuller discussion see textbooks listed in the bibliography.

6. FIRST GENERAL MINING ACT

First mining claims to land which afterwards became part of the public domain were staked in Nev and Cal. The first miners made their own laws, unmindful of legislation by territory, state, or nation. Their regulations were framed to cover local conditions, and embodied ideas and knowledge of the subject possessed by miners from Mexico, Cornwall and other parts of Great Britain, and the continent of Europe. In accordance with these rules "the right of property in mines is made to depend upon *discovery* and *development*; that is, *discovery* is made the source of title, and *development*, or *working*, the condition of the continuance of that title. These two principles constitute the basis of all our local laws and regulations respecting mining rights" (Halleck, Introd to De Foos on Law of Mines, p vii).

Law of July 26, 1866, was the first general statute by which title could be acquired to any public mineral lands within what are known as the mining states and territories. This act has been largely superseded or repealed by subsequent legislation, but is said to have established at least 3 important and beneficent principles:

"1. That all the mineral lands of the public domain should be free and open to exploration and occupation.

2. That rights which had been acquired in these lands under a system of local rules, with the apparent acquiescence and sanction of the government, should be recognised and confirmed.

3. That titles to at least certain classes of mineral deposits or lands containing them might be ultimately obtained" (Lindley on Mines, par 54).

7. MINING ACT OF 1872

On May 10, 1872, Congress passed "An act to promote the development of the mining resources of the United States." This is the famous "Apex Law." With a few additions and amendments, it is the law under which Federal mining rights are now acquired, and in accordance with its provisions the vast majority of mining claims in the territory to which it applies have been located. This law is now incorporated in the U S Code Annotated, Title XXX, Chap 2, which is herein quoted in full. It takes the place of Title XXXII, Chap 6, of the Revised Statutes of U S, on pp 1659–1664 of the Second Edition of this Handbook. The Code Annotated may be found in the library of almost any law firm, and in any public law library.

Text of Chap 2, Title XXX, of the U S Code follows:

21. Reservation of mineral lands from sale under general laws. In all cases lands valuable for minerals shall be reserved from sale, except as otherwise expressly directed by law.

22. Valuable mineral deposits open to location. Who may locate. All valuable mineral deposits in lands belonging to the United States, both surveyed and unsurveyed, shall be free and open to exploration and purchase, and the lands in which they are found to occupation and purchase, by citizens of the United States and those who have declared their intention to become such, under regulations prescribed by law, and according to the local customs or rules of miners in the several mining districts, so far as the same are applicable and not inconsistent with the laws of the United States.

23. Length of lode claim. Discovery essential to location. Width of claim. End lines must be parallel. Mining claims upon veins or lodes of quartz or other rock in place, bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposits, heretofore located, shall be governed as to length along the vein or lode by the customs, regulations, and laws in force at the date of their location. A mining claim located after May 10, 1872, whether located by one or more persons, may equal, but shall not exceed, 1 500 ft in length along the vein or lode; but no location of a mining claim shall be made until the discovery of the vein or lode within the limits of the claim located. No claim shall extend more than 300 ft on each side of the middle of the vein at the surface, nor shall any claim be limited by any mining regulation to less than 25 ft on each side of the middle of the vein at the surface, except where adverse rights existing on May 10, 1872, render such limitation necessary. The end lines of each claim shall be parallel to each other.

24. Proof of citizenship, under this chapter, may consist, in the case of an individual, of his own affidavit thereof; in the case of an association of persons unincorporated, of the affidavit of their authorised agent, made on his own knowledge or upon information and belief; and in the case of a corporation organised under the laws of the United States, or of any State or Territory thereof, by the filing of a certified copy of their charter or certificate of incorporation.

25. Affidavit of citizenship. Applicants for mineral patents who reside beyond the limits of the district wherein the claim is situated, may make any oath or affidavit required for proof of citizenship before the Clerk of any Court of Record, or any Notary Public of any State or Territory.

26. Extralateral and intralimital rights. The locators of all mining locations heretofore made or which shall hereafter be made, on any mineral vein, lode or ledge situated on the public domain, their heirs and assigns, where no adverse claim existed on May 10, 1872, so long as they comply with the laws of the United States, and with State or Territorial regulations not in conflict with the laws of the United States governing their possessory title, shall have the exclusive right of possession and enjoyment of all the surface included within the end lines of their locations, and of all veins, lodes, and ledges, throughout their entire depth, the top or apex of which lies inside of such surface lines extended downward vertically, although such veins, lodes or ledges may so far depart from a perpendicular in their course downward as to extend outside the vertical side lines of such surface locations. But their right of possession to such outside parts of such veins or ledges shall be confined to such portions thereof as lie between vertical planes drawn downward as above described, through the end lines of their locations, so continued in their own direction that such planes will intersect such exterior parts of such veins or ledges. Nothing in this section shall authorize the locator or possessor of a vein or lode which extends in its downward course beyond the vertical end lines of his claim to enter upon the surface of a claim owned or possessed by another.

27. Tunnel rights. Length of tunnels. Where a tunnel is run for the development of a vein or lode, or for the discovery of mines, the owners of such tunnel shall have the right of possession of all veins or lodes within 3 000 ft from the face of such tunnel on the line thereof, not previously known to exist, discovered in such tunnel, to the same extent as if discovered from the surface; and locations on the line of such tunnel of veins and lodes not appearing on the surface, made by other parties after the commencement of the tunnel, and while the same is being prosecuted with reasonable diligence, shall be invalid; but failure to prosecute the work on the tunnel for six months shall be considered as an abandonment of the right to all undiscovered veins on the line of such tunnel.

28. Mining-district regulations by miners. Annual labor on claims pending issue of patent. Expenditure on tunnels considered. The miners of each mining district may make regulations not in conflict with the laws of the United States, or with the laws of the State or Territory in which the district is situated, governing the location, manner of recording, amount of work necessary to hold possession of a mining claim, subject to the following requirements: The location must be distinctly marked on the ground so that its boundaries can be readily traced. All records of mining claims made after May 10, 1872 shall contain the name or names of the locators, the date of the location, and such description of the claim or claims located by reference to some natural object or permanent monument as will identify the claim. On each claim located after May 10, 1872, and until a patent has been issued therefor, not less than $100 worth of labor shall be performed or improvements made during each year. On all claims located prior to May 10, 1872, $10 worth of labor shall be performed or improvements made each year, for each 100 ft in length along the vein, until a patent has been issued therefor; but where such claims are held in common, such expenditure may be made upon any one claim; and upon failure to comply with these conditions the claim, or mine, upon which such failure occurred shall be open to relocation in the same manner as if no location of the same had ever been made; provided that the original locators, their heirs, assigns or legal representatives, have not resumed work upon the claim after failure and before such location. Upon failure of any one of several co-owners to contribute his proportion of the expenditures required hereby, the co-owners who have performed the labor or made the improvements may, at expiration of the year, give such delinquent co-owner personal notice in writing, or notice by publication in the newspaper published nearest the claim for at least once a week for 90 days, and if at expiration of 90 days after such notice, in writing or by publication, such delinquent should fail or refuse to contribute his proportion of the expenditure required by this section his interest in the claim shall become the property of his co-owners who have made the required expenditures. The period within which the work required to be done annually on all unpatented mineral claims located since May 10, 1872, including such claims in the territory of Alaska, shall commence at 12 o'clock Meridian on the 1st day of July succeeding the date of the location of such claim. Where a person or company has or may run a tunnel for the purpose of developing a lode or lodes, owned by such person or company, the money so expended in said tunnel shall be taken and considered as expended on said lode or lodes, whether located prior to or since May 10, 1872; such person or company shall not be required to perform work on the surface of said lode or lodes in order to hold the same as required by this section. On all such valid claims

the annual period ending December 31, 1921, shall continue to 12 o'clock Meridian on July 1, 1922.

29. Patent proceedings. A patent for any land claimed and located for valuable deposits may be obtained in the following manner: Any person, association, or corporation authorized to locate a claim under this chapter, having claimed and located a piece of land for such purposes, who has, or have, complied with the terms of this chapter, may file in the proper land office an application for a patent, under oath, showing such compliance, together with plat and field notes of the claim or claims in common, made by or under the direction of the United States Supervisor of Surveys, showing accurately the boundaries of the claim or claims, which shall be directly marked by monuments on the ground, and shall post a copy of such plat, together with a notice of such application for a patent, in a conspicuous place on the land embraced in such plat previous to the filing of the application for a patent, and shall file an affidavit of at least two persons that such notice has been duly posted, and shall file a copy of the notice in such land office, and shall thereupon be entitled to a patent for the land, in the manner following: The register of the land office, upon the filing of application, plat, field notes, notices and affidavits, shall publish a notice that such application has been made, for the period of 60 days, in a newspaper to be by him designated as published nearest to such claim; and he shall also post such notice in his office for the same period. The claimant at the time of filing this application, or at any time thereafter, within the 60 days of publication, shall file with the register a certificate of the United States Supervisor of Surveys, that $500 worth of labor has been expended or improvements made upon the claim by himself or grantors; that the plat is correct, with such further description by such reference to natural objects or permanent monuments as shall identify the claim, and furnish an accurate description to be incorporated in the patent. At the expiration of the 60 days of publication the claimant shall file his affidavit, showing that the plat and notice have been posted in a conspicuous place on the claim during such period of publication. If no adverse claim shall have been filed with the register of the proper land office at the expiration of the 60 days of publication, it shall be assumed that the applicant is entitled to a patent, upon the payment to the proper officer of $5 per acre, and that no adverse claim exists; and thereafter no objection from third parties to the issuance of a patent shall be heard, except it be shown that the applicant has failed to comply with the terms of this chapter. Where the claimant for a patent is not a resident of or within the land district wherein the vein, lode, ledge or deposit sought to be patented is located, the application for patent and the affidavit required to be made in this section by a claimant for such patent may be made by his, her, or its authorized agent, where said agent is conversant with the facts sought to be established by said affidavit.

30. Adverse claims, filing of, and suit upon. Where an adverse claim is filed during the period of publication, mentioned in Section 29 of this title, it shall be upon oath of the person or persons making the same, and shall show the nature, boundaries, and extent of such adverse claim, and all proceedings, except the publication of notice and making and filing of the affidavit thereof, shall be stayed until the controversy shall have been settled or decided by a court of competent jurisdiction, or the adverse claim waived. It shall be the duty of the adverse claimant, within 30 days after filing his claim, to commence proceedings in a court of competent jurisdiction, to determine the question of the right of possession and prosecute the same with reasonable diligence to final judgment; and a failure so to do shall be a waiver of his adverse claim. After such judgment shall have been rendered, the party entitled to the possession of the claim, or any portion thereof, may, without giving further notice, file a certified copy of the judgment-roll with the register of the land office, together with the certificate of the United States Supervisor of Surveys, that the requisite amount of labor has been expended or improvements made thereon, and the description required in other cases, and shall pay to the Register $5 per acre for his claim, together with the proper fees, whereupon the whole proceedings and the judgment-roll shall be certified by the register to the Commissioner of the General Land Office, and a patent shall issue thereon for the claim, or such portion thereof as the applicant shall appear, from the decision of the court, to rightly possess. If it appears from the decision of the court that several parties are entitled to separate and different portions of the claim, each party may pay for his portion of the claim with the proper fees, and file the certificate and description by the United States Supervisor of Surveys, whereupon the register shall certify the proceedings and judgment-roll to the Commissioner of the General Land Office, as in the preceding case, and patents shall issue to the several parties according to their respective rights. Nothing herein contained shall be construed to prevent the alienation of the title conveyed by a patent for a mining claim to any person whatever.

31. Same; oath of claimant. The adverse claim required by section 30 of this title may be verified by the oath of any duly authorized agent or attorney in fact of the adverse

claimant cognizant of the facts stated; and the adverse claimant, if residing or at any time being beyond the limits of the district wherein the claim is situated, may make oath to the adverse claim before the clerk of any Court of record of the United States or of the State or Territory where the adverse claimant may then be, or before any notary public of such State or Territory. (April 26, 1882 c. 106, Sec. 1, 22 Stat. 49.)

32. Same; findings by jury; costs. If in any action brought pursuant to Section 30 of this title, title to the ground in controversy shall not be established by either party, the Jury shall so find, and judgment shall be entered according to the verdict. In such case costs shall not be allowed to either party, and the claimant shall not proceed in the land office or be entitled to a patent for the ground in controversy until he shall have perfected his title. (March 3, 1881, c. 140, 21 Stat. 505.)

33. Rights under patents issued before Act of 1872. Applications for patents for mining claims under laws existing prior to May 10, 1872 and pending on that date, may be prosecuted to a final decision in the General Land Office; but in such cases where adverse rights are not affected thereby, patents may issue in pursuance of the provisions of this chapter; and all patents for mining claims upon veins or lodes issued prior to May 10, 1872 shall convey all the rights and privileges conferred by this chapter where no adverse rights existed on May 10, 1872.

34. Description of claim on surveyed and unsurveyed lands. Monuments control locations. The description of vein or lode claims upon surveyed lands shall designate the location of the claims with reference to the lines of the public survey, but need not conform therewith; but where patents have been or shall be issued for claims upon unsurveyed lands, the United States Supervisor of Surveys, in extending the public survey, shall adjust the same to the boundaries of said patented claims so as in no case to interfere with or change the true location of such claims as they are officially established upon the ground. Where patents have issued for mineral lands, those lands only shall be segregated and shall be deemed to be patented which are bounded by the lines actually marked, defined, and established upon the ground by the monuments of the official survey upon which the patent grant is based, and the United States Supervisor of Surveys, in executing subsequent patent surveys, whether upon surveyed or unsurveyed lands, shall be governed accordingly. The said monuments shall at all times constitute the highest authority as to what land is patented, and in case of any conflict between the said monuments of such patented claims and the descriptions of said claims in the patents issued therefor the monuments on the ground shall govern, and erroneous or inconsistent descriptions or calls in the patent descriptions shall give way thereto, prior to May 10, 1872.

35. Placers and other forms of deposit not in place may be entered and patented. Claims usually called "placers," including all forms of deposit, excepting veins of quartz, or other rock in place, shall be subject to entry and patent, under like circumstances and conditions, and upon similar proceedings, as are provided for vein or lode claims; but where the lands have been previously surveyed by the United States, the entry in its exterior limits shall conform to the legal subdivisions of the public lands.

Placer locations must conform to public surveys. Homesteads. Where placer claims are upon surveyed lands, and conform to legal subdivisions, no further survey or plat shall be required, and all placer mining claims located after May 10, 1872, shall conform as nearly as practicable with the United States system of public-land surveys, and the rectangular subdivisions of such surveys, and no such location shall include more than 20 acres for each individual claimant; but where placer claims can not be conformed to legal subdivisions, survey and plat shall be made as on unsurveyed lands; and where by the segregation of mineral lands in any legal subdivision a quantity of agricultural land less than 40 acres remains, such fractional portion of agricultural land may be entered by any party qualified by law, for homestead purposes.

36. Subdivisons of claims. Group entries. Maximum extent of placers. Legal subdivisions of 40 acres may be subdivided into 10-acre tracts; and two or more persons, or associations of persons, having contiguous claims of any size, although such claims may be less than 10 acres each, may make joint entry thereof; but no location of a placer claim, made after July 9, 1870, shall exceed 160 acres for any one person or association of persons, which location shall conform to the United States surveys; and nothing contained in this section shall defeat or impair any bona fide preëmption or homestead claim upon agricultural lands, or authorize the sale of the improvements of any bona fide settler to any purchaser.

37. Patents for lodes within placers. Where the same person, association or corporation is in possession of a placer claim, and also a vein or lode included within the boundaries thereof, application shall be made for a patent to the placer claim, with the statement that it includes such vein or lode, and in such case a patent shall issue for the placer claim, subject to the provisions of this chapter, including such vein or lode, upon the

payment of $5 per acre for such vein or lode claim and 25 ft of surface on each side thereof. The remainder of the placer claim or any placer claim not embracing any vein or lode claim shall be paid for at the rate of $2.50 per acre, together with all costs of proceedings; and where a vein or lode, such as is described in § 23 is known to exist within the boundaries of a placer claim, an application for a patent for such placer claim which does not include an application for the vein or lode claim shall be construed as a conclusive declaration that the claimant of the placer claim has no right of possession of the vein or lode claim; but where the existence of a vein or lode in a placer claim is not known, a patent for the placer claim shall convey all valuable mineral and other deposits within the boundaries thereof.

38. Patents obtained on adverse possession. Where such person or association, they and their grantors, have held and worked their claims for a period equal to the time prescribed by the statute of limitations for mining claims of the State or Territory where the same may be situated, evidence of such possession and working of the claims for such period shall be sufficient to establish a right to a patent thereto under this chapter, in the absence of any adverse claim; but nothing in this chapter shall be deemed to impair any lien which may have attached in any way whatever to any mining claim or property thereto attached prior to the issuance of a patent.

39. Deputy mineral surveyors. Expenses of survey and patent. Publication of notices. Designation of newspaper. Fees of officers. The U S Supervisor of Surveys may appoint in each land district containing mineral lands as many competent surveyors as shall apply for appointment to survey mining claims. The expenses of the survey of vein or lode claims, and the survey and subdivision of placer claims into smaller quantities than 160 acres, together with the cost of the publication of notices, shall be paid by the applicants, and they shall be at liberty to obtain the same at the most reasonable rates, and they shall also be at liberty to employ any United States deputy surveyor to make the survey. The Commissioner of the General Land Office shall also have power to establish the maximum charges for surveys and publication of notices under this chapter; and, in case of excessive charges for publication, he may designate any newspaper published in a land district where mines are situated for the publication of mining notices in such district, and fix the rates to be charged by such paper; and to the end that the Commissioner may be fully informed on the subject, each applicant shall file with the register a sworn statement of all charges and fees paid by such applicant for publication and surveys, together with all fees and money paid the register of the land office, which statement shall be transmitted, with the other papers in the case, to the Commissioner of the General Land Office.

40. Affidavits, before what officers to be made. All affidavits required to be made under this chapter may be verified before any officer authorized to administer oaths within the land district where the claims may be situated, and all testimony and proofs may be taken before any such officer, and, when duly certified by the officer taking the same, shall have the same force and effect as if taken before the register of the land office. In cases of contest as to the mineral or agricultural character of land, the testimony and proofs may be taken as herein provided on personal notice of at least 10 days to the opposing party; or if such party can not be found, then by publication of at least once a week for 30 days in a newspaper, to be designated by the register of the land office as published nearest to the location of such land; and the register shall require proof that such notice has been given.

41. Cross-lodes and uniting veins. Where two or more veins intersect or cross each other, priority of title shall govern, and such prior location shall be entitled to all ore or mineral contained within the space of intersection; but the subsequent location shall have the right of way through the space of intersection for the purposes of the convenient working of the mine. And where two or more veins unite, the oldest or prior location shall take the vein below the point of union, including all the space of intersection.

42. Millsites, classes, patents for. Where non-mineral land not contiguous to the vein or lode is used or occupied by the proprietor of such vein or lode for mining or milling purposes, such non-adjacent surface ground may be embraced and included in an application for a patent for such vein or lode, and the same may be patented therewith, subject to the same preliminary requirements as to survey and notice as are applicable to veins or lodes; but no location hereafter made of such non-adjacent land shall exceed 5 acres, and payment for the same must be made at the same rate as fixed by this chapter for the superficies of the lode. The owner of a quartz mill or reduction works, not owning a mine in connection therewith, may also receive a patent for his millsite, as provided in this section.

43. State legislatures may pass supplementary laws. As a condition of sale, in the absence of necessary legislation by Congress, the local legislature of any State or Territory

may provide rules for working mines, involving easements, drainage, and other necessary means to their complete development; and those conditions shall be fully expressed in the patent.

44. Homesteads upon mineral lands. Wherever, upon the lands heretofore designated as mineral lands, which have been excluded from survey and sale, there have been homesteads made by citizens of the United States, or persons, who have declared their intention to become citizens, which homesteads have been made, improved and used for agricultural purposes, and upon which there have been no valuable mines of gold, silver, cinnabar, or copper discovered, and which are properly agricultural lands, the settlers or owners of such homesteads may avail themselves of the provisions of Chap 7, of Title 43, relating to "Homesteads."

45. Secretary of Interior may set apart agricultural lands. Upon the survey of the lands described in Art 44 of this title, the Secretary of the Interior may designate and set apart such portions of the same as are clearly agricultural lands, which lands shall thereafter be subject to sale as other public lands, and be subject to all the laws and regulations applicable to the same.

46. Additional land districts, establishment of. The President is authorized to establish additional land districts, and to appoint the necessary officers under existing laws, wherever he may deem the same necessary for the public convenience in executing the provisions of this chapter.

47. Construction of act, generally. Nothing contained in this chapter shall be construed to impair, in any way, rights or interests in mining property acquired under laws enforced prior to July 9, 1870, nor to affect the provisions of the act entitled "An act granting to A. Sutro the right of way and other privileges to aid in the construction of a draining and exploring tunnel to the Comstock lode, in the State of Nevada," approved July 25, 1866.

48. Lands in certain States excepted. Except as otherwise provided under sections 141–152, 181–194, 201–208, 211–214, 221, 223–229, 241, 251 and 261–263 of this title, the provisions of sections 21–24, 26–30, 33–47, 51 and 52 of this title shall not apply to the mineral lands situated in the states of Mich, Wis, and Minn, which except as otherwise provided in this title are declared free and open to exploration purposes according to legal subdivisions, in like manner as before the 10th day of May, 1872.

The provisions of this chapter shall not apply to the mineral lands situated in the States of Mich, Wis, and Minn, which are declared free and open to exploration and purchase, according to legal subdivisions, in like manner as before May 10, 1872. And any bona fide entries of such lands within the States named since May 10, 1872, may be patented without reference to any of the foregoing provisions of this chapter. Such lands shall be offered for public sale in the same manner, at the same minimum price as other public lands. *Note:* See also Section 49, relating to the exclusion of deposits of coal, iron, lead or other mineral in the states of Mo and Kan. If interested, refer to the original section.

50. Grants to States or corporations not to include mineral lands. No act passed at the first session of the 38th congress, granting lands to States or corporations to aid in the construction of roads or for other purposes, or to extend the time of grants made prior to Jan 30, 1865, shall be so construed as to embrace mineral lands, which in all cases are reserved exclusively to the United States, unless otherwise specially provided in the act or acts making the grant.

51. Vested rights to use water for mining. Right of way for canals. Whenever, by priority of possession, rights to the use of water for mining purposes, have vested and accrued, and the same are recognized and acknowledged by the local customs, laws, and the decisions of courts, the possessors and owners of such vested rights shall be maintained and protected in the same; and the right of way for the construction of ditches and canals for the purposes herein specified is acknowledged and confirmed; but whenever any person, in the construction of any ditch or canal, injures or damages the possession of any settler on the public domain, the party committing such injury or damage shall be liable to the party injured for such injury or damage.

52. Rights subject to vested and accrued water rights. All patents granted, or preemption or homesteads allowed, shall be subject to any vested and accrued water rights, or rights to ditches and reservoirs used in connection with such water rights, as may have been acquired under or recognized by Sec 51 of this title.

8. MINING LAWS EXTENDED TO NON-MINERAL LANDS

Summary of United States Code, Chap and Sec Headings

Reference to the following Chapters and Sections of the U S Code, Title XXX, having no bearing on the apex law, but applying to Federal mineral lands, may be of interest. Chap 3 of Title XXX refers to " Land Containing Coal, Phosphates, Petroleum, Oil, Oil Shale, Gas, Sodium, Potassium, etc., and Building Stone." See sections 71–263 inclusive, together with notes up to 1938 in the Cumulative Section of the U S Code. A copy of these sections is too voluminous for use in this Handbook. Sub-titles of Chap 3 are here given for reference:

Entry on coal lands in general, sections 71–77.

Entry under Non-mineral Land Laws of coal lands, with reservation of coal to United States, sections 81–90.

Entry under Mining laws of lands containing petroleum or other mineral oils or gas, sections 101–104.

Homestead entry of lands in Utah withdrawn or classified as oil lands, sections 111–113.

Agricultural entry of lands withdrawn or classified as containing phosphate, nitrate, potash, oil, gas or asphaltic minerals, sections 121–123.

Locations under Placer Mining Laws of lands, containing phosphate rock, section 131.

Permits to prospect for chlorides, sulphates, carbonates, borates, silicates or nitrates of potassium, sections 141–152.

Entry of building stone or saline lands under Placer Mining Laws, sections 161, 162.

Disposal of lands in Alabama as agricultural lands, sections 171, 172.

Leases and prospecting permits, subdivision 1, general provisions; sections 181–194, subdivision 2, coal; sections 201–208, subdivision 3, phosphates; sections 211–214, subdivision 4, oil and gas; sections 221–236, subdivision 5, oil shale; section 241, subdivision 6, Alaska oil proviso; section 251, subdivision 7, sodium.

Note. All references in Chap 3 apply only to U S lands and the entry upon the same.

9. THE BUREAU OF MINES

(See also Chap 1, of Title XXX, sub-title "The Bureau of Mines," sections 1–11, sections 1 being given in full.)

Section 1. **Bureau of Mines, establishment, director, experts and other employes.** There is established in the Department of Commerce a bureau of mining, metallurgy and mineral technology, to be designated as the Bureau of Mines, and there shall be a director of said bureau, who shall be thoroughly equipped for the duties of said office, by technical education and experience and who shall be appointed by the President, by and with the advice and consent of the Senate; and there shall also be in the said bureau such experts and other employes, to be appointed by the Secretary of the Interior, as may be required to carry out the purposes of this chapter in accordance with the appropriations made from time to time by Congress for such purposes. Sections 2–11 inclusive codify the Acts of Congress relating to the Bureau. An historical note on the Establishment of the Bureau will be found in Chapter I of the above Title, p 27.

10. WITHDRAWALS OF PUBLIC LANDS

The President may, at any time in his discretion, temporarily withdraw from settlement, location, sale or entry, any of the public lands of the U S, including the District of Alaska, and reserve the same for water-power sites, irrigation, classification of lands, or other public purposes to be specified in the orders of withdrawals, and such withdrawals or reservations shall remain in force until revoked by him or by an act of Congress.

By act of Congress approved Aug 24, 1912, the act of June 25, 1910, was amended so as to provide that all lands withdrawn under provision of the act shall at all times be open to exploration, discovery, occupation and purchase under the mining laws " so far as the same apply to metalliferous minerals " (37 Stats at Large, p 497).

11. REGULATIONS OF THE LAND DEPARTMENT

Origin and nature. Establishment of the Department of the Interior was authorised by act of Congress, Mar 3, 1849, and supervision of mineral lands was transferred to the general land office in that department (9 Stats at Large, p 395).

This department, consisting of the Sec'y of the Interior, the Commissioner of General Land Office, and their subordinates, is a special tribunal, vested with judicial powers to hear and determine claims to public lands, and with authority to execute its judgments by conveyances to proper claimants. Decisions of this department as to questions of fact within its jurisdiction are final; there is no appeal to any court, nor may the courts anticipate its action nor take upon themselves administration of public lands (Lindley, p 1644). The department rules, when not in conflict with the law, have the force and effect of laws, and courts take judicial notice of them. The dep't has not power of itself to grant land, but to facilitate and consummate grants authorised by law. When lands are withdrawn by order of Congress or lawful executive order, its jurisdiction is suspended; and when lands have passed into private ownership and title has been transferred from the government, its authority vanishes. Where the land officers have clearly mistaken the law of the case as applicable to the facts, courts of equity may give relief; but "where there is a mixed question of law and fact and the court can not so separate it as to see clearly where the mistake of law is, the decision of the tribunal to which the law has confided the matter is conclusive" (Lindley, p 1 666).

Classification of claims. There are two classes: Lode claims and placer claims.

12. LODE CLAIMS

Dimensions. Under the law of 1872, lode claims may have a maximum length of 1 500 ft, and a maximum width of 600 ft, in no case exceeding 300 ft on each side of the vein at the surface. The owner of a valid location is also given all other veins of which the tops or apices lie within the exterior boundaries of his claim, provided they were not adversely claimed on May 10, 1872.

Initiation of title. No lode claim shall be located until after discovery of a vein or lode within the limits of the claim. Sufficient development work is therefore required by the department to disclose existence of a vein, and if possible its general course and indications that it contains valuable minerals.

Location notice should give the course and distance as nearly as practicable, from discovery shaft on the claim to some permanent, well-known points or objects, such as stone monuments, blazed trees, confluence of streams, prominent buttes, hills, etc, in the immediate vicinity; also names of adjacent claims. A post or monument of stones should be erected at the discovery point or shaft, and at each corner of the ground claimed. Notice posted at the discovery should give name of the lode claim, names of the locators, number of feet claimed and their direction from the discovery, and whether the claim thus staked is wholly or in part on one side of the discovery point. Location notice must be filed for record as required by the state or territorial laws and local miners' rules, if any there be.

Perpetuation of possessory title to a lode claim located since May 10, 1872, is maintained by the performance of at least $100 worth of work upon it each calendar year. This work is not required after entry for patent. Failure to perform the required amount of work subjects the claim to re-location, unless original locator or his heirs, assigns, or legal representatives, have resumed work before re-location. Non-contributing partners may be " advertised out " by publication of notice and summons in the nearest newspaper once a week for 90 days, or by personal notice in writing. If, 90 days after such notice in writing, or 180 days after first newspaper publication of notice, the delinquent partner shall have failed to contribute his proportion of expenditures for assessment work, his interest in the claim passes by law to those co-owners who have paid for the work.

Method of procuring patent. The owner must first have a correct survey made of the claim, under the authority of the surveyor-general of the state or territory containing the claim. One copy of the plat of survey and one copy of the field notes shall be retained in the office of surveyor-general, one copy of the plat given to the claimant for posting upon the claim, one copy of plat and field notes given to the claimant to be filed with the proper register, and finally transmitted by that official, with other papers in the case, to the land office, and one plat to be sent by the surveyor-general to the register of the proper land district to be filed for future reference. The plat is to be posted in a conspicuous place on the claim, together with notice of patent application, containing date of posting, name of claimant, name of claim, number of the survey, mining district and county, and names of adjoining and conflicting claims as shown by the survey plat.

After posting notice, the claimant shall file with the proper register and receiver a copy of plat and field notes, together with affidavits of at least two credible witnesses that such plat and notice are posted conspicuously upon the claim, giving date and place of such posting; a copy of the notice so posted to be attached to and form a part of said affidavit. The claimant must also make affidavit that he has possessory right to the premises described, by virtue of a compliance upon his part and that of his grantors (if he claims by purchase) with the mining rules, regulations and customs of the district and the mining laws of Congress. The affidavit must state the facts constituting such compliance, the origin of his possession, and the basis of his claim for patent. The vein or lode must be fully described, the description to include a statement as to kind and character of mineral, extent thereof, whether ore has been extracted and of what amount and value, and such other facts as will

support the applicant's allegation that the claim contains a valuable mineral deposit. The affidavit must be supported by a copy of each location notice, certified by the legal custodian of the record thereof, and also by an abstract of title of each claim, certified by the legal custodian of records of transfers, or by a duly authorized abstractor of titles. The certificates must state that no conveyances affecting or purporting to affect the title to the claim or claims appear of record other than those set forth. The register will then, at expense of the claimant, publish a notice of the application for 60 days; after which period, upon furnishing an affidavit of publication and another of posting upon the claim, and a certificate of the surveyor-general testifying to the performance of at least $500 worth of work upon the claim, the claimant may pay for the land at rate of $5 per acre, taking a receipt, and receiving in due time a patent, if the papers are found to be regular.

13. PLACER CLAIMS

Nature. As in case of lode claims, a discovery of valuable mineral in place is necessary before location of a placer claim. Proceedings to obtain patents for placer claims, including all forms of mineral deposits, excepting veins of quartz or other rock in place, are similar to those prescribed for obtaining patents for vein or lode claims; but where a placer claim shall be upon surveyed lands, and conforms to legal subdivisions, no further survey or plat will be needed. The price fixed by law for placer claims is $2.50 per acre or fractional part of an acre.

Placer applications should contain, in addition to the recitals necessary in and to both vein or lode and placer applications, such detailed data as will support the claim that the land applied for is placer ground containing valuable mineral deposits not in vein or lode formation, and that title is sought not to control water courses or to obtain valuable timber, but in good faith because of the mineral therein.

This statement, of course, must depend upon character of deposit, and natural features of the ground, but the following details should be covered as fully as possible: If the claim be for a deposit of placer gold, there must be stated the yield per pan, or per cu yd, as shown by prospecting and development work, distance to bedrock, formation and extent of the deposit, and all other facts upon which the applicant bases his allegation that the claim is valuable for its deposits of placer gold. If a building-stone deposit, or deposit other than gold be claimed under the placer laws, applicant must describe fully the kind, nature and extent of deposit, stating the reasons why same is by him regarded as a valuable mineral claim. He will also be required to describe fully the natural features of the claim; course of streams, amount of water carried, and amount of fall within the claim; also kind and amount of timber and other vegetation thereon, and adaptability to mining and other uses.

If the claim be all placer ground, that fact must be stated in the application and corroborated by accompanying proofs; if of mixed placer and lodes, it should be so set forth, with description of all known lodes situated within its boundaries. A specific declaration, as required by section 37 of U S Code (supra), must be furnished as to each lode intended to be claimed. All other known lodes are, by the silence of the applicant, excluded by law from all claim by him, of whatsoever nature, possessory or otherwise.

Further regulations by the Department provide for methods of proof and procedure relative to millsites, citizenship, possessory right, adverse claims, duties of deputy surveyors, charges for publication of notices, conduct of hearings on contests and applications for entry, and various other matters of detail not necessary to be quoted here.

MINING LAWS OF WESTERN MINING STATES AND ALASKA

14. CALIFORNIA MINING ACT

The States of Ariz, Col, Cal, Idaho, Mont, Nev, New Mex, N Dak, Ore, S Dak, Utah, Wash, Wyo and Alaska have all adopted laws for the working of mines, securing of easements, etc, under authority of Section 43 of the U S Code. These Statutes were stated in full in Second Edition of this Handbook, pp 1664–1667 and 1669–1682. As there are constant changes in these Statutes, it is thought advisable to set forth the laws of one typical mining State and refer to laws of other States by title only. The California Acts, as now contained in the Civil Code of 1937, and amended through the 52nd Session of the Calif Legislature of 1937, covering location and methods of location of mining are therefore now given in full.

California Civil Code, 1937 (Deering)

Lode claims, how located. 1 426. Any person, a citizen of the United States, or who has declared his intention to become such, who discovers a vein or lode of quartz, or other rock in place, bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposit, may locate a claim upon such vein or lode, by defining the boundaries of the claim, in the manner hereinafter described, and by posting a notice of such location, at the point of discovery, which notice must contain: *First*, Name of the lode or claim; *Second*, Name of the locator or locators; *Third*, Number of linear feet claimed in length along course of vein, each way from point of discovery with width on each side of center of claim, and general course of vein or lode, as near as may be; *Fourth*, Date of location; *Fifth*, Such description of claim by reference to some natural object, or permanent monument, as will identify the claim located.

Boundaries and extent of lode claim. 1 426*a*. The locator or locators of any lode mining claim must define the boundaries of such claim so that they may be readily traced, but, in no case, shall the claim extend more than 1 500 ft along the course of the vein or lode, nor more than 300 ft on either side thereof, as measured from the center line of the vein at the surface. On all lode mining claims made after this Act takes effect and within 60 days after the location of the claim, the locator or locators shall erect at each corner of the claim and at the center of each end line, or the nearest accessible point thereto, a post not less than 4 in diameter, or a stone monument at least 18 in high.

Record of location of lode claim. 1 426*b*. Within 30 days after the posting of his notice of location upon a lode mining claim, the locator shall record a true copy thereof in the office of the county recorder of the county in which such claim is situated, for which service the county recorder shall receive a fee of $1.

Placer claim, location of. 1 426*c*. Location of a placer claim shall be made in the following manner: By posting thereon, upon a tree, rock in place, stone, post or monument, a notice of location containing the name of claim, name of locator or locators, date of location, number of feet or acreage claimed, such description of claim by reference to some natural object or permanent monument as will identify the claim located, and by marking the boundaries so that they may be readily traced; *provided*, that where the United States survey has been extended over the land embraced in the location, the claim may be taken by legal subdivisions, and no other reference than those of said survey shall be required, and the boundaries of a claim so located and described need not be staked or monumented. The description by legal subdivisions shall be deemed the equivalent of marking.

Record of location of placer claim. 1 426*d*. Within 30 days after posting of notice of location of a placer claim, the locator shall record a true copy thereof in the office of the county recorder of the county in which such claim is situated, for which service the recorder shall receive a fee of $1.

Discovery shaft. 1 426*da*. On every lode mining or placer claim, located after this Act takes effect, the locator or locators thereof shall, within 90 days after the date of location, sink a discovery shaft upon such claim at the point of discovery to a depth of at least 10 ft from the lowest part of the rim of such shaft at the surface, exposing the deposit upon which discovery and location is based, or shall drive a tunnel, adit, or open cut upon such claim at the discovery point to at least 10 ft below the surface, exposing the deposit upon which such discovery and location is based.

Placer locations, work on. 1 426*db*. On all placer mining locations containing more than 20 acres, located after this Act takes effect, the locators thereof shall, within 90 days after date of location, perform at least one dollar's worth of work for each acre included in such claim. This work may all be done at one place on the claim if so desired, and must be actual mining development work, exclusive of cabins, buildings, or other surface structures. Nothing in this section shall be construed as a modification of the requirements of Sec 1 426*da* of this Code.

Relocation of lodes or placers. 1 426*dc*. The relocation of any lode or placer mining location which is subject to relocation, shall be made in the same way as an original location as herein required by law to be made, except that the relocator may either sink a new shaft upon the ground relocated at the discovery point to the depth of at least 10 ft from the lowest part of the rim of such shaft at the surface, exposing the deposit upon which location is based, or drive a new tunnel, adit, or open cut upon such ground at the point of discovery to at least 10 ft below the surface, exposing the deposit upon which location is based; or the relocator may sink the original discovery shaft 10 ft deeper than it is at the time of relocation, or drive the original tunnel, adit, or open cut 10 ft farther.

Tunnel right, location of. 1 426*e*. Locator of a tunnel right or location shall locate it by posting a notice at the face or point of commencement of the tunnel. which must

contain: *First*, Name of locator or locators; *Second*, Date of location; *Third*, Proposed course or direction of tunnel; *Fourth*, Description of tunnel, with reference to some natural object or permanent monument as shall identify the claim or tunnel right.

Boundaries of tunnel location. 1 426*f*. Boundary lines of the tunnel shall be established by stakes or monuments placed along the lines at an interval of not more than 600 ft from the face or point of commencement of the tunnel to the terminus at 3 000 ft therefrom.

Record of tunnel location. 1 426*g*. Within 30 days after posting notice of location of tunnel right or location, the locator shall record a true copy thereof in the office of the county recorder of the county in which such claim is situated, for which service the recorder shall receive a fee of $1.

Amended notice of location. 1 426*h*. If at any time the locator of any mining claim heretofore or hereafter located, or his assigns, shall apprehend that his original location notice was defective, erroneous, or that the requirements of the law had not been complied with before filing; or in case the original notice was made prior to the passage of this act, and he shall be desirous of securing the benefit of this act, such locator, or his assigns, may file an additional notice, subject to the provisions of this act; *provided*, that such amended location notice does not interfere with the existing rights of others at the time of posting and filing such amended location notice, and no such notice, or the record thereof, shall preclude the claimant, or claimants, from proving any such title as he or they may have held under previous locations.

Record of survey of mining claim is prima facie evidence. 1 426*i*. Where a locator, or his assigns, has the boundaries and corners of his claim established by a United States deputy mineral survey, or a licensed surveyor of this state and his claim connected with a corner of the public or minor surveys of an established initial point, and incorporates into the record of the claim the field notes of such survey, and attaches to and files with such location notice, a certificate of the surveyor, setting forth: *First*, that said survey was actually made by him, giving the date thereof; *Second*, the name of the claim surveyed and the location thereof; *Third*, that the description incorporated in the declaratory statement is sufficient to identify; such survey and certificate become a part of the record, and such record is *prima facie* evidence of the facts therein contained.

Millsite, location of. 1 426*j*. Proprietor of a vein or lode claim or mine, or owner of a quartz-mill or reduction works, or any person qualified by the laws of the United States, may locate not more than 5 acres of non-mineral land as a millsite. Such location shall be made in the same manner as hereinbefore required for locating placer claims.

Record of location of millsite. 1 426*k*. Locator of a millsite claim or location shall, within 30 days from the date of his location, record a true copy of his location notice with the county recorder of the county in which such location is situated, for which service the recorder shall receive a fee of $1.

Annual labor required. 1 426*l*. The amount of work done or improvements made during each year to hold possession of a mining claim shall be that prescribed by the laws of the United States, to wit: $100 annually.

Record of proof of annual labor. 1 426*m*. Whenever a mine owner, company, or corporation shall have performed the labor and made the improvements required by law upon any mining claim, the person in whose behalf such labor was performed or improvements made, or some one in his behalf, shall within 30 days after the time limited for performing such labor or making such improvements make and have recorded by the county recorder, in books kept for that purpose, in the county in which such mining claim is situated, an affidavit setting forth the value of labor or improvements made, the name of the claim, and the name of the owner or claimant of said claim at whose expense the same was made or performed. Such affidavit, or a copy thereof, duly certified by the county recorder, shall be *prima facie* evidence of the performance of such labor or the making of such improvements, or both.

Fee for recording proof of labor. 1 426*n*. For recording the affidavit herein required, the County Recorder shall receive a fee of 10 cents per folio, 20 cents for endorsement, and 10 cents for indexing the name of each claim and each owner.

Forfeiture to co-owners. Contribution by delinquent co-owners. 1 426*o*. Whenever a co-owner or co-owners of a mining claim shall give to a delinquent co-owner or co-owners the notice in writing or notice by publication provided for in section 2 324, Revised Statutes of the United States, an affidavit of the person giving such notice, stating the time, place and manner of service, and by whom and upon whom such service was made, shall be attached to a true copy of such notice, and such notice and affidavit must be recorded in the office of the county recorder, in books kept for that purpose, in the county in which the claim is situated, within 90 days after the giving of such notice; for the recording of which, said recorder shall receive the same fees as are now allowed by

law for recording deeds; or if such notice is given by publication in a newspaper, there shall be attached to a printed copy of such notice an affidavit of the printer or his foreman, or principal clerk of such paper, stating the date of the first, last and each insertion of such notice therein, and where the newspaper was published during that time, and the name of such newspaper. Such affidavit and notice shall be recorded as aforesaid, within 180 days after the first publication thereof. The original of such notice and affidavit, or a duly certified copy of the record thereof, shall be *prima facie* evidence that the delinquent mentioned in § 2 324 has failed or refused to contribute his proportion of the expenditure required by that section, and of the service of publication of said notice; *provided*, the writing or affidavit hereinafter provided for is not of record. If such delinquent shall, within the 90 days required by § 2 324 aforesaid, contribute to his co-owner or co-owners, his proportion of such expenditures, and also all costs of service of the notice required by this section, whether incurred by publication charges or otherwise, such co-owner or co-owners shall sign and deliver to the delinquent or delinquents a writing, stating that the delinquent or delinquents by name has within the time required by § 2 324 aforesaid, contributed his share for the year . . . ., upon the . . . . mine, and further stating therein the district, county and state wherein the same is situated, and the book and page where the location notice is recorded, if said mine was located under the provisions of this act; such writing shall be recorded in the office of the county recorder of said county, for which he shall receive the same fees as are now allowed by law for recording deeds. If such co-owner or co-owners shall fail to sign and deliver such writing to the delinquent or delinquents within 20 days after such contribution, the co-owner or co-owners so failing as aforesaid shall be liable to the penalty of $100, to be recovered by any person for the use of the delinquent or delinquents in any court of competent jurisdiction. If such co-owner or co-owners fail to deliver such writing within the said 20 days, the delinquent, with two disinterested persons having personal knowledge of such contribution, may make affidavit setting forth in what manner, the amount of, to whom, and upon what mine, such contribution was made. Such affidavit or a record thereof, in the office of the county recorder, of the county in which such mine is situated, shall be *prima facie* evidence of such contribution.

Records to be received in evidence. 1 426*p*. The record of any location of a mining claim, millsite or tunnel right, in the office of the county recorder, as herein provided, shall be received in evidence, and have the same force and effect in the courts of the state as the original notice.

Copies of record as evidence. 1 426*q*. Copies of the records of all instruments required to be recorded by the provisions of this act, duly certified by the recorder, in whose custody such records are, may be read in evidence, under the same circumstances and rules as are now or may be hereafter provided by law, for using copies of instruments relating to real estate, duly executed or acknowledged or proved and recorded.

Effect of act on mining districts. 1 426*r*. The provisions of this act shall not in any manner be construed as affecting or abolishing any mining district or the rules and regulations thereof within the state of California.

1 426ra. Failure or neglect of the locator or locators to comply with the requirements of Sections 1 426, 1 426*a*, 1 426*da*, 1 426*db*, or 1 426*dc*, of this Code, shall render such location null and void, and no portion of the area within such location shall be subject to relocation by the same locator or locators within the period of three years from the date of such void location.

Failure to perform annual labor—Relocation void. 1 426*s*. The failure or neglect of any locator of a mining claim to perform development work of the character, in the manner and within the time required by the laws of the United States, shall disqualify such locators from relocating the ground embraced in the original location or mining claim or any part thereof under the mining laws, within 3 years after the date of his original location and any attempted relocation thereof by any of the original locators shall render such location void.

§ 2. All acts and parts of acts in conflict with this act are hereby repealed.

§ 3. This act shall take effect and be in force on and after July 1, 1909.

The California mining law has been quoted in full as being one of the more recent expressions of state legislation on the subject of the location of mining claims, upon the public domain, within the particular states.

Laws of 1927, Chap 128, Art IIj, created a State Department of Natural Resources. A Chief of Division shall be in charge of the Division of Mines and Mining, who shall be known as the State Mineralogist.

Laws of 1929, Chap 280, provided for annual reports by mine owners, and lessees to the State Mineralogist, at his request. The word "mining" includes all mineral, oil or gas bearing property.

Laws of 1931, Chap 480, provide for filing with the Department of Finance annual reports on the number of tons of minerals taken from lakes and streams. A royalty of 25¢ per ton is provided for.

Laws of 1933, Chap 161, require employers of miners to have sufficient assets on hand with which to pay wages of miners before the start of any wage period.

Laws of 1935, Chap 482, provide for recording of grubstake contracts and prospecting agreements.

Other Laws have been and will be from time to time passed, but the preceding statements cover the most important of the California Mining Acts. Special provisions for the location and sale or lease of state mineral lands have also been passed by Calif, Mich, Minn, Nev, N Y, Tex, Wis, and some other states.

SUMMARY OF UNITED STATES LAWS

16. HOW MINING RIGHTS MAY BE ACQUIRED

Discovery is the first and DEVELOPMENT the second condition of the right of possession. Halleck says: "Discovery is made the source of title, and development, or working, the condition of the continuance of that act." Just as there can be no valid appropriation of a mining claim without antecedent discovery, so in all of the mining states, except California and Utah, a certain amount of development work is essential to the completion of a location. In addition to this preliminary work, a certain amount of labor and improvement is required as a condition to perpetuation of possessory title. This amount is fixed by the national law at $100 worth annually, and is by different states made to apply to other improvements than actual excavation, or translated into an equivalent in hours of labor.

In the case of Butte Superior Coal Co *vs* Clark-Montana Co, decided Mch, 1919 (249 U S 12) the court held that "priority of right is not determined by date of entries or patents of the respective claims, but by priority of discovery and location, which may be shown by testimony other than the entries and patents," and that "a failure of the earlier location notices to comply with the state law is immaterial if the junior locator, at the time of locating, knew that the earlier locator was in possession and working his claim." See also Cole *vs* Ralph (252 U S 287), decided Mch, 1920, overruling Work Mining & Milling Co *vs* Doctor-Jack Pot Co (194 Federal, 620).

Posting of notice is not specifically required by the federal law. Such formality is, however, made one of the steps preliminary to completion of location by the laws of practically all the mining states; and the place and manner of posting are often prescribed. It is, moreover, in some instances specifically provided that the location shall be void if this requirement be not complied with. It is therefore advisable in each case to read carefully the local or state regulations.

Marking of location on the ground, so that its boundaries can be readily traced, is one of the requirements of the federal statute. This law has been supplemented by most of the mining states; and the number and character of stakes and monuments are specified.

Recording notice of location is not demanded by the national law, but is necessary under the laws of all the mining states. The time allowed in which to record varies from 30 days after date of discovery to 90 days after location. Here, also, care is needed.

17. HOW MINING RIGHTS MAY BE LOST

Forfeiture of a mining claim may be caused by failure of the claimant to perform any of the acts required by the laws for maintenance of possession. (Lindley, p 1 598.)

Abandonment likewise results in loss of mining rights. Judge Lindley remarks: "Abandonment operates instanter. Where a miner gives up his claim and goes away from it without any intention of returning, and regardless of what may be come of it, or who may appropriate it, an abandonment takes place, and the property reverts to its original status as part of the unoccupied public domain." (Lindley, p 1 597.) "Abandonment is always a question of intention. In forfeiture the element of intent is not involved." Resumption of work in good faith before initiation of possessory rights by others operates to prevent forfeiture.

18. PATENT PROCEEDINGS

Patent is the deed or grant of the U S, conveying the title authorized to be given by the mining or other land laws. It establishes the character of the land which it conveys, and is conclusive evidence of performance of all necessary steps leading to its issuance.

Land Department is that quasi-judicial tribunal which has exclusive jurisdiction over the disposition of lands of the public domain under the laws of Congress and the supervision of the Department of the Interior. The department consists of the Secretary of the Interior, the Commissioner of the General Land Office, and subordinate officers, such as registers and receivers of land offices, and surveyors-general. These officials are appointed by the President, the former for the term of four years; the latter for no fixed period. The surveyors-general may appoint deputies who are subject to the approval of the land commissioner.

First step in proceeding to obtain a patent for mining land from the U S is to make application for a survey. The application, addressed to the surveyor-general of the district, must be signed by one of the claimants or legal attorney in behalf of all the petitioners, and should contain:

1. Name or names of the claimants in full.
2. Name of each location embraced in the application.
3. Names of the mining district, state, and county in which the claim is located.
4. Name of the U S deputy surveyor to whom the order is to be issued.

Applicant must also furnish a copy of the location notices of each location to be embraced in the survey, each duly certified by the proper recording officer, and similar copies of each amended location. A deposit must be made to cover estimated cost of fees in office of the surveyor-general. The claimant may employ any deputy mineral surveyor in the district. Fee for the survey is additional to the amount deposited with the surveyor-general, and is adjusted between deputy and claimant by mutual agreement.

In making the survey the following particulars are to be observed:

1. Exterior boundaries of claim, number of feet claimed along vein, and, as nearly as possible, direction of the vein, and number of feet claimed on it, in each direction from point of discovery.
2. Points of intersection of survey lines with those of any conflicting prior surveys.
3. Conflicts with unsurveyed claims, where applicant for survey does not claim the area in conflict.
4. Total area of claim, and also area in conflict with each intersected survey.
5. If claim is situated within two miles of any corner of a public survey, the plat and field notes must show a line connecting the claim with such corner; if there be no such corner within two miles, it must be connected with a U S mineral monument. (Sec 17, Art 16, of this Handbook.)
6. End lines of each claim embraced within the survey must be made parallel.

Where PLACER CLAIMS are upon surveyed lands, and conform to legal subdivisions, no further survey or plat is required. If a known lode exists within the placer, it must be described in the survey, and surveyed as though it were situated elsewhere.

19. ADVERSE CLAIM

Any person asserting an adverse mineral right to all or some portion of the land for which patent is sought may file an adverse claim thereto. "Adverse proceedings are called for only where one mineral claimant contests the right of another mineral claimant." Controversies over the character of the land, *i e*, whether mineral or agricultural, etc, are not proper subjects for adverse claims; but may be heard by the land department under the head of protests. The adverse claim shall show the nature, boundaries and extent of the claim, and all proceedings, except the publication of notice

and making and filing of the affidavit thereof, shall be stayed until the controversy shall have been settled or decided by a court of competent jurisdiction, or the adverse claim waived. Except in Alaska, adverse claims must be filed prior to the expiration of the 60 days allowed by law for publication of the application notice; in Alaska, they may be filed during the time of publication or within 8 months thereafter. The claim must be filed with the register and receiver of the land office in whose district the land is situated. Within 30 days the adverse claimant must then begin action in a court of competent jurisdiction, to determine the question of right of possession, and prosecute the same to final judgment. The jurisdiction to try such cases involving title to real estate is in the state courts; and such actions are almost invariably heard by such courts. Where no action is commenced in court before the expiration of the 30 days, the land department may proceed as if no adverse claim had ever been filed.

20. NATURE OF TITLE CONVEYED BY MINERAL LODE PATENTS

Patent to a lode claim conveys: 1. Exclusive right of possession and enjoyment of all the surface included within the limits of the location, as described in the patent, subject only to pre-existing easements. 2. All veins, lodes, and ledges throughout their entire depth, the tops, or apices, of which lie within the boundaries, the right to pursue the vein in depth outside of such boundaries being limited, however; * * * * 3. *Prima facie*, such a patent confers the right to everything found within vertical planes drawn through the surface boundaries; but these boundaries may be invaded by an outside lode locator holding the apex of a vein under a regular valid location, in working his vein on its downward course underneath the patented surface (Lindley, p 1 897).

Placer patent conveys to the patentee everything within vertical planes drawn downward through the surface boundaries, EXCEPT: 1, such lodes or veins whose tops or apices are within the placer limits, whose existence was known prior to the filing of the application for placer patent, and were not included in the placer application; 2, such segments of veins having their tops or apices elsewhere, as may underlie the placer surface, and which may lawfully be taken by the apex lode locator under a regular valid lode location, pursuing his vein on its downward course. In the last class of cases the question of priority of location is wholly unimportant (Lindley, p. 1 915).

21. EXTRALATERAL RIGHTS

Probable origin. The right given by the mining laws of the U S to follow the vein beneath the surface of land owned by another was aptly termed the " extralateral right " in an early discussion by Dr. R. W. Raymond (*Trans* A I M E., Vol 12, p 387), and has passed into current use in legal phraseology. This provision of the law has given rise to interminable litigation; and in its interpretation volumes of opinions have been furnished by the courts and writers of law books. The manner of its introduction into our system of laws does not seem to be clearly understood. It is at variance with the Spanish and Mexican codes, and, outside of the U S (so far as we have been able to find), exists only in the code of Southern Rhodesia.

However, Thomas T. Read, Professor of Mining at Columbia, under date of June 2, 1939, makes the following comments: "The extralateral rights associated with the law of the apex were not entirely without precedent. In Bolivia in the 16th century, especially at Potosí and Machacamarca, the claim owner was privileged to extend his workings in any direction, provided only he did not cross the workings of any other operator. This led to so many difficulties that the square claim was later adopted. In the tin deposits of Yunnan province, China, a similar arrangement has prevailed since time immemorial, with similar result. In both cases, the deposit must be followed down from the surface; only in the U S was it possible to trace a deposit discovered underground back to a possibly hypothetical surface outcrop and thereby establish a claim to it."

Extralateral rights were also tried for a long period by the Germans in the sixteenth and seventeenth centuries, where a sort of inclined location was allowed, the miner having the right not only to follow the vein beneath the surface, but having also 7 *lachter* (about 25 or 30 ft) on each side of the vein, parallel to its walls, within which to work (R. W. Raymond, "Mineral Resources," 1869, p 195); but it was there abandoned because it gave rise to so much litigation. It was later tried for a short time in British Columbia, but promptly given up, for the same reason. (J. M. Clark, *Trans* A I M E, Vol 43, p 617.) It may have arisen in the U S from the fact that our laws resulted from the local rules of the miners, and that these rules were a product of the evolution and development of the western mines, starting with surface rights only, and at first solely with reference to placers, and being later extended to lodes. Each man located his vein and aimed to work it regardless of its dip or inequalities and without interference with or from his neighbors. In many districts, moreover, there was a general theory, at least in early days, that the veins were all parallel to each other in dip and strike; and such complexities of structure and uncertainty in mining as afterward developed could not have been foreseen.

Extralateral law is now contained in Chap 2, Title XXX, U S Code given in full, Art 7, herein. Section 23 provides that end lines of each claim shall be parallel to each other. It is not believed that this provision of the law operates to defeat extralateral rights, where end lines converge. It has also been held that end lines must not be broken (Lindley, p 863); but the universality of this rule seems to depend somewhat on the definition of " end lines," and relation of the apex of the vein to such portions of the end lines as are parallel. A concise summary of court decisions relative to the vexed questions of extralateral rights was published by Judge Clayberg (California Law Review, May, 1913; *E & M Jour*, Sep 20, 1913, pp 537–543), and is quoted *in extenso* below:

Ideal claim defined. An ideal quartz mining claim is a portion of mineral land, 1 500 ft or less in length, along the vein, and 600 ft or less in width. Fig 1 illustrates the surface of such a claim, showing the apex and course of the vein, and the side and end lines of the claim. Fig 2 illustrates a cross-section of such claim, showing the vertical side lines thereof, and the dip of the vein. The statute, by its terms, seems to refer only to an ideal location, with the vein on its course or strike passing through its two parallel end lines. The planes of the end lines, dropped downward perpendicularly, and extended in their own direction until they intersect the exterior portions of the vein, bound the extralateral rights on such vein. In actual mining, however, an ideal location is the exception rather than the rule. Such conditions result from the inability of the locator to determine the actual course or strike of the vein at the time of completing his location. As a matter of fact, the locator of a mining claim usually judges such course or strike from a small portion of the vein disclosed in his place of discovery. It is almost impossible to determine correctly the true course or strike of a vein from such a small exposure. Veins are irregular in their course or strike, and may be found running through the earth in almost every conceivable direction.

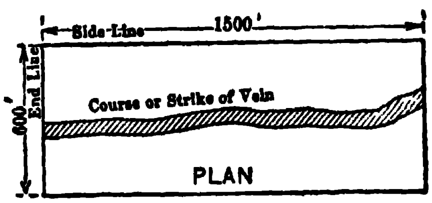

Fig 1. Ideal Location

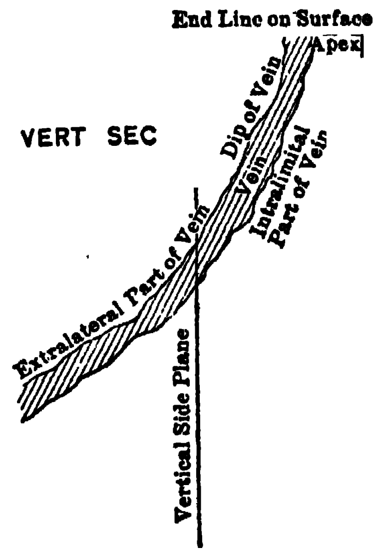

Fig 2. Cross-section, Ideal Claim, Showing Dip

Principles of extralateral rights. The application of the law of extralateral rights, as provided for by the Act, to the varied conditions which have presented themselves, depending on the course or strike of the vein within the surface boundaries of the location, and the form or shape of the location itself, has been the source of prolific litigation in the mining regions of the U S. In applying this statute, certain well-established principles must be always be borne in mind, as follows:

1. The basis of extralateral rights is the EXISTENCE OF THE APEX of vein within surface boundaries of the location, dropped downward perpendicularly, and therefore their extent along the vein should always be limited by the extent of the apex within the claim. This is recognized by Supreme Court of the U S in Del Monte Mining Co *vs* Last Chance Mining Co (U S, 55) in which the court says:

In considering the questions presented, we are dealing simply with statutory rights. There is no showing of any local customs or rules affecting the rights prescribed by the statute, and beyond the terms of the statute, courts may not go. They have no power of legislation. They can not assume existence of any natural equity, and rule that by reason of such equity a party may follow a vein into territory of his neighbor and appropriate it to his own use. If cases arise for which Congress has made no provision, the courts can not supply the defect. Congress having prescribed the conditions upon which extralateral rights may be acquired, a party must bring himself within those conditions, or else be content with simply the mineral beneath his surface. It is true that the primary thought of the statute is the disposal of the mines and minerals, and in interpreting the statute this purpose must be given effect. Hence, when a party has acquired title to the ground within whose surface area is the apex of a vein, with a few or many feet along its course, a right to follow that vein on its dip for the same length should be awarded to him if it can be done under any fair and natural construction of the language of the statute. If the surface was everywhere level, and veins constantly pursued a straight line, there would be little difficulty in legislation to provide for all contingencies; but mineral is apt to be found in regions where great irregularity of surface exists, and the strike of

veins is as irregular as the surface, so that many cases may arise in which statutory provisions fail to secure to a discoverer of a vein such an amount thereof as equitably it would seem he ought to receive. Twenty-one Mining Co *vs* Sixteen to One Mine, 255 Fed 658 (Feb, 1919), held that in following a vein down beyond its sidewalls, the owner of the apex may extend his working beyond the walls of the vein, if necessary for its proper economical working.

2. In order that extralateral rights exist in any location, its END LINES MUST BE PARALLEL (Sec 2 320, U S Rev Stats, Iron Silver Mg Co, *vs* Elgin Mg Co, 118 U S, 196). It is not held that the end lines of a mining location must be parallel in order that such location be valid, but only that they must be parallel in order to give extralateral rights to any vein, the apex of which may lie within the surface boundaries of such location. A prospector has the general right to make his location in such shape as he desires, and it will be held valid if he has otherwise complied with the law. It has also been decided that the parallelism of the end lines need not be mathematically accurate; that a substantial parallelism is all that is necessary.

In the case of Iron Silver Mining Co *vs* Elgin Mining Co, the location involved was one of peculiar character (Fig 3). The lines marked end lines on the location, and which were parallel, were not the lines of the location through which the vein passed on its course, and therefore not end lines governing extralateral rights. The peculiar condition of the apex of the vein was probably occasioned by erosion. The vein lying very nearly horiz, forces of nature had disintegrated certain portions

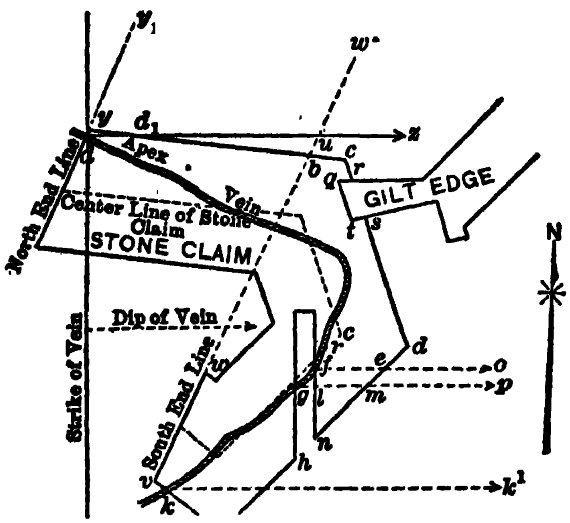

Fig 3. Iron Silver-Elgin Case

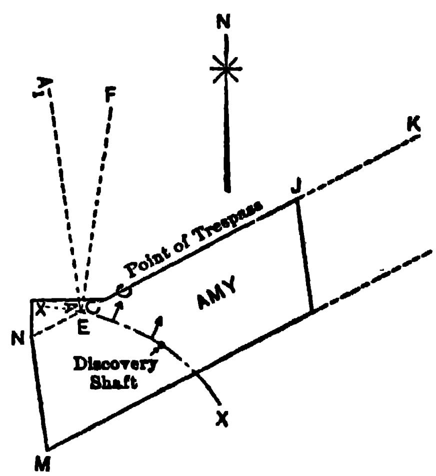

Fig 4. Amy Silversmith Claims

thereof, by wearing out a gulch, which, of necessity, caused a portion of the apex of the vein to recede from the line formerly occupied.

The only method of discussing extralateral rights clearly is by considering the various conditions which may present themselves, and applying the law to each condition, as follows:

1. **Ideal location.** When apex of a vein on its course passes through both end lines of a location, which are parallel to each other, the extralateral rights to such vein are clearly defined by the statute, and are bounded by the vert planes of the end lines extended in their own direction until they intersect the exterior portions of the vein. This condition is illustrated in Fig 1 and 2, and needs no further comment.

2. **Outcrop cutting both side lines.** Where apex of a vein on its course passes through both side lines of a location, which are parallel to each other, the U S Supreme Court has decided that the side lines of the location become end lines, for the purpose of determining extralateral rights to the vein, and such rights are bounded on the strike of the vein by vert planes from such side-end lines extended in their own direction until they intersect the exterior parts of the vein (Flagstaff Mg Co *vs* Tarbett, 98 U S, 463; King *vs* Amy Silversmith Co, 152 U S, 222). This condition is clearly disclosed in Fig 4.

3. **Outcrop cutting two diverging boundaries.** Where apex of a vein on its course crosses two boundaries of a location diverging from each other in direction of the dip of the vein, in our opinion no extralateral rights can exist, because the end lines are not parallel, and one is only entitled to so much of the vein on its dip as he has length of apex thereof within his surface lines. If the apex of a vein within the boundaries of a location is a certain number of feet in length, equitably the owner of such location should be given the same number of feet on the strike of the vein extralaterally, at any depth, and no more (33 Mont, 46). See Fig 5.

4. **Outcrop cutting two converging boundaries.** Where the apex of a vein crosses two boundaries of a location which converge toward each other in the direction of the dip, it has been held, in the case of Carson City Gold Mining Co *vs* North Star Mining Co (86 Fed, 658), that the extralateral rights would exist, bounded by the vert planes of the end lines, projected in their own direction, until they intersect. On this point Judge Lindley states:

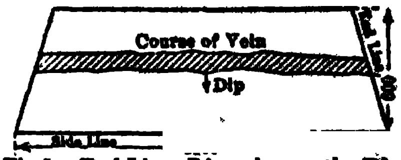

Fig 5. End Lines Diverging on the Dip

There can be little doubt that extralateral rights may be enjoyed under locations made or patents issued under either Act where the end lines converge in the direction of the dip of the vein, giving the locator or patentee less in length on the vein beneath the surface outside of his vert boundaries than he has at the surface.

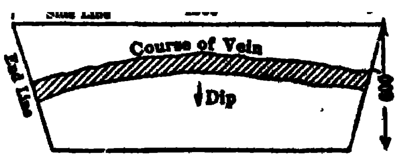

Fig 6. End Lines Converging on the Dip

It is admitted, however, that the decisions of the highest courts are not yet conclusive on these questions, and some lower courts have held the contrary of the opinion expressed above. This case is shown in Fig 6.

5. **Outcrop cutting end and side line.** Where apex of a vein on its course crosses one side line and one end line of a location, the doctrine has been established by the Supreme Court that extralateral rights are bounded by a plane dropped perpendicularly downward through end line of claim through which the vein passes, and a plane parallel therewith, dropped downward perpendicularly through the point where the vein departs from surface boundaries, across the side line. These planes extended in their own direction would bound the extralateral rights on such vein under such conditions (Del Monte Mining Co *vs* Last Chance Mg Co, 171 U S, 55; Clarke *vs* Fitzgerald, 171 U S, 92). See Fig 7.

6. **Outcrop entering and leaving through same side line.** Where apex of a vein on its course enters and departs from the claim through the same boundary line, the Supreme Court of Colo has held that no extralateral rights attach (Catron

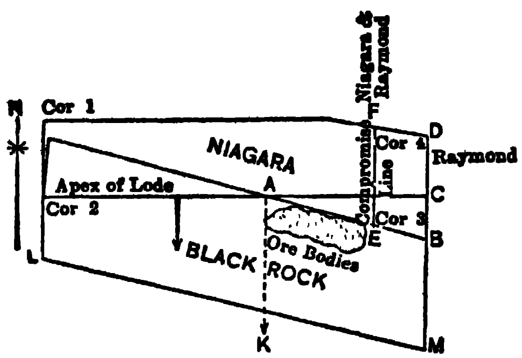

Fig 7. Apex crossing One End Line and One Side Line

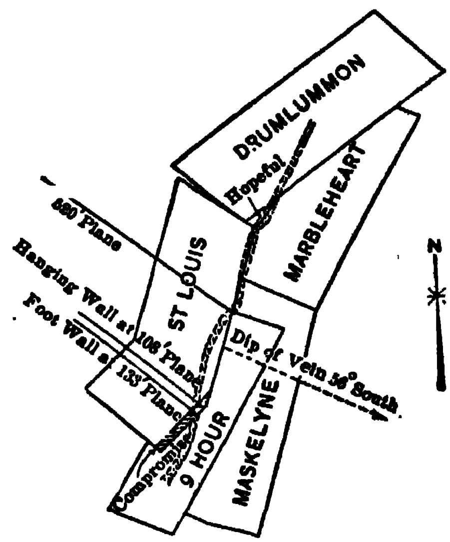

Fig 8. St Louis-Nine Hour or Drummummon Case

vs Olds, 23 Colo, 433). The U S Court of Appeals for the Ninth Circuit, however, holds the contrary (St Louis Mg Co *vs* Montana Mg Co, 104 Fed, 664; C. W. Goodale, *Trans* A I M E, Feb, 1914).

The extent of extralateral rights on a vein in a case such as that last referred to presented an interesting question. The vein in controversy was a wide one, entering and departing from the St Louis claim, at an acute angle, through the same side line. At the point of departure from the St Louis claim, the apex of the vein was conceded to be 25 ft wide, measured along the boundary which it crossed. The St Louis claim was conceded to be the prior location, and the owner thereof claimed that he was, therefore, entitled to all extralateral rights on the vein, so long as any portion of its apex remained within the claim boundaries. The Court of Appeals upheld this contention saying:

The only deduction which can be made from the foregoing rules is that, inasmuch as neither statute nor authority permits a division of the crossing portion of the vein, and the weight of authority favors the senior locator, the entire vein must be considered as apexing on the senior location until it has wholly passed beyond its side line. Fig 8 illustrates this condition, showing properties in conflict in St Louis case.

This decision of the appellate court has been cited by the U S Supreme Court, and thus appears to have received the sanction and approval of the highest court of the land. In a later opinion the Court of Appeals speaks as follows (183 Fed, 61): We are therefore of the opinion that the right of the St Louis Mining Co to extralateral rights in the Drumlummon to the extent that it apexes within the St Louis Mining Co's claim, has been previously determined by this court, and that this determination has been affirmed by the Supreme Court of the U S (204 U S, 204), and that such has become the law of the case.

The vein in question was an incidental or secondary vein, and not the discovery vein; but the rule is the same, because the statute provides that the owner of a lode claim is entitled to follow extralaterally all veins which apex within its surface boundaries. The doctrine here announced gives to the locator precisely the same extent along the course of the vein beneath the surface of the adjacent claims as that which he has upon the surface within his location boundaries.

7. Wide outcrops. Where the apex of a vein on its course is split or divided by a boundary line of a location, or where the vein is wider than the location itself, the U S Supreme Court has decided that the senior location is entitled to the extralateral rights of the entire vein, and the junior location takes it up after the rights of the senior are exhausted (Argentine Mining Co *vs* Terrible Mg Co, 122 U S, 478; Lawson *vs* U S Mg Co, 207 U S, 1; Empire State Co *vs* Bunker Hill Mg Co, 114 Fed, 417). See Fig 9.

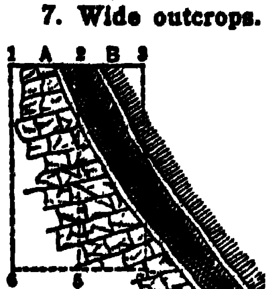

Fig 9. Vein Split by Boundary Line (Vert Sec)

8. Outcrop cutting one end line only, where the apex of an original or discovery vein on its course enters through one line of a location, and ceases before it reaches any other boundary; and

9. Outcrop cutting no boundary line, where the apex of the vein is wholly within the claim, and does not cross any boundary.

These two conditions are clearly analyzed by the U S Supreme Court, in discussing the Del Monte cases (Del Monte Mg Co *vs* Last Chance Mg Co, 171 U S 55), as follows:

The law places a limit on the length of the vein beyond which he shall not go, but it does not say that he shall not go outside the vert side lines unless the vein in its course reaches the end lines. Nowhere is it said that he must have a vein which either on or below the surface extends from end line to end line in order to pursue that vein on its dip outside the vert side lines. Naming limits beyond which a grant does not go is not equivalent to saying that nothing is granted which does not extend to those limits. The locator is given a right to pursue any vein whose apex is within his surface limits, on its dip outside the vert side line, but may not in such pursuit go beyond the vert end lines. And this is all the statute provides. Suppose a vein enters at an end line, but terminates halfway across the length of the location, his right to follow that vein on its dip beyond the vert side lines is as plainly given by the statute as though in its course it had extended to the farther end line. It is a vein, the top or apex of which lies inside of such surface lines extended downward vertically.

The Court of Appeals for the Eighth Circuit is also quoted as follows (Work Min & Mill Co *vs* Doctor-Jack Pot, 194 Fed, 620, 629): It does not follow that to secure extralateral rights the vein must extend from end line to end line, or, for that matter, intersect either end line.

Note.—The rule laid down by Judge Clayberg does not seem to cover the ground in cases 8 and 9. Veins are sometimes faulted or broken by torsional or differential movements which give them a broken and discontinuous apex, but still leave them with continuity beneath the surface. In such case, the extralateral rights might be bounded by vert planes parallel to the end lines of the claim, passed through the ends of the apex on the surface rather than by the vert end line planes themselves.

10. Outcrop departing and returning through same side line. Where a vein passes through both end lines of a location, but in its course departs from the claim through a side line and reënters the claim through the same side line, the case is said to be still a situation without specific ruling by the courts, although discussed in case of Waterloo Mining Co *vs* Doe (82 Fed, 45) as follows: The grant is to lodes having their apex in the ground patented. The fact that a part of the apex might be in the ground patented would not give any right to any part of the vein, the apex of which was not therein, although the apex might be cut by both end lines of the granted premises.

The vein must therefore be deemed, in general, to have extralateral rights within planes parallel to the end lines, for each segment of apex included within its surface boundaries.

—See also discussion as to what constitutes a vein in Utah Con Mg Co *vs* Utah Apex 277 Fed 41 and same *vs* same 285 Fed 249 and cases there cited (1922). See Twenty-one ... o *vs* Original Sixteen to One Mine, 265, Fed 469.

22. EXTRALATERAL RIGHTS ON INCIDENTAL OR SECONDARY VEINS

Statute gives extralateral rights to *all* veins whose tops or apices lie within the surface lines of the location. The vein on which the location is based is called the "discovery" or "original" vein; others are called "secondary" or "incidental" veins. While all veins have equal and similar rights under the law, yet the location or discovery vein, in its relation to the surface boundaries, is the vein which determines the direction of the planes limiting the extralateral rights for all other veins apexing within the claim.

Decisions of the courts in the Providence-Champion case (63 Fed, 552; 171 U S, 293; 18 Sup Court Rep, 909, 43 L Ed 170), the Drumlummon case (Mont Min Co, Ltd, *vs* St Louis M & M Co, 102 Fed, 430; 104 Fed, 664), the Anchoria-Leland (Jefferson Min Co *vs* Anchoria-Leland M & M Co, 32 Colo, 176, 75 Pac, 1 070), and in Supreme Court of Colo (Ajax Gold Min Co *vs* Hilkey, 31 Colo, 131; 72 Pac, 447; 22 Morr Min Rep, 585) have given rise to much discussion. The weight of authoritative opinion seems to support the views of the Colo court, contained in the following:

The end lines constitute a barrier, beyond which a locator can not follow a vein on its strike, whether it be a discovery or a secondary vein; and they also limit the bounding planes within which his extralateral rights are to be exercised in following such vein on its dip. In exercising such extralateral rights the locator can not in any case pursue the vein on its dip beyond the bounding planes drawn through the end lines. * * * The extent of the right depends upon the length of the apex, and the extralateral rights are measured not necessarily by the end lines, and only so when the vein passes across both end lines, but by bounding planes drawn parallel to the end lines passing through the claim at the points where it enters into and departs from the same. It would seem, therefore, necessarily to follow that the extralateral right depends, *inter alia*, upon the extent of the apex within the surface lines, and, while the end lines of the claim as fixed by the location are the end lines of all veins apexing within its exterior boundaries, the planes which bound such rights of different veins may be as different as the extent of their respective apices, though all such planes must be drawn vertically downward parallel with the end lines. It makes no difference in what portion of the patented claim the apex is. Its extralateral rights under this rule can be easily ascertained.

The same court, summing up the opinion of Justice Brewer in the Del Monte case, speaks as follows:

Our conclusion is that for all veins, both discovery and secondary, of a patented claim, the owner has extralateral rights at least for so much thereof as apex within the surface lines; that such rights as to secondary veins are not confined to such veins as apex within the same segment of the claim in which the apex of the discovery vein exists; and while the end lines of the location as fixed and described in the patent are the end lines of all veins apexing within the surface boundaries, and may constitute the bounding planes for such extralateral rights, and in no case can the locator pursue the vein on its dip outside the surface lines beyond such planes continued in their own direction until they intersect such veins, yet these bounding planes, which in all cases must be drawn parallel to the end lines need not be coincident.

Judge Lindley (p 1 378) remarks that "the modern tendency of decision is to apply to all secondary veins at the points of departure planes parallel to the end lines controlling extralateral rights on the original vein."

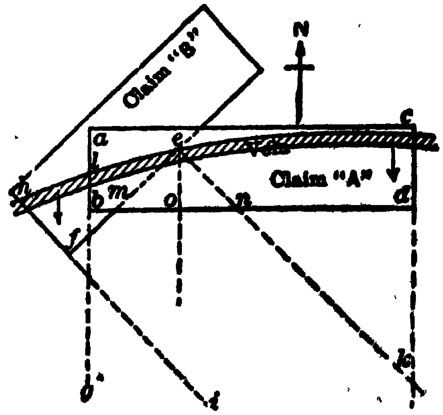

Fig 10. Conflicting Extralateral Rights

Conflicting extralateral rights. Extralateral rights may be curtailed or interrupted by conflict on the dip of the vein with the rights of an older location. In other words, two claims may be so located on the same vein that the planes of their extralateral rights will intersect. In such cases the senior valid location is entitled to those portions of the vein which are in conflict. The junior rights again attach beyond the area of conflict. Thus, in Fig 10, *A*, if senior, owns all ore between its end lines extended in their own direction. If *A* be junior, the vein from *h* to *e* belongs to *B* between the planes of *B*'s west end line and the parallel plane *ek* (with possible exception of triangle *emn* or *emo*).

23. VEINS DIPPING INTO AND BENEATH AGRICULTURAL PATENTS

Whether veins properly located under the mining laws can be followed down beneath the surface of patented agricultural lands seems not to have been decided by the U S Supreme Court. The Ninth District Circuit Court decided (Amador Min Co *vs* S S H Min Co, 36 Fed, 668) that such veins may not be followed by their owners beyond the points where they enter vertically beneath the surface of such prior agricultural grant. With this ruling Judge Lindley takes issue strongly (p 1 462), as follows:

We simply affirm that lodes or veins having their apices outside of the agricultural grant are, to the extent that such lodes or veins on their downward course underlie it, reserved by law out of such grant. Nor does this doctrine militate against the well-established rule of law that the patent is conclusive evidence of the character of the land. The land covered by an agricultural patent is conclusively deemed to be agricultural, but this does not necessarily imply that a lode under its surface apexing outside of it, cannot be reserved without impeaching the patent and changing the legal character of the land. The two classes of grants may exist without conflicting, in a legal sense.

By mutual agreement, the boundaries of extralateral rights, or their entire abolition, may be legally fixed, thus doing away with that dangerous provision of the federal law. Indeed, many such agreements have been made within recent years in many of the copper mining districts of the United States.

24. SOME UNSETTLED QUESTIONS AND RECENT EXTRALATERAL CASES

The opinion is frequently expressed that " all the doubtful points in the law of extralateral rights under the statute of 1872 are practically settled." Its marvelous perfection as a piece of trouble-breeding, perplexing and ambiguous legislation is abundantly illustrated by the fact that, more than 60 years after its enactment, this statement is still far from true. Judge Lindley remarks (p 1 423) that " lack of harmony between courts of different jurisdictions in the construction of the mining laws is a matter of frequent occurrence. For this reason, the law often remains in a state of uncertainty until the questions are finally decided by the Supreme Court of the U S. Even then, courts at times disagree as to the proper construction to be given to the decisions of the court of final resort."

Judge Clayberg, as quoted in Art 21, admits that "the forms of mining locations may be so variant, and the position of veins within the vert boundaries thereof so strange and peculiar, that many complications, now unthought of, may present themselves for adjudication." On this point the late Mr. Winchell expressed himself as follows: "While it is true that the U S Supreme Court has handed down decisions which definitely settle some of the principles of apex law, it is very far from true that no other vitally important questions remain undetermined. There are points upon which the U S Courts of Appeal in different circuits are in direct conflict. There are questions involved in litigation now pending which have never been passed upon by the Supreme Court, and some of these questions contain possibilities which one shudders to contemplate." (Why the Mining Laws Should be Revised. H. V. Winchell, *Trans* A I M E, v 48, p 361.) This is equally true in 1939.

Recent extralateral cases have been summarized as follows by William E. Colby, of the San Francisco Bar.

Whether or not a suit to establish extralateral rights is local in nature, to be tried in the jurisdiction where the mine is situated, depends upon the laws of the state where the question arises.

A suit to quiet title to asserted extralateral rights can not be maintained in the absence of any development showing whether such rights exist. Arizona Co *vs* Iron Cap Co, 27 Ariz, 202, 232 Pac, 549. Certiorari denied 270 U S 642; also see 29 Ariz, 23; 239 Pac, 290.

A deed to a lode mining claim, without express mention, conveys the extralateral portion of a vein apexing therein. Since there can be no priority of title to different portions of the same mining claim, an extralateral plane dividing rights as between grantor and grantee must be passed through the point of intersection of the center line of the apex with the common boundary line. Right to do further work to establish this fact was granted. Midwest-Butte Co *vs* Butte-West Side Mines Co, 32 Fed (2d), 841 (9 C C A).

Burden is on extralateral claimant to prove continuity from apex to point on vein outside boundaries. Facts ascertained by trial judge on inspection of premises are to be considered as evidence. Brugger *vs* Lee Yim, 12 Cal App (2d), 38.

When end lines of a lode claim converge in the direction of the dip of a vein the extralateral right is not destroyed because they are not parallel. Approximate parallelism is

sufficient. As between co-tenants, the purchase by one of an adjoining claim containing the apex of a vein dipping beneath the claim owned in common results in the holding in trust for the benefit of the other co-owner of that portion of the vein situated vertically beneath the claim held in common. Grant *vs* Pilgrim, 95 Fed, (2d), 561 (9 C C A).

The owner of land held under agricultural patent may not convey such land back to the U S and receive a lode-mining patent therefor so as to entitle him to exercise an extralateral right based on such new patent, where the statutory period to set aside the agricultural patent had expired. Such mining patent was void, not voidable, and could be collaterally attacked. Empire Star Mines Co *vs* Grass Valley Bullion Mines, 99 Fed (2d), 228 (9 C C A).

25. VERTICAL SIDELINE AGREEMENTS

The Apex Law of 1872 has led in the past to so much litigation in applying its provisions that many years ago there grew up a practice in some mining districts, to avoid the effect of the Apex Law, by entering into sideline agreements. The application of such agreements in the Bisbee mining district, Ariz, was largely due to the leadership and judgment of the late Dr. James Douglas, where sideline agreements were executed between several of the larger mining companies. Such agreements are now often made, limiting each party thereto to the mining of ore directly beneath the surface of its own claims, and doing away with the provisions of the Apex Law in so far as that law permits following the apex of the vein beyond the sidelines of the claims. A useful form of this agreement follows:

MEMORANDUM OF AGREEMENT, made and entered into this .... day of ...., 19 ...., between ...., a corporation of the State of ...., party of the first part, and ...., a corporation of the State of ...., party of the second part,

WITNESSETH: THAT WHEREAS, the parties to this agreement are the owners of certain mines and mining claims situated in .... Mining District, ... County, ..., some of which claims are adjoining and contiguous to each other, and others located in close proximity to each other; and WHEREAS, under the laws of the United States relating to mining claims, the locator or owner of a mining claim is given exclusive right of possession and enjoyment of all veins, lodes and edges throughout their entire depth, the top or apex of which lies inside of the surface lines of the mining claim extended downward vertically, although such veins or lodes may so far depart from a perpendicular on their course downward as to extend outside the vertical side lines of the surface locations, the right of possession being confined to such portions thereof as lie between vertical planes drawn downward through the end lines of the locations so continued in their own direction that such planes will intersect such exterior parts of such veins, lodes or ledges, which rights are generally known as extralateral rights; and WHEREAS, as a result thereof, disputes and underground conflicts frequently arise involving expensive litigation; and such undetermined rights create uncertainties as to the legal and equitable rights attaching to the ownership of mining claims; and WHEREAS, the parties hereto desire to settle and adjust forever, as between themselves, their respective rights to any veins, lodes, or deposits, or parts of veins, lodes, or deposits, existing within the vertical boundaries of the certain mines and mining claims owned by them respectively, by waiving all such extralateral rights, privileges and ownerships arising under the statutes of the United States, now existing, or which may hereafter be adopted, as against the ownership of the other party hereto,

NOW THEREFORE, in consideration of these presents and the covenants, conditions and privileges herein set forth and the grants, conveyances, relinquishments and releases which are hereby made by and between the parties hereto, it is hereby covenanted and agreed by and between the parties hereto as follows:

(1) That in all cases where any vein, lode, or deposit of mineral bearing rock or earth, having its top or apex within vertical planes drawn downward through the surface boundary lines of any mining claim herein mentioned and referred to and owned by the party of the first part, shall pass on its downward course or otherwise outside of and beyond vertical planes drawn downward through the boundary lines of said mining claim of the party of the first part and into and beneath the surface of any mining claim owned by the party of the second part, and herein referred to, the party of the first part does hereby relinquish and release to, and forever vests in, grants and conveys to the party of the second part that portion of every such vein, lode, or deposit which is beneath the surface of any such mining claim of the party of the second part. This provision is intended to relinquish and release to, convey, grant and vest in the party of the second part only such part of any vein which is beneath the surface of the mining claim of the party of the second part and not to deprive the owner of said apex of extralateral rights against mining claims other than those of the party of the second part, herein referred to.

(2) That in all cases where any vein, lode, or deposit of mineral bearing rock or earth, having its top or apex within vert planes drawn downward through the surface boundary lines of any mining claims herein referred to and owned by the party of the second part, shall pass on its downward course or otherwise outside of and beyond vertical planes drawn downward through the boundary lines of said mining claim of the party of the second part and into and beneath the surface of any mining claim owned by the party of the first part and herein referred to, the party of the second part does hereby relinquish and release to, and hereby forever vests in, grants and conveys to the party of the first part that portion of every such vein, lode, ledge or deposit which is beneath the surface of

any such mining claim of the party of the first part. This provision is intended to relinquish and release to, convey, grant and vest in the party of the first part only such part of any vein which is beneath the surface of the mining claims of the party of the first part and not to deprive the owner of said apex of extralateral rights against mining claims other than those of the party of the first part, herein referred to.

(3) That upon the application of either party hereto for a United States patent for any claims herein referred to, no protest, objection or adverse claim or suit shall be entered, made, filed or instituted by the other party on account of the working or mining of any vein, lode, or deposit of mineral bearing rock or earth or extraction of ores therefrom upon the dip of any such vein or lode.

(4) That in all cases in which United States patents may be hereafter granted to any mining claim, herein referred to, of either of the parties hereto, this agreement shall operate as a covenant on the part of each of the parties hereto that, upon the acquisition by either party of the outstanding title of the United States in such unpatented claims, all the covenants herein shall be deemed immediately applicable to and shall control and determine the rights of the parties hereto in relation to following any vein or lode of mineral-bearing rock or earth in such patented claims beneath the surface of any mining claim of the other party hereto, notwithstanding the terms of the grant and conveyance by the United States to either party hereto or the provisions of the Federal mining laws.

(5) That either party hereto, upon the request of the other and without further or additional consideration, shall and will make, execute and deliver to the other, such further or additional instrument or conveyance as shall, in accordance with the foregoing paragraph, absolutely vest the ownership of the portion of any such vein, lode, or deposit in the other party to this agreement in so far as such vein, lode, or deposit is beneath the surface of any mining claim of the other party, herein referred to.

(6) That the party of the first part for the considerations herein expressed and in consideration of the sum of One Dollar ($1) to it paid by the party of the second part, the receipt whereof is hereby acknowledged, has forever released and discharged, and by these presents does forever release and discharge the party of the second part from any and all debts, claims, demands, damages or suits at law or in equity for or on account of any trespass or injury done or committed in working in or upon any vein, lode, or deposit of mineral-bearing rock or earth within the vert boundary lines of any mine or mining claim owned by the party of the second par' and herein referred to.

(7) That the party of the second part for the considerations herein expressed and in consideration of the sum of One Dollar ($1) to it paid by the party of the first part, the receipt whereof is hereby acknowledged, has forever released and discharged, and by these presents does forever release and discharge, the party of the first part from any and all debts, claims, demands, damages or suits at law or in equity for or on account of any trespass or injury done or committed in working in or upon any vein, lode, or deposit of mineral bearing rock or earth within the vertical boundary lines of any mine or mining claim owned by the party of the first part and herein referred to.

(8) That the mine and mining claims and interest and parts of mining claims referred to in Schedule A hereto annexed constitutes the property of the party of the first part hereto, and the mines and mining claims, interests and parts of mining claims mentioned and referred to in Schedule B hereto annexed constitutes the property of the party of the second part hereto, and said Schedules are annexed hereto, and made a part of this agreement.

(9) This agreement shall extend to, inure to the benefit of, and be binding upon the parties, their successors and assigns.

IN WITNESS WHEREOF

26. DEEDS OF SURFACE RIGHTS IN MINING PROPERTIES

It is often necessary or desirable for a mining company to convey a deed of surface rights, reserving to itself the ores and minerals beneath. The following form of deed, to be made by the owner of the surface to the purchaser of the surface, for such consideration as may be stated in the deed, has been frequently used with advantage.

Quit-Claim Deed .... unto said party of the second part and unto his heirs and assigns forever, all the right, title, interest, claim and demand which the said party of the first part has in and to the following described real estate and property situate in the County of ...., State of ...., to wit: That portion of the surface of the .... Mining Claim situate in the .... Mining District, in .... County, ..., the United States Patent whereof is of record in the office of the County Recorder of .... County, in Book .... of Deeds, at Page ...., covered by that certain lot, piece or parcel of land known and described as Lot Numbered .... (   ), in Block Numbered .... (   ), of the Town of .... County, according to the .... of said Town of ....; together with the improvements thereon situate.

This deed is not intended to convey and does not convey any of the above described premises to a greater depth than .... (   ) feet immediately beneath the surface, nor any of the ores, minerals, or metal contained therein, and said party of the second part, his heirs and assigns, shall not have the right of lateral or subjacent support, as against said party of the first part, ..., its successors and assigns, and said party of the first part, its successors and assigns, shall not be liable for any damages caused by the subsidence or other disturbance of the surface or other part of said premises on account of mining or other operations beneath the premises hereby conveyed, or beneath the adjoining or other premises not hereby conveyed. Said party of the second part will and by the acceptance of this deed does, for himself and for his heirs and assigns, hereby release said party of the first part, ..., from any and all liability for any property

loss sustained upon said premises by reason of any operation or business carried on by said party of the first part, its successors or assigns, or caused by fire, smoke, gas, flood, damages from mining, milling, smelting, or reduction of ores, railroads, electrical transmission lines, or directly or indirectly connected with any of the same owned or controlled by said party of the first part. TO HAVE AND TO HOLD the same, together with all and singular the appurtenances and privileges thereunto belonging, or in anywise appertaining, and all the estate, right, title, interest and claim whatsoever, of the said party of the first part, either in law or in equity, in possession or expectancy, to the only proper use, benefit and behoof of the said party of the second part, his heirs and assigns forever, subject to the foregoing reservations.

IN WITNESS WHEREOF

FEDERAL TAX LAWS RELATING TO MINES

Summarized by PAUL ARMITAGE, of Douglas & Armitage, of the New York Bar

With the advent of Federal Income and Profits Taxes mine valuations became important. Engineers should have a general knowledge of the occasions when such problems may arise under the Federal Tax Laws.

Beginning with the Revenue Act of 1913 provision was made for an allowance for depletion of the mines, and this depletion allowance was enlarged and extended in the various subsequent Revenue Acts. Depletion, like depreciation, has the same basic concept of voiding a tax on capital, and, as in many cases, it is voided on a mine valuation, it is important for mining engineers to be familiar with these laws. Similar questions often arise under state laws in assessing income and inheritance taxes.

27. CLASSIFICATION

The five principal cases in which mine valuation may become essential are in determining: (*a*) depletion; (*b*) profits or losses on resale or disposition of a mine; (*c*) invested capital or paid-in surplus; (*d*) depreciation or obsolescence, including amortization; (*e*) value for estate taxes of a decedent's interest in a mining property.

28. DEPLETION

Basis for determination. As a mine is a wasting asset, provision must be made by owner or lessee for the return of the capital out of operating profits. Beginning with the Revenue Act of 1913, which merely allowed " five per cent of the gross value of the mine on the output for the year " (1913 Act, section b), Federal Tax Laws recognized this, and now allow annual depletion as a deduction from gross income in order to arrive at net taxable income. There have been developed over a series of years various extensions of the method and basis of computing depletion. In the 1938 Revenue Act there are four distinct bases:

(1) If the property was acquired before Mch 1, 1913, the basis of depletion is the fair market value of the mining property on that date.

(2) If the property was acquired after Mch 1, 1913, the depletion base is the out-of-pocket cost of the property to the taxpayer.

(3) If the mine was discovered (but not purchased or acquired as a proven tract) by the taxpayer after Mch 1, 1913, and the discovery value is " materially disproportionate to the costs," then the value on the discovery date, or within 30 days thereafter, forms the depletion base. This discovery value extends not only to the discovery of a new mine, but includes " minerals in commercial quantities " in an existing mine or mining tract, " if the vein or deposit thus discovered was not merely the uninterrupted extension of a commercial vein or deposit already known to exist." Depletion, of course, is only applicable for tax purposes if the discovered minerals can be separately marketed at a profit (Revenue Act of 1938, section 114). However, the annual allowance is limited to 50% of the net income for the current year from the discovered property.

(4) In the case of coal and metal mines and sulphur, depletion is allowed as a percentage of the gross income from the property during the taxable year, 5% in the case of coal mines, 15% in that of metal mines and 23% in that of sulphur deposits. A similar percentage is applied to oil and gas lands, amounting to 27.5% of the gross. However, such allowance shall not exceed 50% of the net income from the property. This percentage depletion first found its place in the Revenue Act as applicable to coal, metal and sulphur mines in 1932, and the taxpayer was afforded a right to elect for 1934 and sub-

sequent years. New elections were granted under the 1936 and 1938 Acts, but only as to newly acquired property. If the operator of a mine has not availed himself of this election, then he must find his depletion on the other bases. Hence, as to all mines acquired or discovered prior to Mch 1, 1913, the value on that date becomes the basis for depletion, and if discovered after that date, but before 1932, the discovery value becomes the basis for depletion. On the taxpayer or his engineers therefore, rests the burden of establishing this value to obtain a proper depletion allowance. The depletion rate is obtained by dividing this value by the estimated units in the mine (ton, lb or oz). The unit depletion rate applied to the annual extraction gives total yearly depletion. For example, on the valuation of a mine as of Mch 1, 1913, at \$50 000, containing by estimate 1 000 000 lb, the taxpayer is allowed a depletion rate of 5¢ per lb. Assuming in a given year a production of 200 000 lb, the total depletion deduction for operating profits for that year would be 200 000 × 5¢ = \$10 000.

Operating owners, lessors, lessees, sub-lessors, sub-lessees, life tenants, purchasers of royalty interests, owners of fractional or over-riding royalty interests, tenants in common and trusts and beneficiaries of the same, are each entitled to their respective shares of the allowance, and the Supreme Court has held that the right to depletion does not depend upon the retention of ownership, or of any other particular form of legal interest in the mineral content of the land. It is enough if the taxpayer has retained a right or share in the mineral content produced. Stockholders are not directly entitled to a depletion allowance, but distributions to the stockholder, made from a depletion reserve based upon cost or other basis of the property, are not considered as being paid out of earnings or profits, but the amount thereof reduces the cost or other basis of the stock upon which distributions were declared, and are non-taxable until the cost or other basis has been returned. However, if such distributions are from a depletion reserve based upon percentage depletion or discovery value, to the extent that the reserve represents the excess of percentage depletion, or the discovery value over the cost, they are taxable as an ordinary dividend. (Regulations 101, Section 115, Revenue Act 1938). But, any distributions are considered as paid out of current earnings until such earnings are all distributed (ibid).

In certain cases where, as a result of operations or development work, it is ascertained that the prior estimate of recoverable units on which depletion was based is in error, a revision of such prior estimate of the units may be made and the depletion base accelerated or retarded accordingly. But the Federal Treasury Dept has declined to allow any revision of the base for depletion, even though the estimate of recoverable units has formed a major factor in arriving at the same (such as a case of valuation).

Where beneficiation of the ore occurs after extraction, knotty problems arise in segregating and detaching from the price paid for the finished product the value added by such process of smelting, refining or concentrating. The Treasury regulations have established extensive rules for accomplishing this, as in the case of copper, gold, silver and coal mines.

Of course, the annual allowance for depletion of the mine and the base thereof is distinct from and in addition to the annual allowance for the depreciation of the plant and equipment used to operate the same.

29. INVESTED CAPITAL OR PAID-IN SURPLUS

Under the FEDERAL REVENUE ACTS OF 1917, 1918 AND 1921, imposing excess and war profits taxes, invested capital, including paid-in surplus, became a material factor. Also, where the capital stock of a corporation was paid up by the transfer of a mining property, its value at date of transfer may be a factor in arriving at the corporation's invested capital and paid-in surplus under the tax laws.

30. GAIN OR LOSS ON SALE OF MINING PROPERTY

Basis for determining gain or loss on sale of mining property is the same as that provided for depletion, except that no discovery value is allowed. That is, if the mining property was acquired before Mch 1, 1913 and subsequently sold, its value on that date becomes the basis for determining the taxable gain. If the property was acquired after Mch 1, 1913, the cost becomes the basis for determining gain or loss.

In some of the earlier Acts there was a special limitation of surtaxes in case of sale of mines, the principal value of which "had been demonstrated by prospecting or exploration or discovery work by the taxpayer." In 1926 this limitation was fixed at 16% (Revenue Act of 1926, Section 211-b).

31. VALUE FOR ESTATE TAX OF A DECEDENT'S INTEREST IN A MINING PROPERTY

On the death of a taxpayer owning an interest in mines or mining property, it becomes part of his estate and taxable both for federal estate taxes and local state inheritance taxes. Thus, a valuation of the mines is required as of the date of death, and similar proof of values of the mine must be made by competent engineers familiar with the property. The engineers of the Federal Revenue Bureau have recognized and adopted standard methods of valuing mines prevalent in the mining community, such as the Hoskold formula, and this has been followed by the tax boards, courts and state taxing commissions.

32. CAUTION TO MEMBERS OF THE MINING PROFESSION

As each successive revenue act has changed the phraseology of prior acts, under both the depletion provisions and those relating to gain and loss, the engineer will find it difficult to follow development of the laws without specialized study of each case, and it is essential to refer to the particular act under which a problem arises, and the decisions thereunder. Hence, the discussion in Art 27–31 gives only a general outline of the different cases in which valuation of a mine becomes essential, and should be read only as an index or guide to examining the statute itself and the decisions and regulations thereunder.

MINING LAWS OF CANADA

Summarized by GORDON MCMILLAN, K C, Toronto, Ontario

Administration of lands. The Dominion Government owns public lands in Yukon and North West Territories, administering them through the Dept of Mines and Resources. Public lands in the Provinces are administered by their respective Depts of Mines.

33. NORTH WEST TERRITORIES

Quartz mining claims. License (which costs $5 for an individual and from a minimum of $25 on a sliding scale to $100 per $1 000 000 of capitalization for a company) entitles holder to stake 6 claims, each 1 500 ft square, for himself and up to 6 each for 2 other licensees; a total of 18 claims.

Representation work amounting to $100 per year must be done, and claims up to 36 in number may be grouped for this purpose. Geol investigation, aerial reconnaissance or other like preliminary operation may be allowed.

Lease for 21 years, renewable for a like period, is granted for a fee of $10 per claim plus $50 rental per claim (renewals $200 per claim for 21 years) upon performing work to the value of $500 surveying claims and finding valuable mineral thereon. Lease lapses on non-payment of rental within 3 months.

Staking is by 4 posts, No 1 bearing name of claim, name and license number of licensee, date and hour of staking, and if claim is staked on behalf of another his name and license number. Witness posts may be erected.

Recording of claim must be within 15 days, unless claim is over 10 miles from Recording Office, when an extra day is allowed for each additional 10 miles. If claim is over 100 miles from Recording Office any 5 licensees may appoint an "emergency recorder" from among their number.

Royalty. On annual profits in excess of $10 000 and to $1 000 000, 3%; on excess over $1 000 000 to $5 000 000, 5%; on excess over $5 000 000 to $10 000 000, 6%; on excess over $10 000 000 a proportioned increase of 1% for each $5 000 000. All mines under same general management may be dealt with as one mine.

Placer claims are of 3 classes: (1) CREEK (on natural water courses with aver width at low water of 100 ft or less) are 500 ft in length along water course and 1 000 ft wide on each side of base line. (2) RIVER (on water courses over 100 ft wide) are on one side of river only, 1 000 ft along stream by 1 000 ft deep. (3) INLAND claims are rectangular, 1 000 ft square. The first locator on any creek is entitled to a discovery claim 1 500 ft long, and on a river or inland area to a discovery claim 3 000 ft long, with provisions for additional claims depending on size of locating party.

Any person over 18 years of age may locate claims. Upon location a grant for 1 year may be obtained on payment of $10 fee, and renewed on payment of the same fee and showing performance

of work to value of $100. Locating is by 2 posts, one at each end of the base line for creek and river claims, and at each end of the side nearest the creek or river on which they front for inland claims. Application for claim must be made within 10 days after location; if over 10 miles from Recorder's Office, an added day for each 10 miles, and if over 100 miles distant any 5 locators may elect an "Emergency Recorder." Transfers and other agreements affecting title must be in writing and recorded with Supervisor of Mines. Special provisions are made for obtaining the right to divert water for working claims.

34. YUKON TERRITORY

Quartz mining claims. Any person over 18 years of age may personally locate a claim 1 500 ft square by setting a legal post at each end of location line bearing appropriate inscription. Claims must be recorded within 15 days if within 10 miles of Recording Office, with one day extra allowed for each added 10 miles. If over 100 miles from Recording Office, 5 locators may appoint one of their number an "Emergency Recorder." If a power of attorney is filed in advance, 2 claims may be staked by proxy. Once located and recorded, a claim is good for 1 year and thence from year to year, provided holder performs work thereon to value of $100 per annum or pays that sum to Recorder. When holder has performed work to value of $500 (or paid that sum to Recorder), found a lode or vein, and had a survey of claim made, he may obtain a lease for 21 years at rental of $50 for the period; renewable for 21 years more at rental of $200.

Iron and mica location up to 160 acres may be recorded, in which case assessment requirements are doubled and rentals are $150 for first 21 years and $600 for subsequent periods.

Placer claims. Any person over 18 years may locate claims 500 by 1 000 ft, and not more than 500 ft in length along creek or parallel to creek on which they front. Staking is by 2 posts, one at each end of base line. First locator on any creek, hill, trench, bar or plain, is entitled to one claim 1 500 ft long; and, if party consists of 2 or more persons, 2 claims 1 250 ft long in length, claims to be of regular size. Recording is within 10 days, with one extra day allowed for each 10 miles after first 10. After location a grant may be obtained for 1 or 5 years at $10 per annum, with right of renewal upon payment of fee and performance of work to value of $200 per annum. Provisions are made for granting rights to divert water for mining purposes. Royalty of 2.5% is charged on all gold shipped from territory. A lease to prospect for 1 year, renewable for 2 years, may be obtained on certain conditions covering an extent of 5 miles in length (if abandoned ground or 1 mile if not previously prospected), at rental of $25 per annum per mile. Lessee must expend $1 000 per annum per mile and may before termination of lease stake out claims in area covered by lease.

Coal mining leases may be obtained in Yukon and North West Territories at rental of $1 per acre per annum; max area, 2 560 acres; royalty, 5¢ per ton of output. Provision is made for granting prospecting licenses where surface rights have been disposed of.

35. ALBERTA

Quartz mining claims are 1 500 ft square, staked by 4 corner posts. Any person over 18 years may locate and record in 1 year 3 claims in his own name and 2 each for 2 other persons, at $10 per claim. Claims must be recorded within 15 days, but if over 10 miles from Recording Office 1 day is allowed for each added 10 miles; provision is made for appointment of "Emergency Recorder." Claims may be retained from year to year upon performing work to value of $150 per claim, or paying that amount to Mining Recorder. LEASE (fee $10) may be obtained after performance of work to value of $750 (in which survey is credited up to $150 for location of vein or lode and survey of claim). Leases are for 21 years; rental, $50 for first 21 years, and $200 on renewals. Surface rights may be leased at $1 per acre per annum. Leases contain a reservation of royalty fixed by Order-in-Council. Transfers must be in writing, and in case of leases consent of Minister must be obtained.

Iron and mica claims 160 acres in area may be granted, work requirements being double those for Quartz Claims; rental, $150 for first 21 years and $500 for subsequent periods.

Placer claims. Regulations are similar to those in North West Territories, except that minimum work requirement in Alberta is $150 per annum.

Petroleum and natural gas leases, with maximum area of 1 920 acres, may be obtained at rental of 50¢ per acre for first year and $1 per acre per annum thereafter; term, 21 years, and leases are renewable. In unsurveyed territory applicant must locate by planting

2 posts, and apply for lease within 30 days, with extra day allowed for each 10 miles over 100. Machinery and equipment satisfactory to Minister (but not exceeding $10 000 in value) must be on property within 1 year and drilling operations must be commenced within 15 months. Royalty rate is fixed by Order-in-Council.

Coal mining rights are leased at annual rental of $1 per acre for 21-year period. Maximum area is 2 560 acres on unsurveyed territory and 640 acres in surveyed territory. In unsurveyed territory there must be a location by applicant. Operations must be commenced within 1 year from notification by Minister, and a specific amount of coal must be produced. Royalty of 5¢ per ton is payable in addition to rental.

36. BRITISH COLUMBIA

Miner's certificate. Holder of a FREE MINER'S certificate (fee for an individual $5; fee for a joint-stock company varies with its capital) may prospect on Crown lands, stake out claims and mine. He is restricted to staking 1 mineral claim on same vein or lode, but may acquire others by purchase. A free miner may locate 1 placer claim or leasehold in his own name, and one for each of 2 free miners for whom he acts as agent, on any separate riverbed, bar or dry diggings, but other claims may be acquired by purchase.

Mineral claim is a rectangular (unless it has one or more boundaries of previously recorded claim) piece of land not exceeding 51.65 acres in area. It is located by erecting 3 legal posts: discovery post where mineral in place is discovered and posts No 1 and 2 on line of ledge or vein and marking ends of claim. Each post must bear name of claim, name of locator and date of location; on No 1 post an inscription indicating direction of No 2 post and number of ft on right and left of line between them. Location line between posts 1 and 2 must be distinctly blazed if in a timbered area, or, if in bare country, marked by earth or rock monuments. 15 days are allowed for recording, plus 1 day for each 10 miles from recording office, after first 10 miles. Until a Crown grant is issued the claim is held practically on a yearly lease; minimum assessment-work, $100 value yearly, or equal sum paid to Mining Recorder, and assessments must be recorded within year. When $500 assessment-work is recorded and survey made, owner of claim is entitled to a Crown grant on paying $25 fee and giving notices required by Act.

Placer claims are of 4 classes: creek, bar, dry and precious stone diggings. CREEK DIGGINGS: claim to be 250 ft in direction of general course of stream and 500 ft wide on each side of middle of same. BAR DIGGINGS contain up to 250 ft on any bar covered at high water, or 250 ft long at high-water mark, and width extending from high-water to extreme low-water mark. In DRY DIGGINGS a claim is 250 ft square. Discovery claims, varying in number and length with the number of free miners in discovery party, have same width as ordinary placer claims. Discovery to be established to satisfaction of Gold Commissioner, and thereafter no discovery to be permitted within 5 miles measured along water-courses.

Placer claims are as nearly as possible rectangular, marked by 4 legal corner posts with name of locator, number and date of issue of free miner's certificate, date of location and name given to claim marked on each. In timbered areas boundary lines must be blazed and marked by posts not over 125 ft apart; in bare areas monuments of earth and rock may be substituted for all posts except at corners. Provisions for recording are the same as for mineral claims, but placer claims must be recorded before expiration if to be held for more than one year. A claim must be worked by owner or person on his behalf continuously as far as practicable during working hours; if work is discontinued for 7 days, except during close season or for other reason to Gold Commissioner's satisfaction, claim is deemed abandoned. Gold Commissioner may declare close season for all claims in his district, or a lay-over if water supply is insufficient. He may also grant tunnel and drain licenses, and easements over other claims. Mining partnerships are authorised for both mining and placer claims.

Placer-mining leases. Gold Commissioner of district may grant leases of unoccupied Crown lands approx 80 acres in extent, after location is made by staking along a location line not more than 0.5 mile in length (2 640 ft). Only an initial and final post are required. Width of leasehold is not to exceed 0.25 mile (1 320 ft), and locator, on both initial post and in notice of intention to apply (posted at Mining Recorder's Office), must state how many feet in location to right and left of location line. Annual rental is $30; $250 to be expended annually on development work.

Iron and steel bounties. By act of 1929, Lieutenant-Governor in Council may agree to pay bounties on pig-iron and steel shapes, when manufactured within the Province, not exceeding certain amounts per ton. A bounty, as on pig-iron, may also be paid on molten iron of a particular character.

Phosphate mining. By Act of 1925, tricalcium phosphate is removed from "Mineral Act" for purpose of administration, so as to permit staking of phosphate claims 1 mile square. There are special provisions relating to prospecting, staking, licensing and renewals.

Coal, petroleum and natural gas. For 640-acre blocks, with N–S and E–W boundaries and no side exceeding 80 chains in length, a license to prospect may issue for 1 year, subject to renewal for second or third year. Annual fee, $100. Discovery of coal being made during or within 30 days of expiry of license, land being surveyed and license conditions fulfilled, a lease may issue for 5 years at rental of 15¢ per acre, subject to renewals for 5 successive 3-year periods on payment of $100 per lease in addition to annual rental. After bona fide working, lessee may purchase the lands at $20 per acre where surface is available, or at $15 per acre if surface rights are not available. Royalty in addition of 2.5¢ per bbl (35 Imperial gal) of crude petroleum.

Taxes. Special provisions are made for leasing and subsequently purchasing Crown-granted mineral claims, reverting to Crown through non-payment of taxes. These claims are taxed 25¢ per acre per year. Output tax (payable quarterly), of 2% on gross value of mineral less transportation and treating costs, is imposed on all mines except coal, but refunded if ore shipments of mine do not realize market value of $5 000 in any year. Income from all mines subject to income tax are subject to exemptions and allowances in "Income Tax Act"; but, if output tax is payable, only the excess of income tax over output tax is payable. Coal is subject to tax of 10¢ per ton of 2 240 lb (payable monthly), except where shipped to coke ovens in Province. Coke and coal land are also taxed.

37. MANITOBA

Gold and silver. The holder of a miner's license (fee for an individual $5; for a Company, from $25 on a sliding scale to $100 per $1 000 000 capitalization) may stake 3 claims for himself and 6 for other licensees. Claims are 1 500 ft square in unsurveyed territory, and 40 acres in surveyed territory. Staking is by 4 posts with name, license number and date on No 1 post. Recording must be within 15 days of staking, but if over 10 miles from Recording Office an added day for each 10 miles; and if over 200 miles, 3 licensees may appoint one of their number an Emergency Recorder.

Assessment work consists of 125 days work in 5 years, at rate of 25 days per year. Diamond or core drilling counts 5 days for each 4 ft, and drilling by compressed air 2 days for each man employed. Survey counts 50 days, if made in first 2 years, and 25 days if made thereafter.

Lease, which is obtainable after performing assessment work, surveying claim and furnishing security for damage to owners of surface rights (if any), is for 21 years and costs $10, plus rental of $1 per acre per annum. Leases are renewable, but at double the original rental. Surface rights may be leased at $1 per acre per annum. Transfer must be in writing, and in case of lease must be approved by Minister.

Income tax on mining companies is as follows: Income up to $100 000, 5%; from $100 000 to $400 000, 6%; from $400 000 to $700 000, 7%; from $700 000 to $1 000 000, $8%; from $1 000 000 to $1 300 000, 9%; over $1 300 000, 10%. There is also a tax of $5 per claim.

Placer claims are as far as possible governed by the above regulations.

A Mining Board of 3 members has power to hear and determine disputes between licensees.

38. NEW BRUNSWICK

Prospector's license, fee $10, entitles holder to stake ten 40-acre claims, which must be recorded within 30 days. 25 day's work must be performed by Dec 31, unless claim is staked after Oct 31.

Mining license, at $10 per claim, may be obtained on showing that work has been done, claim surveyed and bond posted to indemnify owners of surface rights (if any), and is renewable on same terms. Licenses are in effect up to Dec 31 in year following year of issue; renewable upon performing 25 days' work per claim on payment of $25 per claim. The license gives right to mine.

Mining Lease. Holder of mining license, who has opened a mine and operated it for 6 months, may obtain a lease at $10 per year for each 40 acres, but rental is reduced by amount paid as royalty. Lease is for 20 years, renewable to 80 years and is for specified minerals. Minister may cancel lease for failure to operate for over 6 months.

Transfer of claims must be in writing and registered, and consent of Minister of Lands and Mines is necessary in case of leases.

Royalties. Coal and oil shale, 10¢ per long ton; petroleum and natural gas, 5% of value at well's mouth; other minerals, as fixed by Order-in-Council.

39. NOVA SCOTIA

Gold and silver. Mining claims are 40 acres. Application may be made for Prospecting License covering any number of mining claims, at 25¢ per acre and good for 1 year. Special licenses for 3 months may be obtained covering areas to 10 sq miles for $10. Within limit of license, a lease may be obtained good for 40 years' fee, which is 50¢ per acre with annual rental of 50¢ per acre. Work requirements are 2 days' work per acre of the claim, with diamond drilling and surveys allowed. Special provision is made for forcing owner to sell undeveloped areas either for cash or on a royalty basis and for rendering assistance by the Province to operators in development of mines.

Minerals other than gold and silver. Prospecting licenses (fee $30) and mining leases (fee $50) are granted on areas up to 1 sq mile, with a max length of 2 miles. License is good for 1 year, and 100 days' work per area of 1 sq mile or less must be performed, one-half thereof within 3 months. Diamond-drilling counts as 2 days per ft and surveys at 1 day for each $4, with max of 30 days; geological, laboratory or chemical work also accepted. Rental is $30 per annum per sq mile.

Royalties. Coal 12.5¢ per long ton; copper per unit (1%) per long ton, 4¢; lead or zinc per unit, 2¢; iron ore, 5¢ per ton; gold 35¢ per oz.; silver 2¢ per oz; other minerals, 5% of value. Lessee may offset against rent any greater amount paid as royalties in any year. Prospecting on private lands is permitted, subject to compensation to land owner for damages.

40. ONTARIO

Miner's license is necessary to stake out or acquire Crown lands for mining purposes; fee, $5 per year for an individual; for companies, $25–$150, depending on the share capital. Holder may stake out and apply for 9 claims in any mining division in any year on his own license, including up to 3 each for 2 other licensees.

Claim in unsurveyed territory, is a square, 20 chains on a side, of 40 acres, with lines N–S and E–W astronomically. In surveyed territory claims have an area of approx 40 acres, and not exceeding 50 acres, and constitute subdivisions of lots of varying sizes. Claim is staked by placing post No 1 at N E angle, No 2 at S E angle, No 3 at S W angle, No 4 at N W angle, and by blazing the lines connecting the posts if on timbered land, or erecting mounds of earth or rock in bare country.

Application for claim must be filed with Mining Recorder within 15 days after staking, one extra day being allowed for every additional 10 miles from Recorder's office. Fee for filing, $5. Within 4 months after recording, metal tags bearing number of claim (provided by Recorder) must be affixed to posts, and 30 days' work done in sinking, trenching, etc, except in winter (Nov 16–Apr 15). Including first 30 days, a total of 200 days of 8 hr is required, and not less than 40 days yearly within 5 years from recording date. Contiguous claims held by same owner may be combined in groups of 6 for assessment work. In computing assessment work credit is allowed for diamond drilling at rate of 1 day for each foot drilled; for survey by a recognized geophysical method, at rate of 1 day's work for each man necessarily employed in such survey; and for survey of claim by Ontario Land Surveyor, when required, at rate of 40 days per claim. Affidavits proving performance of work must be filed with Recorder within 10 days after expiration of each period, and when work is completed the holder obtains a grant in fee simple on payment of $2.50 per acre in unsurveyed, or $3 in surveyed lands; or, if in a Provincial Forest, a 10-year lease, renewable, rental first year $1 per acre; subsequent years, 25¢. If in unsurveyed land, an Ontario land surveyor's plan and field notes must be filed. On timbered land, permission to work claim may be withheld until timber is removed.

Provision is made for dredging leases, but no special rules are provided for placer workings, these not being a feature of mining in Ontario.

Petroleum, natural gas, coal and salt may be prospected for in Northern Ontario under authority of a Boring Permit, on staking out a block of 640 acres and paying a fee of $100. Permit for 1 year; renewable. If a workable deposit is found, a lease may issue for 10 years; annual rental, $1 per acre, subject to expenditure of not less than $2 per acre per year.

Mining Court of Ontario has power to hear and determine all disputes relating to mining lands, whether patented or unpatented. It has power to grant such rights and easements as necessary for proper operation of a mine.

Taxes. A graded tax is collected on annual profits exceeding $10 000 and up to $1 000 000, at rate of 3%; on excess above $1 000 000 and up to $5 000 000, 5%; on excess above $5 000 000, 6%. Where there is no municipal taxation, an annual tax of 5¢ per acre is levied on mining lands. Natural gas is taxed at 2¢ per thousand cu ft; a rebate of 75% being allowed if the gas is used in Canada.

41. QUEBEC

Mining lands may be acquired: (*a*) as a concession by purchase; (*b*) by occupying and working same under a mining license. In either case, a Miner's Certificate ($10) is necessary; holder may stake for himself 1–5 claims, and same number for each of 2 other certificate holders. Claim is a square of 40 acres, 20 chains to a side, running N–S and E–W; numbered stakes planted at corners, as in Ontario. In subdivided lands a claim is restricted to a half or quarter lot; where the lot contains more than 120 acres, size of claim depends upon area of the lot. Claim must be registered with the Dept of Mines or nearest local agent within 15 days; if 50 miles from a RR, an extra day is allowed for each added 10 miles. Metal tags bearing claim number must be affixed to stakes within 3 months. Claims are valid for 1 year (2 years if over 100 miles from RR, and assessment work is done in first year). After the year (or 2 years) a DEVELOPMENT LICENSE may be obtained on (*a*) payment of $10 and rental of 50¢ per acre, and (*b*) showing performance of 25 days' work per claim; licenses valid for 1 year; renewable. Provision is made for extending time for renewing and in certain cases for paying added rental of 50¢ per acre in lieu of assessment work. Five contiguous claims (subject to increase by Dept) held in one name may be grouped for assessment work. If a mine is opened on private lands, owner must be compensated.

Mining concession (grant) of the land may be had at any stage on payment of $5 per acre for SUPERIOR METALS and $3 per acre for INFERIOR METALS, conditions of the grant being that mining shall begin within 2 years and that during that time there be expended for each 100 acres at least $1 000 in case of superior metals and $500 for inferior metals. LETTERS PATENT may issue after granting of concession and performance of conditions. COMPANIES, unless wholly constituted under laws of Quebec, may not acquire any right in hydraulic power, land, forest, or mine forming part of the public domain of the Province on Mch 15, 1937, or which may form part thereof at any time after such date.

Taxes on profits: between $10 000 and $1 000 000, 4%; on excess of $1 000 000 to $2 000,000, 5%; on excess above $2 000 000 to $3 000,000, 6%; on excess above $3 000 000, 7%; exploration and development work may be deducted in determining profits.

42. SASKATCHEWAN

Quartz mining claims. Holder of a miner's license (fee for an individual $5; for a company from $25 on a sliding scale to $100 per $1 000 000 capitalization) may stake 3 claims for himself and 3 each for 2 other license holders. Claims are 1 500 ft square on unsurveyed territory and 40 acres in surveyed territory. Minister may grant iron and mica locations of 160 acres. Staking is by 4 posts, No 1 bearing name of claim and staker, date and hour of staking and license number. Claims must be recorded within 15 days, but if over 10 miles from Recorder's Office, one day is allowed for each added 10 miles; and if over 300 miles from Recorder's Office, 5 licensees may appoint an Emergency Recorder from among themselves.

Assessment work of $100 per year must be done in each of first 5 years. Diamond or core drilling counts $5 per ft; drilling by compressed air counts $7.50 per ft; survey work is allowed at cost and a geophysical survey may be counted as 1 year's work.

Lease, obtainable after performance of work, survey of claim and discovery of mineral, is for 21 years, and costs $10 plus rental of $5 per claim per annum; $15 in case of 160 acres claim; renewable for further period at double original rental. Security for damages to surface rights (if any) must be given before beginning operation. TRANSFERS must be in writing and for leases, consent of Minister must be obtained.

Royalty on precious metal ores, with aver value of $5 per ton or less is 2.5¢ per ton. Over $5 per ton, royalty rate is obtained by dividing aver value per ton by 10 in the case of precious metals and by 20 for other ores; the quotient is then multiplied by the royalty rate to obtain royalty per ton of ore. Mines under same general management or control may be considered as one mine. All royalties and penalties constitute a special lien on properties and machinery.

Placer claim regulations are same as those in North West Territories.

Petroleum and natural gas leases cover a minimum of 40 acres and a maximum of 1 920 acres in unsurveyed territory, and a minimum of 40 acres and a maximum of 19 200 acres in surveyed territory. In unsurveyed territory, no more than 3 leases may be held except by assignment. Rental, 50¢ per acre for the first year, $1 per acre for subsequent years. Machinery and equipment for prospecting satisfactory to the Minister must be on property within 1 year. Boring operations must begin within 15 months and be continuous, or at least $2 000 must be expended per year (provision for extension by Minister). Bond must be furnished before drilling begins, and all

drillers licensed. Royalty is payable at rate fixed by Order-in-Council, being not less than 2.5% or not more than 5% for first 5 years and not less than 5% or more than 10% thereafter.

Coal mining rights. An area up to 640 acres may be leased for 21 years at rental of $1 per acre per annum; licenses renewable. For mining operations, license to operate must be obtained from Coal Administrator. Royalty of 5¢ per ton is payable. Operations must begin within 1 year and at least 5 tons per acre mined in each succeeding year, subject to waiver by Minister. Surface rights may be leased at $1 per acre.

Alkali mining. An area up to 1 920 acres may be leased at 25¢ per acre per annum. Lessee must expend $10 000 per lease or group of leases; $2 500 first and second year and $5 000 third year, unless sooner expended. Royalty, 12.5¢ per ton. Surface rights may be leased at $1 per acre.

MINING LAWS OF MEXICO

Summarized by ROBERT T. BRINSMADE, Associate of Basham & Ringe, Attorneys, of Mexico City

43. HISTORY

The history of Mining Rights in Mexico comprises 3 periods: (a) Pre-Colonial; (b) Colonial; (c) the period following the Independence of Mexico. In the pre-Colonial (prior to 1516) and the Colonial (1516–1821) periods, the ownership of all subsurface rights was vested in the Spanish Crown and was inalienable and imprescriptible. The " Ley de Partidas " (1265), " Ordenamiento de Alcalá (1348) and the Law of John I (1387), also recognised that ownership of all mines in the Spanish Dominions was in the Spanish crown, but Spanish subjects could work mining properties under license from the Crown, by paying the Crown a royalty of two-thirds of the profits. The first law affecting mining concessions in New Spain (Mexico) was enacted in Dec, 1526, and known as the "Real Cedula"; it contained the principles of the earlier Spanish laws, and the "Ordenanzas de Minería," enacted 1563 and 1584, both in the reign of Philip II, retained the principal provisions of the earlier laws; the second "Ordenanzas" being more liberal, in permitting the King's subjects to work mines without a special license.

In 1783 the last "Ordenanzas de Minería" were enacted. These referred specifically to mines in Mexico, and after its independence they became the basis of its mining legislation. Under these " Ordenanzas " a mining claim was acquired as follows: (a) make a denouncement; (b) register the same; (c) pay the required tax to the Royal Treasury. Articles 1 and 2, Title 5 of these " Ordenanzas " provided that the owner of a mining claim could sell, rent or assign it.

After Mexico became independent, mining continued to be a public utility and all subsurface rights were vested in the Mexican Nation and like the ownership during the Spanish Crown was inalienable. In 1857 a new Constitution was adopted, and power to legislate on mining matters was by implication granted to the Mexican States, most of which adopted in toto the substantive provisions of the " Ordenanzas " of 1783. In 1883 the Federal Constitution was amended, and mining legislation was entrusted to the Federal Congress; and in 1884, the first complete Federal Mining Law was enacted. In 1892, the Mining Law of Mexico was amended for the purpose of encouraging exploration and exploitation of mining claims. The Mining Law of 1909, without modifying the principles established in the laws of 1884 and 1892, reaffirmed their essential features. The Law of extralateral rights governing claims in the U S is not recognized in Mexico.

44. BASIC PRINCIPLES

These are set forth in the Constitution of Mexico (1917) now in force. Paragraphs 4 and 6 of Article 27 of the Constitution are as follows:

" In the Nation is vested direct ownership of all minerals or substances which in veins, layers, masses, or beds constitute deposits whose nature is different from the components of the land, such as minerals from which metals and metalloids used for industrial purposes are extracted; beds of precious stones, rock salt and salt lakes, formed directly by marine waters, products derived from the decomposition of rocks, when their exploitation requires underground work; phosphates which may be used for fertilizers; solid mineral fuels; petroleum and all hydrocarbons, solid, liquid or gaseous."

" In the cases to which the foregoing paragraph refers, the ownership of the Nation is inalienable and may not be lost by prescription; concessions shall be granted by the Federal Government to private parties or civil or commercial corporations organised under the laws of Mexico, only on condition that said resources be regularly developed, and on the further condition that the legal provisions be observed."

45. MINING LAW OF 1930, NOW IN FORCE

This law, promulgated Aug 7, 1930, consists of 137 Articles, divided into 14 Chapters and is too extended to be included here. However, the first 7 Articles, also Articles 9–13 under the subtitle of " Mining Claims," are quoted in full, and a brief reference is made to some other Articles that are of particular interest. No attempt is made to give the procedural steps in acquiring concessions, and many other important sections are only briefly summarized. (The engineer or mining company desiring further information is advised to consult competent mining attorneys in Mexico. Editor)

Art 1. Scope of the law. This law shall regulate the exploitation, extraction and treatment of all natural mineral substances except petroleum and its derivatives, and those enumerated below, which will be regulated by special laws or by the Civil law: I. Soils suitable for agriculture or forestry. II. All rocks not commercially useful in the mining or petroleum industries. III. Products derived from the decomposition of the rocks mentioned in the foregoing paragraph, when their exploitation does not require underground workings. IV. Substances contained in suspension or dissolution by underground waters not having their source in any mine. V. Materials used for constructions purposes. VI. Products from salt deposits (when not formed directly by sea water), and " tequesquite " (saline surface crust).

Art 2. Minerals subject to this law are divided into: I. Metallic minerals; II. Nonmetallic minerals, including guano and amber; III. Coal and graphite.

Art 3. Exploitation and treatment of minerals subject to the provisions of this law are of public utility, and are therefore to be given preference over any other form of land utilisation.

Art 4. Concessions in general. The right to exploit and treat any minerals hereinbefore mentioned is originally acquired from the Nation, through concessions granted by the Dept of National Economy.

Art 5. Concessions are of 3 classes. I. Prospecting concession (Cateo), which authorizes and protects the person obtaining same to discover and work minerals susceptible of exploitation. II. Exploitation concession, which authorizes the person obtaining same to exploit and treat all minerals extracted from the land covered by the concession. III. Concessions for smelting plants (Plantas de Beneficio), which authorize and protect the construction and operation of smelters and mills.

Art 6. Concessionnaires. Only Mexican citizens and Mexican companies or associations have the right to obtain prospecting and exploitation concessions; foreigners may be granted the same right, provided they first comply with the provisions of Article 27 of the Federal Constitution and its reglamentary laws. Foreign companies, Governments, and Sovereigns cannot under any condition obtain such concessions.

Art 7. Rights derived from a concession can not be transferred in whole or in part to foreign governments or Sovereigns, nor can these be admitted as partners, co-partners or shareholders nor hold any right under the concession. Consequently, any act or contract in violation of this prohibition is null and void.

Art 9. Mining claims. The unit of a concession is the mining PERTENENCIA (claim), which is a solid of indefinite depth, bounded on the surface by 4 vertical planes corresponding to a horizontal square of 100 meters on each side.

Art 10. A mining claim is an isolated pertenencia or group of adjoining ones, although they only touch at one point, and which are protected by a single title of concession.

Art 11. When because of adjoining mining properties, it is not possible to reduce the claim to entire pertenencias, the resulting fractions may be added to it, in which case the claim will be deemed to be formed of as many pertenencias as there are hectares comprised in its horizontal projection, each fraction of hectare being considered as one entire pertenencia.

Art 12. If, because of the circumstances set forth in the preceding Article, it is not possible to form one entire pertenencia, the lot or claim may consist of a fraction of a pertenencia, but the area shall be computed in the manner provided for in that Article.

Art 13. In order that the division, amplification, reduction and unification of an exploitation concession may be legally effective, petitions requesting the same must be filed, and the procedure prescribed in this Law and its Regulations for the issuance of new titles and the cancellation of former ones must be followed.

Art 16. provides that surface owners have a preferential right to a concession.

Art 17. Assignment of a mining concession may be only to persons or companies who, according to the provisions of this law, have the power to obtain the same from the Nation. Assignments will only be effective against the Department or third persons, from the date they are recorded in the Public Mining Registry.

Art 20. Prospecting (Cateo), concessions, area: I. Claims must consist of 9 pertenencias included in a square of 300 by 300 meters, with positions fixed astronomically from N to S and from E to W. The starting point of the survey shall be in the center of the square, but such portions as invade titled or pending claims, and any fractions not contiguous to the one containing the starting point, shall be deducted from said square. II. Concessionaires may dispose of ore obtained from working the above mentioned concessions and erect mills for the treatment of such ore. III. They shall be granted for 2 years. IV. The beneficiaries shall have the exclusive right to petition for exploitation concessions, to replace the prospecting concessions in whole or in part, provided said petitions are filed while the latter are free. If a concession which has been requested is pending when the above term expires, the prospecting concession, with its rights and obligations, shall be extended until the new concession is issued or a final decision is reached.

Art 21. Location of the prospecting concession on the land shall be limited to fixing the starting point and to the erection of the corresponding identifying monuments. The prospector will not be required to erect boundary monuments.

Art 22. Mining agents shall grant to the applicant, prior to the issuance of the respective title, permits to do mining work and to dispose of the products so obtained, subject to the approval of the Department.

Art 24. No person or company can be the owner at one time of more than one prospecting concession.

Art 25. Exploitation concessions shall only be granted for the purpose of exploiting one of the following: (1) metallic minerals; (2) non-metallic minerals; (3) coal and graphite. They shall be granted for an unlimited period and their surface area shall not exceed 100 pertenencias, except in the case of coal, when their surface area may be 1 000 pertenencias. This Article also provides that the concessionaire must prove annually the regular work required by Article 27 of the Federal Constitution and shall pay an annual surface tax.

Art 27. Rights of a concessionaire. The concessionaire may during the life of his exploitation concession construct within or without the area of his concession means of transportation, storage stations, aqueducts and pipe lines, pumping plants, power transmission lines for his exclusive use, metallurgical and treatment plants and all other installations necessary for the purposes of the concession. All the foregoing shall be subject to the provisions of the Regulations of this Law.

Art 28–30 provide that proof of regular work must be made annually.

Art 33. Forfeiture of concessions. Exploitation concessions shall be forfeited in certain cases.

Art 34, 35, 36 provide for concessions for mills, the character of the concession for Public Service or private service and method of application therefor.

Art 37, 38, 39 deal with rights and duties of the mill concessionaires in treatment of ores delivered by the public and the rates therefor.

Art 40, 41 provide that a concession for a mill shall be forfeited in certain cases.

Art 42. Right of expropriation. A concessionaire under this law has the right to expropriate, after proper indemnification, such land as is absolutely essential, in the opinion of the Department, for offices, installations and other fixtures necessary to operate the concession, for dumps, tailing deposits, waste, etc, and to utilise mine and other waters.

Art 43. If the concessionaire is a foreigner, the expropriation requested by him will not be considered unless he can prove that he has complied with the provisions of Article 27 of the Federal Constitution and its Regulatory laws.

Art 44–51 deal with rights and duties of the concessionaire and his limitations in expropriation, and the rights of the landowner.

Art 52–73 refer to procedure for obtaining a concession from the Mining Agency and the Department, with reference to applications therefor, and in application for a concession to erect a mill and oppositions thereto.

Art 74, 75 provide for filing Articles of incorporation, concessions, lease or other contracts, relating to the concession, with the Public Mining Register. Only documents and contracts which affect mining concessions will be recorded in the Register.

Art 80. Documents originating in a foreign country, and which in accordance with the laws of Mexico should be in form of a public document, must be protocolised within the Republic before being recorded.

Miscellaneous provisions. Chapter XII includes Articles 98–125. The pertinent provisions are: mining enterprises, contracts for the purpose of prospecting, exploiting or transferring a mining concession or disposing of ores derived therefrom are considered mercantile acts and therefore subject to provisions of the Commercial Code when not otherwise provided for by this Law. The beneficiaries of exploitation and mill concessions must submit annual reports to the Department,

setting forth the details of operation, nature of work executed and quantity of ore extracted. Reports must be accompanied by plans of the projected horizontal and vertical workings.

Concessionaires must permit students of the Mining Schools in the country to study and to acquire practice in the mines and plants operated by them, and provide said students with facilities and data for their advancement.

The concessionaire must keep a duly authorised representative or agent in the Republic of Mexico, with full power to receive and execute all instructions issued by the Department and decide any questions which may arise. Concessions granted in accordance with the Mining Law of May 3, 1926, or prior laws may be changed for exploitation concessions authorised by this Law, and thereby become subject to all rights and obligations established by the latter. Guarantee deposits made in accordance with the Mining Law of 1926 shall be returned to the beneficiaries upon the issuance of the new title, provided they prove due compliance with all obligations inherent in the former concession.

Art 130–137. Commission to promote mining. This among other purposes has for its object the following: to establish public mineral exchanges for buying and selling ore, to establish supply warehouses for miners, install local and regional metallurgical plants to treat ore from the public or the Commission, buy and sell concentrates, and give financial and technical aid to mining cooperative societies. The Commission shall also be charged with the exploration and exploitation of National Reserve zones, and supervision of mining operations carried out by concerns with which the State may enter into contracts for such exploitation.

Regulations of the mining law, enacted Sept 24, 1930, comprise 162 Articles, outlining the procedure to be followed in making application for mining and mill concessions, and also the procedure for effecting expropriations and registering documents in the Public Mining Register. MINING POLICE AND SAFETY REGULATIONS were enacted Oct 17, 1912.

46. MINING TAX LAW

A Mining Tax Law was enacted Aug 31, 1934, imposing taxes on mining properties, on the production of metals and metal compounds, and the production of non-metallic minerals. Charges dependent upon the monthly fluctuation in the price of ore *in New York*, are also imposed on the following: Sampling, assaying, smelting, minting and inspection. Taxes are also imposed on mining concessions based on the area, and on non-metallic mineral concessions. There is likewise an export tax of 12% on all exports of minerals. Most of the cooperative mining societies have been exempted from payment of this tax by a special Presidential decree.

SECTION 25

MINE EXAMINATIONS, VALUATIONS AND REPORTS

BY

WILLIAM YOUNG WESTERVELT

CONSULTING MINING ENGINEER

Note.—Numbers in parentheses refer to Bibliography at end of this section.

MINE EXAMINATIONS, VALUATIONS AND REPORTS

1. GENERAL CONSIDERATIONS

Object of an examination is to form the engineer's judgment; that of a report is to set forth this judgment in such form and detail as will be most intelligible and legitimately useful to the client.

Diversity of temperament and circumstance of engineers and clients, coupled with that of the character, location, size, value, and state of development of properties, occasions great differences in method and scope of both examinations and reports. Examinations of developed mines that have been worked for considerable periods tend to become standardised in proportion to growth of standard conceptions of operating principles and practice. But, an examination even of such a property, while giving due weight to all data obtainable, must be treated as an original problem if the client's needs are to be met.

Standardization of method is sought and practiced by examining engineers whenever feasible, but no method capable of general application is likely to be developed.

Since the value of a mine is its resources for producing future profits, that value is no more susceptible of accurate determination than any other expectancy, even in the ideal case of an absolutely developed mine. Fluctuation in market value of any product may change a profit into a loss or the reverse; and it is seldom, if ever, determinable whether or not further discoveries, laterally or in depth, will resuscitate an apparently exhausted deposit, or whether improvements in treatment, transport facilities, or labor conditions, will render profitable a seemingly valueless mine. The engineer must bear in mind these uncertainties, use his best judgment to determine their probable combined effect and, though it is clear that he should bring his conclusions to as definite a "yes" or "no" as is possible, the uncertainties in the bases of these conclusions should be so expressed in the report as will indicate to the client the degree of importance they occupied in the engineer's judgment.

In this section an attempt is made to set forth generally recognized principles and practice, to describe methods found useful under certain conditions, and to cite illustrations which may help practitioners to meet the problems confronting them.

Theory of procedure in an examination is to secure, carefully weigh, and assign to its proper place in the engineer's judgment, all obtainable information bearing on the enterprise requisite to make the property profitable, or which will tend to prove that profitable operation is impossible under attainable conditions. In examination work, practice departs from theory so far as to eliminate investigation which the engineer judges unlikely to yield a gain to his client proportionate to the outlay of time and money involved.

Conservatism, though as essential to sound judgment in mining as to any other undertaking, should not be made an excuse for timidity or indifference. To attain the closest approximation to fact (not the largest possible discount of favorable data) is the engineer's obligation and the client's due, and is necessary to progress. An exact forecast being impossible, and error on the side of conservatism being usually less disastrous to the client than a mistaken optimism, the inevitable error should be kept on the conservative side. Proper margins of safety are essential, but a serious underestimate of value is as great an error as an overestimate; it may be as disastrous to the client, and it is but little less blameworthy, though it usually involves less conspicuous censure. As close an approach as possible to the property's true value must be made, and the engineer must do this fearlessly, without concealing either favorable or unfavorable aspects.

Relation and responsibility of engineer to client are similar to those of the lawyer. No honorable means of serving the client's interest should be neglected, and every effort should be made so to present data that their meaning to the client shall be that which the engineer's judgment indicates as most nearly correct. Though the engineer is justified in charging such fee as he believes the examination to be worth to his client, or in contracting to do the work for less if he believes this to be to his own interest, it is improper and ultimately unprofitable to regulate the extent and thoroughness of the examination (or the care in preparing the report) according to the amount of the fee. Within the scope of the examination (which should be thoroughly understood and preferably embodied in a letter or other writing before the work is undertaken), the client has a right to expect that the engineer will give the best of which he is capable.

Client is the individual, individuals, or organization, by whom the engineer is employed and to whom he is responsible, makes his report, and looks for his fee.

In dealing with organizations, the engineer has both a right and an obligation to assume that the legally authorized officers who employ him properly represent their organization and will use his services solely for its advantage. But it is obviously the duty of the engineer, and to the ultimate advantage of his reputation, that he should sufficiently acquaint himself with the character and conduct of these officials to be assured that his services are not being used to the detriment of his true client, the organization as a whole.

Engineer is the individual or individuals responsible for the examination and report. ASSISTANTS are here included to the extent of their responsibility for either function.

2. LOCATION, GEOLOGY, MAPS, EQUIPMENT, ACCOUNTS, AND REPORTS

Location. Distance from sources of SUPPLIES and from the MARKET for the output, also cost per unit, safety and reliability of existing means of TRANSPORT, should be ascertained. If transport improvements are essential or desirable, data concerning means, costs, and advantages should be secured.

Mines producing much high-grade ore have been successful in unfavorable locations and with primitive means of transport, as, for example, the backs of men; but hard-rock, low-grade properties (the output of which has a gross value of say $5 per ton of crude ore) are workable only when on rail or water transport lines. Difficulty of access to the property from the FINANCIAL CENTER furnishing development capital may retard development of small or low-grade deposits. Location with respect to supply of LABOR, WATER, and FUEL, or of HYDRO-ELECTRIC POWER, is of prime importance; if these are lacking, the cost of supplying them should be estimated, and an adequate amount added to capital required. CLIMATE and its effect on operation of the property should be noted. Nature of the GOVERNMENT of the country in which the property is located is important, if there is question as to its stability or ability and inclination to give proper protection to industry. Tendency to levy excessive taxation, to pass restrictive laws, or to obstruct operation of the property by permitting illegitimate interference should be considered.

Local geology is studied for the light it may throw upon the probability of presence or absence of economic quantities and values of the minerals sought, upon the relation of exposed values to quantity of assured mineral (Art 11), upon the probable persistence laterally and in depth of values and characteristics already revealed, and upon the best methods of exploitation. See Table 1.

Strikes, dips, pitches, pinches, stratifications, and other rock characteristics, faults, horses, and primary or secondary enrichments of possible influence (Sec 2), should be considered in deciding upon the amount of ore proved by existing or likely to be proved by proposed development. These data, particularly when scanty, should be supplemented by similar information regarding neighboring properties or districts; especially those having the same values, or those of similar character with different values. Government or private geological maps and reports of the property and district, or of neighboring properties or districts, should be investigated for such information. U S Geol Surv folios, which include topographical and geological maps, geological sections, and descriptive matter, are valuable. They may be had by writing the Survey office, Washington, D C, ordering by number as in Table 1, and enclosing price in currency or P O order, payable to Director of the Survey. Maps and folios by the geological surveys of the respective states are frequently available at state capitals or universities.

Original geologizing, including geophysical surveying, should be undertaken so far as is likely to throw light on the value of the property with expenditure of available time and money. For details of geophysical methods see Sec 10 A. It should include a thorough examination of surface and underground exposures, and study of existing drilling records or cores (Sec 9). Character and position of wall rocks, and of the deposits themselves, should be considered as to their influence in determining the best method of exploitation.

Examples. Method and cost of working flat-lying seams, as many coals, clays, and phosphate beds, may be influenced by the strength and permeability of roof and floor. Depth, character, and relation to topography of the overburden of flat-lying secondary enrichments, as the copper porphyries, determine the utility of the caving system of mining, or of the removal of overburden and open-cut work (Sec 10). The workability of a placer deposit by dredging, hydraulicking, ground sluicing, or drift mining, is determined almost as much by the character, condition, and slope of bedrock, occurrence, disposition and size of boulders, and depth and character of overburden as by the engineering features of quantity and head of water and débris disposal (Sec 10).

Maps of mine, property, and general topography, both private and government, should all be investigated and their reliability determined (as far as concerns data of

interest) by comparison with each other and with the reality. They are studied for information as to dimensions and positions of boundary lines, existing or possible transportation, drainage, topography, outcrops, underground exposures, and drilling developments.

Whenever practicable, copies should be made of all maps of interest. If the original are on linen, silver negatives are recommended as furnishing a record from which copies can be cheaply made when desired; new titles drafted on small pieces of linen, and black bordered to conceal the linen edge, may be added in the printing frame in making these negatives. Otherwise, tracings or photographic negatives should be made, which, though more expensive, are readily reproduced. If insufficient or lacking, maps should be supplemented by original sketches, or made from original surveys to the extent justified by the circumstances (Sec 17, 18, 19). U S Geol Surv topographical maps

an advanced price, those of their district.

Mine equipment should be examined as to its future utility, and whether its alteration, enlargment or replacement would improve operating conditions. Except in cases of obvious inutility, a complete INVENTORY is desirable.

If much of the property value is in equipment, if property is to be acquired on purchase or lease, or if the engineer assumes responsibility for subsequent operations, a fairly complete inventory is essential. It should state the condition as well as items of all realty, machinery and its foundations, grading, costs of erection, tools, supplies, and general merchandise. Items of plant having value if moved should be distinguished from those which are valueless except in place (as grading, foundations, and erection costs), the two classes being designated as MOVABLE and FIXED PLANT. Amount and value of securities held, cash and balance of good accounts receivable and payable, should be ascertained. Character and cost of improvements and additions necessary for further operation should be noted with such detail as accords with the engineer's responsibility in the matter, respecting machinery required for mine, mill, smelter or transportation system, and general equipment, including offices, laboratories, houses for management, staff, foremen and general labor and commissary, also water supply and sanitation (Sec 22, 23).

Operating methods in use should be studied to determine whether advantages could be gained by modification or entire change. If so, an estimate, in such detail as is justified by circumstances, should be made of cost of change and of probable saving to be effected.

Accounts and reports; operative and special. All available periodic reports of enterprises that have been based on the property should be examined for the light they may throw upon total and average outputs and values, equipment and operating costs, profits and losses, capital employed and authorized, expenditures and resources, the skill shown and the difficulties encountered in operating with the equipment used.

These reports may range from daily to annual, and include records of development, production, assays, financial transactions and conditions, costs, and profit and loss. Those of sufficient importance to justify it under the scope of the examination, are best studied by tabular compilation (below). By this method periodic summations, averages and rates per ton, oz, lb, ft, or other unit, can be made as desired, and checks secured against the ledger accounts, which in turn can be checked against the bank accounts. Reports by superintendents, managers, consulting engineers or directors, should also be checked against the results of these compilations. Much important information of determinable reliability can sometimes be thus secured, together with important suggestions as to points requiring investigation. Data of neighboring or similar properties are sometimes available and can also be profitably studied. If the examination and records are of sufficient importance, and the ledger accounts are numerous and detailed (Sec 20, 21), the services of an expert accountant may be advisable.

Terms of acquisition. The engineer should assure himself whether he is to be responsible for the effect the terms may have on the success of the enterprise. If so, he should familiarise himself with these terms; if not (and the nature of the case fails to make this obvious) he should bring out the fact in the report in an inoffensive manner.

3. TITLES, LEGAL ASSISTANCE, AND FORMS

Titles. A mining engineer may not be well qualified to pass upon questions of title, but tenure and ownership are of such vital importance that he should inform himself thereon as fully as possible. Terms of tenure, such as operating concession, working bond or lease, or ownership in fee simple, and the chain of title on which the tenure is based, should be thoroughly understood, unless the client prefers to take all responsibility, or has specifically limited the scope of the examination so as to eliminate these questions. In the latter cases the report should definitely but inoffensively state the situation. Otherwise the engineer should investigate along the above lines until he can make definite statements.

To illustrate, the engineer may have occasion to make one of the following statements in his report: A. In view of the client's assurances, all questions of title have been ignored; or the titles have been assumed to be perfect. B. The titles have been examined, or the engineer has had them examined by competent attorneys (whose names should be given), and found perfect; or certain defects, (which should be specified) have been found. C. In case of defects which attorneys and engineer agree are remediable, recommendation should be made as to incurring further expenditure on the property, or stopping it pending perfection of title. In case of irremediable defects, a joint opinion should be given as to whether the chances of gain are enough greater than chances of loss to justify proceeding regardless of these defects.

Legal assistance (preferably that versed in local laws and practice when of sufficient caliber and reliability) should be secured not only on questions of title, but in making any important agreement, as a deed, working bond, or escrow agreement. In absence of legal advice, following forms (2) may be used:

Deed

This Indenture, Made the .... day of ...... A.D., 19.., between ...., the part... of the first part, and ...., the part ... of the second part;

Witnesseth: That the said part ... of the first part, for and in consideration of the sum of...... ...... dollars, lawful money of the United States of America, to .... in hand paid by the said part ... of the second part, the receipt whereof is hereby acknowledged, ha... granted, sold, and forever quitclaimed, and by these presents do .. grant, sell and forever quitclaim, unto the said part ... of the second part, and to .... heirs and assigns, all the following described real estate, situate in .... mining district, county of .... State of ...., to wit: (Here follows description)...... Together with all and singular the mines, minerals, lodes and veins within the lines of said claims and their dips and spurs, and all dumps, plant, fixtures, improvements, rights, privileges, and appurtenances thereunto in anywise belonging. To have and to hold the lands, tenements, and hereditaments hereby conveyed unto the said part ... of the second part .... heirs and assigns forever.

In Witness Whereof, the said part ... of the first part ha.. hereunto set .... hand .... and seal ...... the day and year first above written.

Signed, Sealed and Delivered
in the Presence of .... Seal

....

.... Seal

(To be signed, witnessed, sealed, and acknowledged before a Notary or other proper commissioner, to meet the requirements of the State or County in which the property is situated. Provisions for recording should also be observed.)

Mining Lease

This Indenture, Made this .... day of .... A.D., 19.., *between*................., of......................, lessor, and................., of................ , lessee;

Witnesseth: That the said lessor, for and in consideration of the royalties hereinafter reserved, and the covenants and agreements hereinafter expressed, and by the said lessee to be kept and performed, ha.... granted, demised and let, and by these presents do . grant, demise and let, unto the said lessee, all the following described mine and mining property, situated in .... mining district, county of ...., State of ...., to wit: (Here follows description) .... Together with the appurtenances to have and to hold unto the said lessee for the term of .... from the date hereof, expiring at noon on the .... day of ...., 19.., unless sooner forfeited or determined through the violation of any covenant hereinafter against the said tenant .... reserved.

And in consideration of the said demise the said lessee does covenant and agree with said lessor as follows: to wit: To enter upon said mine or premises, and work the same in the manner necessary to good and economical mining, so as to take out the greatest amount of ore possible, with due regard to the development and preservation of the said premises as a workable mine, and to the special covenants hereinafter reserved. (Here insert Special Conditions and Agreements of Lease, Work to be done, etc.)

In Witness Whereof, etc. (See deed, except that usually the lessor will require the signature of the lessee, with corresponding alteration of form.)

Working Bond

(A lease and option, also known as a working bond, is a common and preferable form of purchase. At end of the mining lease above outlined, and preceding the final paragraph, proceed as follows:)

And in consideration of the foregoing lease and the expenditures to be made thereunder and the well and faithful keeping of the covenants thereof, the said lessee shall have the right to purchase the said premises, together with all improvements, etc, for the sum of .... dollars ($............), to be distributed in the following payments: On or before the .... day of ...., 19.., the sum of .... to be paid (designate manner and place of payment), and on or before the .... day of .. .., 19.., the sum of .... (Here insert further conditions of payment.)

Time being of the essence of this contract as to such payments, and upon the tender of such payments, the lessor will execute, acknowledge and deliver at his own cost, good and sufficient deeds to the lessee, or such person or company as the lessee shall nominate, conveying the said premises clear of incumbrance. (Deeds to the property are generally placed in escrow with some bank or responsible party, to whom payments are made when due under the agreement, and who delivers the deeds when payments are completed.)

The forefeiture, surrender, or termination of the above lease for any cause shall render the option void, and the above mentioned payments may not thereafter be tendered.

It is expressly agreed and understood that this Agreement shall be considered as an option to purchase only, and not as obligating the said lessee to purchase said property.

In Witness Whereof, etc. (See close of Mining Lease.)

Notice of Right to Water

The undersigned claims the water running in this............stream to the extent of.......... inches for mining purposes to be conveyed by (ditch or flume) from this point to the.............. placer claim.

Dated............, 19... ....

Locator

(This notice to be posted near the stream outlet, and the following form duly recorded in the district or county recorder's office.)

Pre-emption of Right of Way for Ditch and Location of Water

To whom these presents may concern, know ye, that I,............, of the county of.........., in the State............, a citizen of the United States, do hereby declare and publish as a legal notice to all the world, that I claim, and have a valid right to the occupation, possession and enjoyment of all and singular, that tract or parcel of land lying and being in the county of.......... in the State of.............., for the exclusive right of way for the purpose of constructing a flume or water ditch from................stream to.................placer claim, more particularly described as follows: Commencing (here describe the exact route for ditch or flume).

I also claim, and have a valid right to the enjoyment and use of............inches of water from said stream for mining purposes, to be conveyed through such flume or water ditch to said claim, together with all and singular, the hereditaments and appurtenances thereunto belonging, or in anywise appertaining.

Witness my hand and seal this............day of.........., A.D., 19..

(Name)

....

Notice posted on the stream.........., 19...

Ditch commenced at claim or at stream.........., 19...

............of..........County of.............., ss.

On this,....... day of ...., 19.., before me, a .... in and for the county aforesaid, in the state aforesaid, personally appeared........................, to me personally known to be the person who executed the foregoing written instrument, and acknowledged that he executed the same for the uses and purposes therein set forth

Witness my hand and official seal

....

Escrow Agreement

The enclosed deed of the .... lode is hereby placed in the .... Bank of ....in escrow. If A.B. shall place, or cause to be placed to the credit of C.D. and E.F., in said............Bank of......................, or on before.............., 19..,

the full sum of................dollars, then and in that case the said Bank is hereby authorised to deliver the enclosed deed to A.B., or his order. In case the said A.B. shall fail to deposit the said sum of..............dollars, as above provided.................., then the said Bank is hereby authorised to deliver the enclosed deed to the said C.D. and E.F. or their joint order.

(Signed) C.D.
E.F.
.................., 19... (Place and date) A.B.

(When the option for purchase of a mine is desired by a third party, it is safest and best for the owner to put a deed in escrow. It saves incumbering the record, and averts questions that might arise concerning payment of money. The deed should be a warranty, quitclaim, or mining deed, as agreed, fully executed and acknowledged, ready for delivery, put in a sealed envelope and placed in a bank, or left with a responsible person, with an agreement written upon the envelope, as above.)

For information as to location notices and patent proceedings, see Sec 24.

4. THEORY OF SAMPLING; METHODS OF CRUSHING, CONING, AND QUARTERING

Sampling is the process of securing more or less representative samples of ore for the purpose of gaining information as to the composition of the whole by investigation of the part (see also Sec 29, "Definition"). It is necessary unless the conditions are such that more reliable information can be gained from records of operation. The process is essentially one of approximation: only by special care can the heterogeneous masses with which the mining engineer usually has to deal be made to yield samples more than roughly representative. These should approach the truth as closely as practicable, and when used with full knowledge of their limitations may be valuable. But, if the number of points from which equal and sufficiently large parts of the sample are taken is great enough in proportion to the irregularity in composition, and if these points are uniformly distributed, it is possible to draw a sample as exactly representative of the average composition of the mass as may be desired. The greatest difficulty in securing accurate samples is due to the inaccessibility of most of the interior of the mass. Dumps, or superficial deposits easily penetrated, can usually be sampled by sinking drill holes or pits. In case of mineral masses in place, especially those exploited by underground workings, sampling is generally limited to EXISTING EXPOSURES. These are made in the ordinary course of mining, and not to furnish uniformly distributed and convenient points for taking samples.

Sampling is thus usually reduced to securing as accurate samples of the different exposures as circumstances admit and justify. The average contents of the deposit are then determined by calculation of combinations made according to judgment, after studying the geology, and the relative position and size of the exposures (Art 10). Methods of sampling vary in detail according to size, character, accessibility and general condition of the deposit, the degree of accuracy required and the means available.

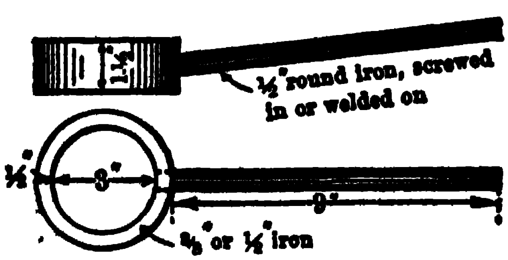

Fig 1. Ring for Crushing Samples

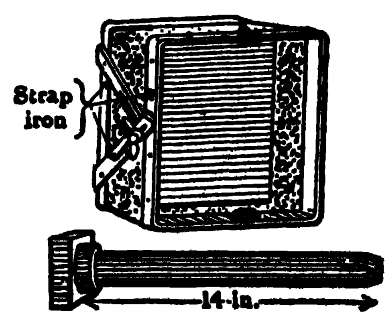

Fig 2. Coal-sampling Mortar and Pestle

Crushing the sample. Unless a mass is composed entirely of relatively fine particles, or is practically homogeneous, one of the most important features of sampling is crushing. It is a laborious process, and power crushers should be employed when feasible (Sec 28, 29). But much of the crushing necessary in mine sampling must be done on the spot, where power crushers are not available. Therefore, the miner's hammer and an anvil consisting of an old stamp head, large sledge, or piece of hard, barren rock, are usually employed. Iron rings with handles (6) (Fig 1) are useful to hold the piece on the anvil, so that few chips fly and the fingers are not exposed.

Hand-hammer crushing should be done on a sampling sheet or quartering floor, to prevent loss of material or introduction of foreign matter. An iron mortar, with pestle operated through a hole in a canvas cover, to prevent loss by flying chips, is good. Soft materials like coal may be crushed in a light mortar, with iron-covered wood bottom and collapsible canvas sides (7) (Fig 2).

In working down a sample, the largest piece must always be so small in proportion to the total volume that its retention or rejection will have little effect on the result, even though such piece contain the maximum amount of impurity or value possible in the circumstances. Crushing to a maximum size of piece weighing 0.001 of the mass to be quartered (as a 1-oz piece in a 62.5 lb lot) is usually satisfactory. The extreme case of a 1-oz piece of chalcocite (containing say 75% Cu) would raise or lower the sample assay by 0.15% Cu, if it occurred in the last quartering, while compensating errors in the whole series of quarterings would probably reduce this error considerably. If care is taken that very rich or impure pieces are crushed comparatively fine, and thoroughly mixed throughout the mass during the work, accurate results can be secured by quartering masses containing ordinary pieces several times the above size limit; and when it is known that no pieces of erratic value are present, the maximum size may be considerably increased. But, unless the work is in well-trained hands, fine crushing before reduction is preferable when erratic values are present. Under prescribed conditions proper crushing can be insured by using a screen as is done by the U S Bureau of Mines, which provides a $^3/_8$-in mesh screen with its coal-mine sampling outfit. But trained observation can determine and regulate the suitable size with sufficient accuracy (see also Sec 31).

Coning and quartering (see also Sec 29, Art 3). The crushed mass is worked into a cone by shoveling all the material to one point on the quartering floor, in such manner that the particles roll down in all directions from the central point. Irregularities in composition of the mass are thus distributed as concentric layers of a cone. The top of the cone is then flattened with the edge of the shovel, by spreading the material equally in all directions until a disk is formed, thickness of which is about 0.1 the diam. This disk is marked into quadrants, and the diagonally opposite quarters are cut out, care being taken that all material in the rejected quadrants is removed, but no other. The mass now contains half the original quantity and, after reducing the large pieces proportionally, coning and quartering are repeated, thus securing one-quarter of the original. The cycle of crushing, coning, and quartering, is repeated until the sample is of the desired size. With sufficient care that the cones are made up of layers of each shovelful, evenly distributed about a fixed center, and that the cones are flattened by being worked out evenly from the center in all directions (coning about a fixed vertical rod (12) insures accuracy in these respects), results of any desired accuracy are obtained, provided sufficient crushing is done either before or during the process.

Unless the sample is corrosive, the best quartering floor is a piece of boiler plate, large enough to hold the disk of material prepared for the first quartering. When available, the turn-plates at shaft landings make good quartering floors. A well-laid floor, preferably of hard wood, is the next best. When neither is available, a platform may be made by laying boards as solidly and evenly as possible on the ground and covering them with a sampling sheet. Cloth covering is harder to keep free from residual fines than a plate or wood floor, but thorough brushing with a whisk, or scrub brush, usually suffices, and the cloth yields better results than when working on a floor containing cracks in which fines can lodge and be lost or inopportunely reappear. The whole process, including preparation, is often referred to as quartering.

Rolling. When using a sheet in reducing lots of 100 lb or less, time is saved by rolling instead of coning. It consists of mixing the mass by drawing one corner of the sheet forward towards the diagonally opposite corner, until the material has been rolled over and over on itself to the limit of the capacity of the sheet. The first corner being laid back in place and the diagonally opposite corner pulled over the sample, the process is reversed, and so back and forth. The material then being left in a long mass across the center of the sheet, rolling is done at right angles to it, by working with the other diagonally opposite corners of the sheet.

Two cycles, of two rolls each back and forth with each set of corners, give good mixing and leave sample ready for final rolling into the center by all four corners preparatory to quartering. Mixing may be imperfect unless the folded-over corner of the sheet is held horizontally as it is pulled forward; otherwise the material may slide on the sheet instead of being rolled over on itself. Also, if the mass is wet and sticky it will adhere to the sheet and the mixing will be imperfect.

5. SPLITTING, DECIMATING, TRENCH, PIT, DRILL, SMALL-PARCEL, DUMP, AND LARGE-SCALE SAMPLING

Splitting is the reduction of a mass by some type of splitter, or series of parallel troughs which alternately retain and reject a series of equally broad sections from a stream of crushed material poured over them (Sec 30, Art 3).

For this the Jones sampler (9) is recommended, as giving results equal to the best quartering. In using it, care should be taken to insure the usual proportion between the size of the largest piece and that of the mass about to be split (Art 4); to maintain a steady, full-width flow from the shovel; to see that the entire lot is put through and that the apparatus is kept clean. The form shown in Fig 1, Sec 30, is best, as it is readily cleaned with an ordinary brush. Splitting should not be used on wet,

sticky samples. Quartering in such case is less objectionable than other methods of reduction, but, unless unavoidable, reduction of wet, sticky samples should not be attempted by any process.

Decimating. A mass in process of shipment or other movement is most conveniently sampled by decimating; that is, by selecting for the sample every tenth car, barrow load, shovelful, or other unit of handling.

For accuracy, the number of units taken for sample must be large in proportion to irregularity in composition of the mass, and if the units of handling are large compared with the whole, every 5th, 3rd, or even 2nd unit may be required for the sample. With fairly uniform materials, such as the product of a good coal seam, 10 units in a sample give results accurate enough for most purposes. Ores of not very high grade and free from large masses of rich material may be satisfactorily sampled by taking 100 units in sample. Very rich, spotty ores may require 1 000 units, and it is difficult to secure a good sample from them without carefully working down the entire mass. Unless already fine enough, the whole sample secured by decimation is crushed and reduced by further decimation, quartering, splitting, or by use of a MECHANICAL SAMPLING equipment (Sec 29).

Trench sampling consists in cutting a series of trenches in a dump or superficial deposit, and decimating or otherwise reducing the product, or interval-sampling the sides of the trenches. The samples will be satisfactory if all classes of material composing the mass are cut in their true proportions.

Pit sampling. A number of pits or vertical shafts of small section are sunk in a manner similar to trench sampling. In dumps and superficial deposits, where large pieces usually accumulate at the bottom, variations in composition are more marked with depth than with horizontal extent. A good sample can therefore be secured if a sufficient number of pits are so regularly distributed as to cut uniformly across this greatest variation.

Pits in dump material must be supported by timbering, or other means, for retaining the vertical walls necessary to secure a uniform yield from top to bottom. In stiff clay, and with short-handled tools, 36-in diam round shafts can be sunk 100 ft or more without any support. Small elliptical shafts (13) only 28 in on largest diam, have been sunk in dumps to depth of 50 ft, lining with corrugated iron sheets, driven as poling, and supported on $^3/_8$ by 1.5-in elliptical iron rings, spaced by $^3/_8$-in round iron hooks.

Drill sampling. Though a single pit yields better samples than a single drill hole, where drill sampling is practicable it is preferable because, at same cost, many more points can be tested by drilling than by sinking pits. This is especially true in sampling flat deposits beneath rock overburdens, as many coal seams, secondary enrichment "porphyry" copper deposits of western U S, flat-lying lead deposits of S E Missouri, and zinc deposits of Oklahoma or Wisconsin. Drill holes should be located with the same regularity as pits, close enough together to average the irregularities of the deposit and the drilling must be done with care (Sec 9, 10).

Small-parcel sampling. Lots of a few tons or less can be sampled by quartering, splitting, decimating, or mechanically at a sampling works (Sec 29). With care any of these methods will give accurate results; though decimating, the cheapest and commonest method, is essentially the least accurate unless it is modified by taking every alternate shovelful. The value may be fairly approximated by careful grab sampling, particularly if the lot is first well spread out (Art 4, 5).

Dumps containing more than a few tons may be sampled as above when their value and irregularity justify it. Decimation of rich dumps by shoveling is quite usual. If the contents are not exceptionally irregular, dumps may be sampled with sufficient accuracy by trench, pit, or drill; the latter, however, only when there are not enough large pieces to interfere with hand drilling, or when the dumps are large enough to justify installation of power drill.

Large-scale samples of many tons, or even thousands of tons, may be taken to determine the value of erratic ores; especially those containing metallics, as native gold, silver or copper, or very rich minerals, the average occurrence of which can be determined only by handling large amounts. Large samples are also taken to determine amenability to treatment by mill or smelter tests.

Difficulty of maintaining efficient surveillance in taking and handling large samples so reduces their usefulness that they are taken only where other methods fail, as in the Lake Superior native-copper deposits, or where full-scale treatment is desirable. Such samples are usually secured by mining from the entire exposure a sufficient, uniform thickness to furnish the desired amount. If this would give too great a bulk, miniature stopes may be made, of fixed size, and at regular intervals; or the tonnage may be further reduced by making blasts at regular intervals, and taking equal quantities from the average of each blast. Judgment and care must be exercised in this work, and rules are of little service.

6. INTERVAL-CHANNEL, CHIP, AND GRAB SAMPLING

Interval-channel sampling is done by cutting channels at regular intervals along the length of the exposure. To secure an accurate average, the intervals must be small enough, relative to the irregularity in composition and value of the exposure, to insure proper representation in the sample of any considerable irregularity. The amount from each cutting must be sufficient to counteract the effect of erratic occurrence of rich spots. Thus, the metallics of the Lake Superior copper deposits require mill-runs instead of assays. Usually a few lb or even less per ft of channel will suffice. Channels cut in a flat surface for combination into one sample must be equidistant, of equal length (or of full width of the exposure), and of uniform depth and width, to yield a constant quantity per linear ft of channel.

To sample a curved or oblique surface, which for calculation must be considered as flat and normal either to the dip or to the vertical, the channel lengths are assumed to be on the projection of the curved surface upon such normal flat surface, and the depth and width of channel must be decreased to yield the uniform quantity per ft of projection, instead of per ft of actual length of channel. Thus, the curved back of a drift in a banded gold vein, sufficiently rich and well-developed to warrant such detail calculation, should be measured and sampled in the regular way only between *B* and *C* (Fig 3). *AB* and *CD* are measured on their projections *AB′* and *C′D*, and the size of the channel reduced so as to furnish the regular yield per ft of projected distance (5). It is generally undesirable to make these adjustments in the field. Separate samples are usually taken from each channel, and if great diversity in composition occurs, or adjustment for curvature is necessary, from each fraction of channel requiring such adjustment. Adjustments are made on basis of measurements taken at time of sampling. Channels in well-banded masses should cut across the banding. Otherwise the direction of individual channels may bear any relation, from normal to parallel, to that of the line of interval measurement, provided they do not so converge as to emphasize or neglect any particular sampling area.

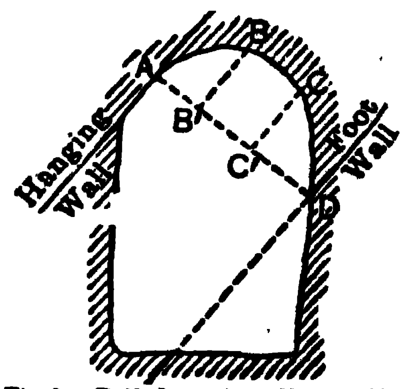

Fig 3. Drift Sampling; Narrow Vein

Mode of cutting. In soft, comparatively uniform material, as coal or clay, channels are readily cut with a prospector's or a miner's pick. In hard ore, picks are almost useless, and in mixtures of hard and soft it is almost impossible to pick down proper proportions of each. Hence, in all but uniformly soft materials, the channel should be cut with moil and hammer, either single or double-hand according to hardness of the ground.

1, 2, or 3 men may thus be required, depending on whether a single-hand hammerman holding his own moil works on a sample sheet, or a sample box has to be held, or a double-hand hammer is used besides holding moil and box. A small pneumatic drill and moil steel may be used if compressed air is available. In any event, there should be an ample number of hands and eyes, to insure careful, watchful work. Moils are usually of 0.75-in octagonal steel, forged to a diamond point on a taper about 2 diam long. The point for about 0.5 in from tip is at a larger angle, to increase its strength. Moils vary from 6 to 18 in long; most of them, 10 to 12 in. For hard ground, at least a dozen should be kept ready, to avoid delay caused by using dull points. Hammers are double or single-hand, of weight suited to the strength of the hammerman. They vary from 3 lb for single, to 7 lb for double-hand work and should be as heavy as can easily be swung by the sampler on all-day work, but, if too heavy, the worker suffers unnecessary fatigue.

Precautions. After determining where the channel is to be cut, care should be taken that the ore surface at this place is free from dust, foreign matter, and any efflorescence or decomposition, which may change the character of the minerals since first exposed.

Dirt or dust can usually be removed by brushing with a whisk or wire brush, or washing with water, but efflorescence and other altered matter must be chipped off down to a solid surface. In firm ground, where there is little danger of jarring off loose pieces outside the channel, the sample may be caught on a canvas sampling sheet, say 6 ft square, or large enough when spread on the floor under the channel to catch all material cut, including flying chips. When using a sheet, extraneous matter may drop on it without the engineer's knowledge, and enter the sample. Hence, cuttings are often caught in a dynamite or candle box, in a gold or a round-cornered rectangular bread pan, in a canvas bucket with round bottom, or a sack the mouth of which is kept open by being bound on a wire ring. Chips are then prevented from flying by the sample catcher placing his gloved hand over the point being cut. Objections to this method are the possibility of spill from the cutting point down past the receptacle, and the added attention required. Since a sample sheet will serve to prevent contamination or loss while hammer crushing,

samples may be immediately reduced on it to a few pounds weight, or small enough to be readily protected from salting (Art 9). Before beginning to cut a channel, it is well to mark its delimitations (usually by making soot streaks with the lamp flame) along each side and for the entire length. To lessen opportunity for salting the sample in place, the channels should not be marked until they are actually to be cut. Considerable ingenuity may be demanded in cutting samples from exposures difficult of access. In high-backed drifts and backs of old stopes it may be necessary to build platforms on light timbers wedged like stulls between walls, or, in a wide stope, to erect light scaffolding on "horses."

Sampling shafts. UNTIMBERED SHAFTS and WINZES are usually best sampled from platforms on light stulls. If the material is easy to sample, the work in a vertical shaft or winze may be done while seated on a short plank suspended through the center on a windlass rope, and held as close against the side as is desired by a light cross pole hinged to the plank and extending obliquely up and back to the far side of shaft (5). The sampler, seated astride the rope, fixes his position as rigidly as desired by pressing his feet against one side of shaft, thus acting against the pole, which points back and a little up against the opposite side. The sampler's hands are thus free for cutting the sample which he can receive on a sheet spread over his legs or on the shaft bottom.

To sample CLOSE-LAGGED SHAFTS part of the lagging must be cut out, and if care is taken to expose but a small area at a time and promptly to replace the lagging, no injury to the shaft should result.

In lagged shafts running down with the banding of the deposit, the full width of exposure is made accessible by cutting out entire panels between timbers; when necessary this can be done by cutting out, sampling back of, and replacing, one piece of lagging at a time. Shafts in the midst of a mass, as test pits of a placer deposit, may be sampled by removing part of the lagging between timber sets, and cutting a uniform channel of such size as the dimensions of the opening admit. If values vary greatly between sides of the shaft, channels should be cut on both sides and handled separately. Otherwise it should suffice to cut a single channel between sets, locate it on the side next to that in which the channel just above was cut, and so work around the shaft as depth is gained (Art 7).

Chip sampling. Some unstratified masses, as the pyrrhotite deposits of Ducktown, Tenn, are so hard, tough and close-grained, that cutting channels is extremely difficult. Fortunately these qualities produce a broken surface, the irregularities of which are independent of composition, so that chip sampling gives satisfactory results. The work is like channeling, except that the sample material consists of chips moiled off along an assigned line. As in channeling, the chips must be so broken as to represent equal distances by equal quantities. A proper proportion of fines and coarse must be secured from each point of chipping, and the number and size of chips determined in accordance with the irregularities of the exposure.

Grab samples are taken by "grabbing" pieces at random. Information as to general characteristics can thus be gained quickly, and by careful adaptation of interval sampling a method of some precision is developed. The value of a dump surface, for example, may be determined with as much accuracy as desired by making the "grabs" at regular and closely-spaced intervals, securing at each point the proper proportion of coarse and fines.

7. UNDERGROUND AND PLACER SAMPLING

Underground mineral exposures are usually best sampled by interval-channeling or chipping (Art 6). As stated, deposits the values of which are largely in native metals or other rich minerals can not be sampled and assayed in the usual way, and large-scale sampling followed by mill or smelter runs is requisite. Such work must always be checked against previous operating records and a general estimate of value based on careful inspection of ore exposures. In fact, before undertaking any sampling, the peculiarities of the deposit should be determined as far as possible by such inspection. For this purpose fresh fractures should be made at frequent intervals, by breaking off pieces with a pick, or, in tough material, with moil and hammer.

Time and fatigue will be saved, and the engineer's efficiency increased, if this work be done by 1 or 2 good hammermen, at points indicated by the engineer, who is thus left to devote his entire attention to studying the exposures. The sample interval is usually 5 or 10 ft; preferably 5 ft, which is short enough to afford means of check by calculating two sets of results on alternate samples. Precious-metal deposits should be studied carefully for rich streaks and shoots, and sample interval made short enough to include all exceptionally high or low values. In case of streaks, it is often desirable to divide the channel across the banding into two or more samples, to insure proper proportioning and

make it possible to exclude (when revealed by assay) low-grade or barren streaks occurring so that in subsequent mining they could be left untouched (Art 6).

Placer sampling must be done in a manner to show much smaller values than are considered in solid deposits. Large-scale dredging, favorably located, as that on American or Yuba rivers, Cal, gives high percentage of recovery at pre-war cost of about 5¢ per cu yd, and in such cases 10¢ ground is profitable when in quantity sufficient to keep a dredge at work for a number of years (Sec 10).

Under favorable conditions (properly sloping bedrock, abundant water under sufficient head, and ample dump room) (Sec 10), hydraulic mining costs even less than dredging. 10¢ per cu yd is between 7¢ and 10¢ per ton (0.0035 to 0.005 mg per assay ton, or about the minimum an assayer can report with any assurance of accuracy), but placer samples are reported to the nearest 0.1¢ and averages calculated to nearest 0.01¢. For this the samples are measured and concentrated by rocking and panning before being assayed. Fig 4 gives details of a practical rocker (11).

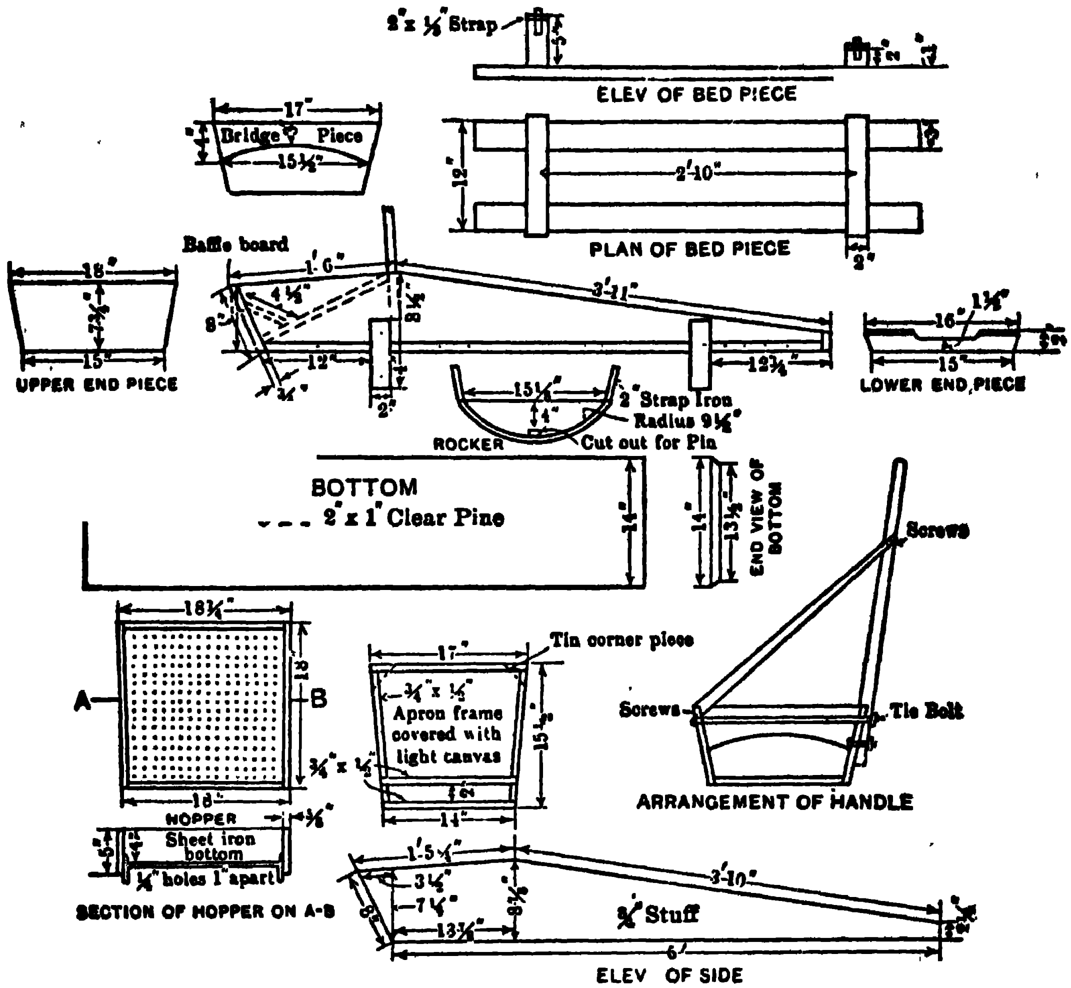

Fig 4. Placer Gold Rocker

Besides determining amount, condition (whether coarse or fine), grade and distribution of the gold, other features should be noted at time of sampling. If the property is to be dredged, it is desirable that the gravel (material up to size of a man's head) be free from boulders. Strongly-built dredges, with buckets of a few cu ft capacity, will handle, at some additional operating cost, pieces up to 2 ft diam, while 15 and 16-cu ft bucket dredges will handle boulders weighing over a ton. But, for a low operating cost, few large boulders can be present. Cemented gravel increases cost as does sticky clay, which clogs the entire equipment, resists washing, and carries off values (Sec 10).

Maximum dredging depth has thus far not much exceeded 150 ft in regular, average cost practice. Of this as high as 40 ft has been carried in the bank and the balance below water level. Experienced dredge builders, such as Yuba Manufacturing Co. of San Francisco, Calif, however, feel that for a deposit of sufficiently large scale and high value to justify initial cost, a dredge could be designed and built which would operate satisfactorily at considerably greater depth to bedrock, which must be cleaned to prevent loss of gold.

Minimum depth to bedrock must exceed that required to float the dredge, and clear the sag of the bucket chain, with the ladder in any necessary operating position. Cost of removing surface timber, including stumps, must be determined. Presence of any considerable amount of buried timber prohibits dredging.

Provision for handling débris is largely a question of dirty water, which can not be settled to a clear overflow; 50 miner's inches flowing into a dredge pond will usually keep water clean enough for gold saving and offset seepage losses. Rapid-running streams in narrow valleys subject to unmanageable freshets preclude dredging, because of danger to the boat. Very hard, rough bedrock, containing crevices in which gold value would be lost, is equally impracticable for dredging. But, what shows in a stream bed as hard rock may be covered beneath the gravel by a soft, decayed, but sufficiently firm layer, suitable to cleaning by dredging (Sec 10).

Methods of sampling placers. The only exposures available in a virgin placer are those made by freshets and streams. But some prospecting will probably have been done before the engineer's examination, usually consisting of pits for mining by hand methods, or of shafts or drill holes. Each accessible point must be sampled, and note made whether BEDROCK has been reached. If possible, bedrock should always be reached, to inspect and sample the gravel lying immediately upon it. Character, strike, and dip of bedrock can then be determined, comparison with similar observations elsewhere precluding possibility of deception by a large boulder. The exposures, if large enough, should be interval-channel sampled and each sample panned (Sec 10 and 31) or "rocked" independently. After recording, all the "colors" from a single pit are usually combined for final weighing and assay (Art 5). Table 2 is useful for calculating valu from fineness (2). The value of a mg of gold 800 fine is 0.09¢, a factor which may be used when weighing colors from placers where the average fineness of gold has not yet been determined.

Table 2. Fineness and Value of Gold Basis, $35.00 per oz

Fineness	Value per oz	Value per grain	Value per mg	Fineness	Value per oz	Value per grain	Value per mg
950	$33.25	$0.0693	$0.00107	750	$26.25	$0.0547	$0.00084
925	32.38	0.0674	0.00104	725	25.38	0.0529	0.00082
900	31.50	0.0656	0.00101	700	24.50	0.0510	0.00079
875	30.63	0.0638	0.00098	675	23.63	0.0492	0.00076
850	29.75	0.0620	0.00096	650	22.75	0.0474	0.00073
825	28.88	0.0602	0.00093	625	21.88	0.0456	0.00070
800	28.00	0.0583	0.00090	600	21.00	0.0438	0.00068
775	27.13	0.0565	0.00087				

A deposit which has been proved by drilling can be CHECK-SAMPLED only by fresh drilling or shaft sinking. When the water flow is not enough to prevent shaft sinking, the sinking of pits on say half a dozen holes of representative location and varying value is the best checking method. Measured representative amounts of the material from each 5 ft of sinking can be rocked, and after the shaft is complete these results may be checked as many times as desired by interval-channel sampling of the sides of the shaft. To be successful the shaft must reach and thoroughly clean the bedrock, particular care being taken in measuring and rocking gravel close to and on bedrock, where most of the value frequently occurs. All the gold in a measured amount of gravel in place should be cleaned off the bedrock into the sample, but the rich gold-bearing sand surrounding but outside of the measured sample must not be allowed to run in and contaminate the sample.

When, because of wet ground or other reason, shaft sinking is difficult and costly, and a drill and crew are available, adequate check can be secured by re-drilling holes instead of sinking shafts on them. That is, a second hole is bored within a few ft of the original hole, or as close as possible without risk of entering ground disturbed by previous drilling. A portable churn drill, such as "Keystone No 3," is usually employed (Sec 9). This machine, with 6-in tools and properly used, yields 1 cu yd of gravel from approx 100 ft of hole. When a new outfit must be purchased for boring only a few holes, so that first cost is a large item, or when labor is cheap and unskilled, or when transportation is difficult, a light hand-power outfit, like the "Empire" (Sec 9) is useful. Bedrock must be penetrated far enough to determine its character, and that it is genuine and not simply a large boulder. The character and amount of ground drilled and the number of colors secured should be noted ft by ft, and the ground-water level recorded (Art 5).

Whether the work be done by pits or drill holes, a close check of individual holes or pits is largely accidental, and whether the results of a certain amount of drilling are to be accepted (though with modification) is a matter of judgment.

The engineer must determine if the average of the checking holes is in sufficient agreement with the average of the holes or shafts checked, or if the divergence is too great in

proportion to the possible operating profit to permit use (after discount) of the original data. Methods of combining data are discussed under Conclusions, Art 10. 75 to 80% of the prospecting value is usually considered to be recoverable by dredging, while 100% has occasionally been secured in practice.

8. CARE OF SAMPLES, NOTES, AND ASSAY MAPS

Sample tagging. A good method is to write the number (and any descriptive matter) with soft lead or indelible pencil in heavy lines on strong bond paper, like that of ordinary loose-leaf notebooks. The sheet is folded close, to enclose and protect the writing, and placed on top of the sample just inside the container. This marking may be confirmed, in case of sack containers, by marking the number with pencil on the sack, either within the throat just outside the tying, or on the outside if there is no objection to showing the sample number.

Some prefer thin strips of soft wood, about 0.1 by 1 by 2 in, on which the sample number is written in heavy pencil marks which can not be obliterated by a moist sample. Others use small paper or linen shipping tags, one inside, the other tied outside the container; or brass number tags placed inside. The marking should always be in duplicate, so that the sample can not become valueless through loss of a single mark.

Field notes should show date of sampling, name, and connection with the samples of every one concerned in or present at time of sampling, and other information regarding the specific day's work. As each sample is taken its number and the data regarding it are recorded, including a full description of the sample itself; as, exact location referred to an established point (preferably a survey station), length and character of cut, and any peculiarities of deposit or workings noted at or near the point sampled.

In an examination involving a considerable amount of sampling, the notes may be systematised by using a tabular form arranged for specific conditions. Fig 5 shows a form suitable for underground interval-sampling.

Office record. To provide against loss, and for convenience, it is well to copy field notes into a permanent office record. Fig 6 is a form of office record adapted to field notes in Fig 5. Since field notes are made as samples are taken, samples of work in progress become scattered over a number of pages, but by keeping a separate sheet in the office record for each working (preferably in a loose-leaf binder) samples will appear in the order of their position underground.

Sample containers. Samples of ores, the moisture or other volatile contents of which need not be considered, are best sacked as taken, or immediately after such reduction as is made at the point of sampling. If, as is often the case, interests exist which might be served by deception, the sacks should immediately be sealed or placed under lock and key. The latter can best be done in the field by using a locked leather mail sack, in which the samples are in little danger of being tampered with, even by injection of values in solution (Art 9). But, given sufficient time and motive, salting can usually be accomplished, and even the best protected samples should as little as possible be left accessible to others than the engineer's confidants.

When moisture or other volatile contents is to be determined, samples should be taken on an enameled cloth or rubber sheet, and should completely fill the container. They are best carried in screw-top cylindrical galvanised or tin cans, which can be hermetically sealed by screwing the top

down on a rubber gasket, or by binding the joint with several layers of adhesive tape. Corrosive solids are best carried in glass fruit jars with glass tops; liquids and gases in glass or earthenware bottles, or demijohns with cork, rubber or glass stopper, according to the character of the sample.

Assay maps are the best method of permanently recording sampling results, of studying these results in relation to each other and to the property as a whole, and of submitting these data in a report. They are made by tracing a map of the mine, entering the sample positions thereon by dot or line, and writing the number, assay, or value of each sample alongside its location (Sec 19, Fig 1).

For entry of a single value for each sample, the scale of 1 in = 50 ft is as satisfactory for assay plans as for most other work. If several constituents are to be entered for each sample, a scale of 1 in = 20 ft is preferable. If several entries per sample are necessary, and only small-scale maps are available (1 in = 50 ft or smaller), the sample number only may be written at the point of location, and a table of all data desired placed in a corner of the map sheet. This is not so good as the direct entry of the data at the location, as the variation in value in the different workings is less obvious. Variations in assays for a single element, or currency values of several elements, are sometimes indicated by intensity of shading, variety in coloring, or design symbols, the fluctuations being thus shown at a glance. This method has gained favor on the Rand, So Africa.

Besides the assays, assay maps should show the tonnage calculation blocks, in amounts and average values. For steeply-dipping deposits, these blocks are best shown on longitudinal elevations or on slope plans. For flat deposits, plans are most instructive.

9. SALTING

Salting, the process of intentionally or unintentionally raising the value of a sample above that of the exposure sampled, must be continually guarded against. The possibility of intentional salting being attempted must be borne in mind even when circumstances seem to give little occasion for it.

Example. *An engineer examining a copper mine, taken on operating lease with privilege of purchase, recommended that the smelter be operated on average ore to be obtained by taking a slice of uniform thickness from the floor of each level. The mine foreman, however, extracted all the ore for the test run from a particularly rich lot which he knew to exist in the floor of one of the levels and, in absence of the engineer (who had been employed only for the single examination), the lessees received the impression from the smelter returns that workings actually averaging 3% contained between 4 and 5% copper. The foreman had no connection with the owners of the property, was solely the employe of the lessees, and had no apparent object in the deception. But he was a resident and property owner in the district, and when subsequently tasked with the fraud explained that he feared that if the lessees had known the truth they would not have completed the purchase, the property would not have been regularly worked, and the expected rejuvenation of the district dependent on operation of the property would not have been realized.*

Since the commonest cause of salting is the desire of vendors to effect a sale, the only safe practice for the engineer is to take every precaution against salting, even if the vendor's reputation and the general circumstances are such as to allay suspicion. Though it is not the examining engineer's province to analyze the motives of those with whom he deals, he is responsible for so conducting his examination as to assure himself that deception has not been practiced upon him. On the other hand, unnecessary obtrusion of the precautions essential to such assurance is not only a breach of courtesy, but may cripple or retard examination work, since the sympathetic assistance of those who are showing the property is of advantage in promptly calling the engineer's attention to such features as might otherwise be noted only late in the examination, or possibly be entirely overlooked.

Salting has been effected by preparing the ore exposures from which samples were likely to be drawn, or by limiting the exposures to those showing high values. The latter is usually done by timbering and close lagging, or by heavy blasting so as to cause a cave (or the appearance of one) in barren sections. Rich ore may be placed in piles throughout the mine, as though blasted from adjacent faces, in the hope that samples will be taken from them rather than the faces. The practice of stopping each heading while it happens to be in good values is also employed. But in such case there is a fair chance that the vendor himself may be deceived by having discontinued development just as large values are about to be encountered.

The commoner method of contaminating the sample itself may be practiced upon the engineer at any point where he allows unprotected samples to be handled by others than himself or his confidential assistants. Local miners employed to cut samples can readily salt them by adding valuable mineral, by breaking into the sample an undue proportion of the richer streaks through which the sample is being cut, or by picking out pieces of waste during the work. Also, misleading results may be produced unintentionally.

Example. The early history of one of the great copper properties in southwestern U S was checkered by incorrect conclusions based upon hundreds of progress samples averaging 4% copper, from ore actually containing only 2%. These samples were taken by the operating company for its own information, by a system of interval-channel sampling laid out by a reputable European engineer. The actual sampling, however, was left to the casual Mexican miner who happened to be least needed on other work and he, minerlike and wholly innocently, broke down and retained in his samples the best ore showing at the points sampled.

Samples may be salted by syringe injection of valuable solutions through the cloth of sack containers. Exposure of samples during the quartering process affords excellent opportunity for salting by adding highly concentrated values shaken from the hair, finger nails, or clothing, or by introducing them as expectorant, tobacco ashes or what not. By manipulation of the reduction process, an undue proportion of barren material may be thrown into the reject. In fact, the methods which ingenuity can devise for salting a sample, even though it be in a sealed sack, are innumerable. The only safety for the engineer is to check constantly both sampling and assaying, and so far as possible, keep his samples out of the hands of all except his confidential assistants. A sample known to be barren, and purposely carried for assay with the others, may catch some of the salter's values if the lot is tampered with, and the sampler will be thus placed on his guard. (See also Sec 30, Art 9.)

10. SAMPLING CHECKS AND CONCLUSIONS

Checks on accuracy of both sampling and assaying should be made in sufficient number to give assurance that results are as reliable as circumstances admit or make desirable. When possible, ERRATIC SAMPLES should be retaken with special precaution against inaccuracy or contamination. When assays can not be made prior to leaving the property, it is well to duplicate 5 or 10% of the sampling, selecting the samples for duplication at random, but so as to include those which appear to be of high, low and average value.

Assaying should be checked by sending for assay a small percentage of duplicates (the reject of the last reduction in sample preparation), and a few blanks of known barren rock, all under new numbering. Also, a few duplicates should be sent to a different assayer. These may not always agree in detail, but the average of the duplicates by either assayer should not vary from that of their originals by more than a small percentage of the values contained. Provided the assaying is accurate, the DUPLICATE SAMPLING should check in a similar manner; that is, actual duplicates may vary considerably, but the AVERAGE of duplicates and originals should show reasonable agreement. If sampling has been done on a short interval, compared to the total length of exposure (say 5 or 10 ft on large work), the average of alternate samples should closely agree with that of the intervening samples; the greater the number of samples, the closer should averages agree.

Conclusions from results of sampling should be based upon proportioned averages; that is, the quantity of material represented by an assay should be as much a factor in calculating an average as is the assay itself. Thus, in a well-defined vein, exposed over its full width and sampled at regular intervals, each assay is multiplied by the sample width, and the sum of the products divided by the sum of the widths to determine the true average. If sample intervals are irregular, the width is first multiplied by the interval to the succeeding sample (using the last interval on both the last and next to last sample) and this product multiplied by the assay. The sum of the interval-width-assay products divided by the sum of the interval-width products then gives the proportioned average.

In valuing ore exposures containing large and irregular proportions of heavy minerals in light gangues (as galena in quartz), a SPECIFIC-GRAVITY DETERMINATION is sometimes made on each sample, and the interval-width product multiplied by it before multiplying by the assay. The sum of the interval-width-gravity-assay products divided by the sum of the interval-width-gravity products then gives an average assay, which includes allowance for the specific gravities of different parts of the ore exposure. This refinement is unusual. Cases are rare in which the engineer's knowledge of the mining value of the deposit would be sufficiently increased by gravity determinations to justify the added cost; for, since the value usually follows the heavy mineral, the probable effect is to raise the average assay. This, unless subsequently discounted, seems more likely to increase than to decrease error in determining the mining value. Owing in part to the more friable nature of the valuable minerals, and particularly to the inevitable inclusion, when mining, of some of adjacent low-grade or barren material (which can not properly be added to the sample), the yield per ton of a carefully sampled deposit is generally lower than the calculated average, and the tonnage higher. An allowance (say 10%) should therefore be made for this in reporting values.

A precaution sometimes taken against over-valuation is the ELIMINATION of all HIGH

ERRATIC VALUES, substituting for them the average of the two adjacent samples, but this practice is questionable. If there are enough erratic values to effect the result seriously, there may also be enough high values to justify inclusion of all. The proper disposition of erratic samples calls for careful study of each case, and for the engineer's best judgment.

When the deposit is wider than the exposure in drift, upraise or stope, and samples of uniform widths have been taken at regular intervals, the width and interval factors disappear and the mathematical average of the assays applies to the area sampled. But, unless the workings sampled are uniformly distributed throughout the deposit, mathematical average should be applied only to the immediate and smallest possible area, and area assays should then be combined with their respective area factors. That is, the average of the whole is found by dividing the sum of the assay-area products by the sum of the areas. This avoids the common error of applying to the whole the average of samples secured chiefly from a small, well-developed portion of a comparatively large but little developed area.

Calculation of average values is facilitated by using a form like Fig 7. From sample numbers, assays, measurements, and their products, the sums and averages can be recorded, and final summations and combinations made, from which to secure proportioned averages of different blocks and of the whole.

Fig 7. Form for Calculating Average Assays. (Blank columns for unexpected additions)

A pocket adding machine (as the "Ve-Po-Ad") and a slide rule assist in making field calculations. More elaborate adding and calculating machines (as the "Monroe") are excellent for office work.

In drawing conclusions from results of sampling, it should be borne in mind that the development of a deposit, or even a portion of it, is never so complete that an accurate, mathematical description is possible. The value of a mass of ore can not be accurately known until it is mined and treated, and allowance must always be made for contingencies.

A single block of ore may be sufficiently developed to give results by sampling and calculation closely approaching those ultimately secured by actual mining. But the engineer should scrutinize the data of each block, to determine whether its development is of this thorough nature, or whether allowances must be made in the light of his knowledge of the characteristics of the deposit. This knowledge should have due weight in determining his declaration of assured values of the entire deposit, which of course are based primarily upon his sampling and calculation. The report should include all important data bearing upon the conclusions reached.

11. DETERMINATION OF QUANTITY AND VALUE OF ASSURED MINERAL

Assured mineral is the amount existing of which the engineer can give definite assurance. It is necessarily a minimum, not an ultimate quantity, though in case of mineral well blocked out relatively to the known irregularity of the deposit, there may be masses of proved mineral which can be quite accurately calculated. The term ORE IN SIGHT has been widely employed, but has been so variously used and misused that it has ceased to have a precise technical meaning. It has been suggested that ore exposed on at least 3 sides be termed "in sight;" but, in irregular deposits ore so exposed may still be uncertain in quantity and value, while in regular deposits the ore may be assured, although not exposed on 3 sides. Hence, the use of the term is being abandoned by those who wish to convey a definite idea. An engineer's statement of assured mineral is essentially a conclusion based upon judgment, not merely the result of mathematical calculation.

Methods of calculation, though simple, must be carefully applied in each case, so that the relation of amount and reliability of data to extent and importance of conclusions may be fully realized. Assay maps (Art 8) best show this relation, especially when studied in three dimensions (plan and elevations), and form one of the prime sources of information

as to size, shape, value and relationship of the different ore exposures. Structural geology of the deposit must also be studied, so that isolated exposures will not be considered consecutive and intervening barren volumes calculated as of value (Art 2). The average assay value of the exposures of a given block being determined, volumes are calculated by multiplication of average area by average thickness, by inclined distance between exposures, or by depth between levels, according as the block is in a flat-lying seam, bed or zone of enrichment, in an inclined vein, seam or lens, or in a deposit of vertical extent or development (Art 10).

In a well-defined, strong vein of fairly evenly distributed values showing no tendency to concentrate into shoots, the value areas, measured normally between walls, and exposed at consecutive levels close enough together to preclude unexpected irregularities, are multiplied by the dip distance between levels to determine the volume of mineral, and the values of the exposures, combined proportionately to their respective areas, may be taken as the value of the block.

In large masses, developed by well-defined and sampled cross-sections, the accuracy of calculation may be increased by using the prismoidal formula. A mid-section is constructed by plotting adjoining sections, connecting their definitive points, and forming an area by connecting the mid-points of the connection lines, as in railroad earthwork practice (Sec 17). Masses that are well developed by drilling cross-sections are advantageously so calculated, the volume being found by multiplying $^1/_6$ of the distance between consecutive sections by the sum of the areas of these sections plus 4 times the area of the plotted mid-section.

Unless the development and sampling of a deposit is so uniform that the size, exposure, and number of samples of each block are practically the same, the blocks should be as small as the data will permit, so that a minimum number of assays will be grouped into an arithmetical average before being combined with the volume factor which they represent (Art 10). General averages are then obtained by including the volume factors.

An adaptation of Fig 7, by substituting tons" for "feet," facilitates determination of totals and average values of any desired combination of ore blocks. In laying out blocks for calculation, care must be taken that all available data are included, and that such as are available suffice to assure the presence of the full calculated volume and value; or, if only a portion, what proportion is assured. Possible influence on each block of unexposed faults, pinches, horses, low-grade spots, shoots, rich masses or other inclusions, should be decided only after careful investigation of the development of the deposit in question, and similar deposits. Minable ore of less than stoping width must either be diluted in the calculation by enough barren rock to make workable width, or the cost of separate mining of the necessary waste included in the cost estimate. The engineer's trained judgment should be brought to bear on each block.

Though the practice is regrettable, flat-lying deposits (especially placers) are often tested by irregularly placed pits or drill holes, so that the mathematical average of values shown gives an erroneous idea of the average value of the deposit, even though the depth factors are included. As the tendency is to sink the greatest number of pits or drill holes in the richest spots, the error almost always exaggerates the true value.

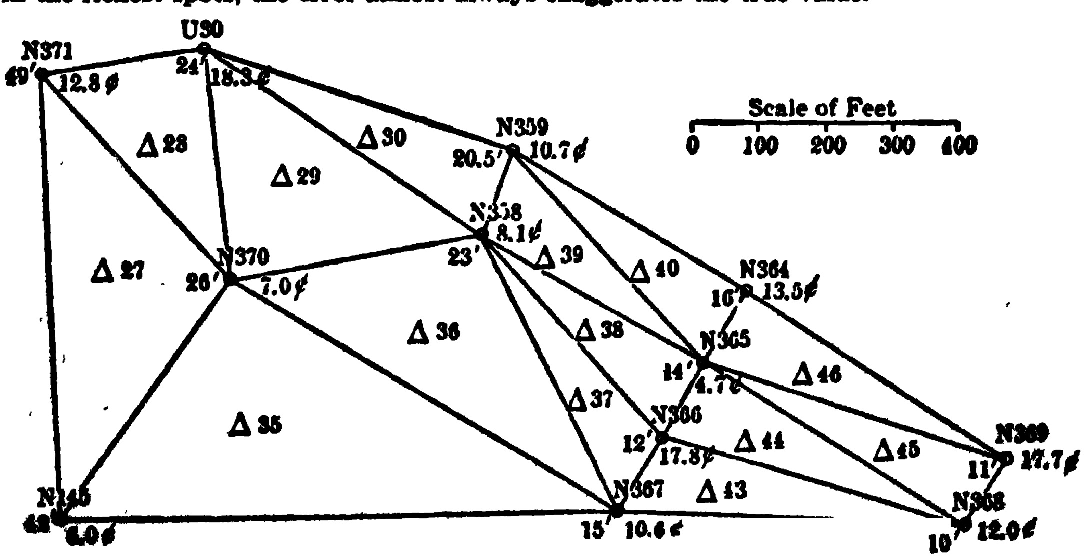

Fig 8. Example of Irregularly Spaced Drilling

To minimise this error, divide the area of values on the map into as many triangles as possible, having their angles at the pits or holes as in Fig 8. Avoid over-emphasizing any hole by centering an

unusual number of triangles about it. Number triangles and assign to each the average depth and value of its corner holes. In computing average value, include respective depth factors. These data may be arranged as in Fig 9. Another table (Fig 10) should show the scaled base and half altitude, and the calculated product or area of each triangle. Add to this (from Fig 9) the depth and value of each triangle, and calculate the volume and total value of each. Dividing total of the values by the total volumes, gives a value per volume (¢ per cu yd, in case of gold placers), in which theoretical errors or proportioning irregular developments are much reduced, provided the triangles have been so laid off as to avoid overemphasizing any hole. Equilateral triangles are ideal (each angle = 60°), and by introducing the factor of the number 60° units (or decimals) in each angle of each triangle, greater theoretic accuracy is attained (24). But, good judgment in using the simpler method often gives as close an approximation to the actual values present as is attainable with the unsystematic exploration under consideration. Regular exploration is always best.

Fig 10. Volumes and Values

Besides natural variations from apparent values, artificial variations may occur. Abandoned workings may be concealed by timbering or muck, intentionally or by accident. The latter is common in mines which have passed through many managements, and may reveal unlooked-for conditions in apparently well-defined blocks. A case is on record in which a rich ore-block, defined by excellent exposures in backs of levels above and below and in upraises at either end, had been almost completely gutted through a winse in floor of upper level, which had been timbered over and covered with tram-road muck (4). When the decision hangs on presence *in toto* of a few well-developed blocks of ore, care must be taken to insure that neither natural peculiarities nor vicious intentions deceive; possibilities which must be recognised and guarded against (Art 10). But such deception can rarely be practiced on sufficient scale materially to affect conclusions. After being shown over the property, the engineer should put directly to the executive in charge (and, as opportunity offers, to each subordinate independently) the question whether the engineer may be assured that he has seen every known opening or exposure, and whether any such exposures are incorrectly shown on, or omitted from, the maps submitted. Unintentional oversight will usually be thus discovered, and, in case of intentional deceit, some one reply may be sufficiently evasive or contradictory to arouse suspicion and lead to discovery.

Tonnage factors. The factor by which the volume in cu ft should be divided to reduce it to tons is determined by dividing 2 000 lb (or 2 240 lb for the long ton) by 62.5 lb (wt per cu ft of water) × sp gr of the mineral mass (Sec 1, Art 3).

To determine sp gr take the aver of a number of sp gr bottle-tests on aver crushed samples. Fill a narrow-neck bottle to a mark with distilled water at 60° F and weigh (a). Introduce a weighed amount (b) of sample, restore water level to the mark after insuring removal of all air accompanying the sample (done by boiling, if ore is sufficiently insoluble) and take final wt (c). Then, sp gr of the mineral = $b \div [(a + b) - c]$. (See Sec 1, Art 3.) After estimating aver ore composition, the aver tonnage factor may be computed from Table 3 (1).

Example. A ton of ore in place, composed of 70% pyrrhotite, 7% chalcopyrite, and 23% schist, will occupy a volume = (70% of 7) + (7% of 7.6) + (23% of 11.9) = 8.2 cu ft; or, in practice, call tonnage factor 9 cu ft.

As in the example, it is advisable to allow for inaccuracies by using a larger tonnage factor than calculated, regardless of basis of calculation. For porous mineral masses,

1, 2 or more cu ft may have to be added, to get correct tonnage factor. In important cases, where uncertainty exists, the weight of an accurately measured excavation should be taken to determine the proper factor. If deposit is large enough for planimeter measurement of reserve areas, and if production records are sufficient, a tons-per cu ft factor

Note.—For compositions and specific gravities of minerals, see Sec 1.

may be used for computed volumes and known tonnage produced. That is, if vol of extraction V yielded T tons, how many tons will reserve-vol V^1 yield?

Roughly, cu ft of anthracite coal may be reduced to long tons by dividing by 24; bituminous coal to short tons by dividing by 25; quartz and feldspar masses by dividing by 13 (or by factors down to 10, if sufficiently sulphided); sulphide and iron-oxide masses by 10, 9, 8, or 7, according as they consist chiefly of limonite, ZnS, FeS, FeS_2, Fe_2O_3, Fe_3O_4, or PbS, or contain more or less gangue, or are dense or porous in structure. Less than 5 cu ft of pure PbS make 1 ton. In dumps, the volume usually ranges from 1.6 to 1.9 times the volume of same material in place. Calculation of combined tonnages and values, as of individual exposures, are best made in tabular form (see Fig 3.)

12. PROSPECTIVE VALUES, PERCENTAGE OF RECOVERY, COST OF PRODUCTION

Prospective quantities and values. This subject requires more highly trained judgment than, and is of as much vital interest to the client as, any other part of an engineer's report. Having collected all available data as to past yield and present showing of values, geological conditions in which these values occur and records of similar conditions and deposits in vicinity or elsewhere, a careful sifting, balancing, and digestion of these data must be made in order to form as definite an opinion of the prospects as possible. To crystallise this opinion in practical form, the engineer may propound to himself the following questions: 1. What are the geological and artificial limitations, as folds or change of formation, well-determined faults, and property lines (including apex-law limitations), and to what extent do these preclude possibility or probability of further development of values in depth or horizontal extent? 2. Are there any highly probable continuations or indications of independent values on the property? If so, what is the least development and cost which will yield definite information regarding such values, and what development and cost is necessary to prove thoroughly these values, for establishing a profitable industry thereon? 3. In addition to highly probable values, what hopes may reasonably be entertained as to extent and value of the ultimate mineral resources of the property, what scale of outlay is likely to be involved and justified, and what, if any, definite limitations do local conditions place on such hopes? In general, deposits not definitely limited are likely to contain at least 25 to 100% more ore than can be actually assured.

Example I. (Question 1) A deposit was limited at one end by a property line across which the orebody passed to an adjoining mine, while the structural geology showed plainly that the main workings bottomed in and were limited by a synclinal trough. (Question 2) Comparatively small outlying developments on what could be traced as the downturn of an anticlinal fold succeeding the syncline, exposed a small but excellent ore showing at a lower level than the bottom of the syncline. The property being in regular operation and equipped for diamond drilling, $1 000 spent in boring in the floor of the bottom ore was likely to add many times this amount to the value of assured ore reserve. (Question 3) The drilling was also likely to trace ore to sufficient depth to justify sinking a winze, so as to render a new level accessible to drilling. The winze, including drilling at the lower level, would cost $5 000. Granting the first favorable diamond-drill showing, the general features of the deposit and the reputation of the district warranted the hope that enough ore could be proved and indicated to justify opening this outlying deposit direct from the surface (replacing the long crosscuts and hoisting winzes through which previous development had been made) by an efficient main shaft to cost about $100 000. This shaft in operation, a low-grade outlying deposit on the strike (of which there was hope, because of the 25 to 50% increase in value with the depth of the deposit being developed) could readily be proved and exploited in depth. This outlying body once proved valuable, in addition to the main deposit, the mine would have an indefinitely great future, notwithstanding the limitations of property line and fold (Question 1). Since the mine was equipped and in profitable operation, its purchase at the full profit value of all assured ore, figured on the highest likely average market, was attractive for those skilled in the business and looking for promising, mining ventures, and it was a serious question whether a cash purchase was not advisable at a much higher price. Ultimately, all expectations were so largely fulfilled that the true value proved to have been but slightly forecasted by the value of the assured reserves.

Example II. (Question 1) An obviously secondary enrichment, lying between a clay overburden and underlying limestone, was found exposed by an open-cut working supplying a small concentrating mill, the operation of which investigation proved could be made profitable. Test pits to bedrock at different points about the open cut showed ore extending out on 3 sides and proved considerable value. At no point on the property were commercial values found in the underlying limestone. Property lines were at considerable distances in all directions from the open cut. Post-hole-digger holes to bedrock, the records of which in many cases showed ore, were found scattered about the open cut, but as many of them were reported barren, it was doubtful whether the deposit extended over any considerable area of the property. (Question 2) Though the records of holes within the area proved by test pits showed the values to be exaggerated, continual recurrence of records of barren holes suggested that the exaggeration was due rather to error in judgment than to intention, and that the presence of ore could at least be presumed in holes having a record of ore value. Therefore, systematic prospecting could be expected to add considerably to the values already assured. The facility with which both holes and pits had been sunk through clay and ore to the limestone proved the practicability of cheap exploration, and it was obvious that for $1 500 the entire property could be tested in the following simple manner. The area was laid out in 500-ft squares and a hole bored at each corner; then holes were bored at corners of 100-ft squares laid out around each hole showing ore indications. The 100-ft square system was then extended until all ore areas developed were completely surrounded by barren holes. Ore areas thus defined were finally proved by test pits at corners of 200-ft squares. (Question 3) Though expectation of a definite increase in reserves beyond those actually assured at time of examination was fully justified, the barren hole record showed that such increase would be moderate, and that the present assured reserves must be considered as forming a large proportion of the ultimate reserves, at least in so far as the secondary enrichment was concerned. Primary values in the limestone being lacking in the exposures, they

received little consideration and the property was prospected for secondary-enrichment values, as described. The above inferences being found substantially correct, the cost of equipment and scale of operations were proportioned to the known limitations of the secondary-enrichment values, and the highly profitable operations thus inaugurated were not overburdened with necessity for returning large equipment outlay.

Percentage of gross value recoverable and cost of production. Estimates of recovery and costs are based on past and present accomplishment on the property; on results of investigations of the ore by field, laboratory, or ore-testing works; on the operation of a small but practical preliminary plant, erected for the purpose; and on practice in mining and treating similar ores elsewhere. ACTUAL ACCOMPLISHMENT on the property can best be determined by investigating the records, and checking them against each other, against tailing-dump samples and, if feasible, against test runs of the equipment (Art 2). Equipment should be carefully inspected to determine its adaptibility, condition, and whether general appearances, coupled with available records, indicate that the management could be improved. PANNING AND SIZING TESTS often assist in suggesting possibilities of treatment by concentration. ORE-TESTING WORKS treatment of larger lots may be of still greater value (Sec 31). MUFFLE-ROASTING AND LEACHING TESTS in the laboratory may suggest possibilities of treatment other than by concentration. On large, low-grade properties, demanding heavy capital outlay for equipment before profitable operation can begin, it is customary to erect a PRELIMINARY OPERATING PLANT, of sufficient capacity (sometimes hundreds of tons per day) for ore treatment by full-size machines, under working conditions. Such a mill is operated for a number of months at least, even though at a loss, simply to secure data and to test various modifications of treatment, preliminary to designing a large equipment for regular operation. Its design is as flexible as possible, so as to include all promising modifications of treatment which preliminary tests in laboratory or testing works have suggested. ACTUAL PRACTICE in mining and treating similar ores elsewhere is important for estimating operating costs and percentage of recovery.

Conclusions drawn from practice must be based on study of the similarity of general conditions, and of the mineral to be treated. Relative cost of labor and supplies and the scale of operations at successful properties, as compared to those feasible at the property in question, should be thoroughly understood. SCALE OF OPERATION often determines operating costs. Thus, concentration costs in the great porphyry-copper mills in western U S, each treating thousands of tons per day, have been as low as 50¢ per ton treated. The same treatment in a 100-ton mill might cost 80¢, $1, or even more per ton (Art 14). In general, the important estimates of percentage of gross value recoverable and cost of production should be made only after analyzing all information obtainable. In estimating total costs, ample allowance must be made for general overhead charges, selling and sampling costs, freight to market and contingencies, the last usually being put at 10% (Sec 21).

13. MARKET PRICE OF MINERAL PRODUCTS

Theories and difficulties. Gold, because of its relation to currency, has been held by the U S gov't, since 1934, at $35 per Troy oz. Prior to 1933 the statutory price had been (with the exception of the Civil War specie payment suspension) $20.67+ per Troy oz since 1837. During 1933 the price, with fluctuations, continued to rise to the present (1938) value, fixed Feb 1, 1934. This price, made by presidential proclamation, is to continue until altered or modified by proclamation "as the interest of the United States may seem to require;" under present law, between $34.45 and $41.34+ per Troy oz. Fluctuations in market price of all products form one of the most uncertain elements of mine valuation. Being essentially a commercial question, business men having experience in dealing in the product in question can often estimate more closely than can the engineer the average price it will command in the future. But, as opinions may conflict, the engineer himself is often forced to choose the standard of price for the basis of his estimates.

Current prices may be adopted, but may lead to false impressions, and conclusions that become absurd before the property is developed. Hence, the engineer should consider at least one other price, or preferably several others. In case of metals or coals having a standard market, it is questionable whether an engineer should recommend purchase of a property which he estimates is incapable of making a small profit, when mining its choicest reserves and selling its product at the MINIMUM PRICE of any the 48-yr record shown in most items in accompanying table; unless the property itself, or one very similar, has already achieved considerable success and continues to do so. The value of a property which would fail to make an attractive profit under normal operation, at the AVERAGE PRICE for a like period, is even more doubtful. In case of mineral products having no standardised open market value, especially when their prices depend on empirical gradings as to color, texture, etc, there should be similar hesitation in acquiring a property which, though meeting other requirements, fails to promise an output comprising enough of the highest grade product to insure a profit regardless of out-

Notes: * Nickel: domestic refined '95–'99, foreign refined '00–'37. Pure rolled nickel (small part of gross imports, including ore, matte, oxide, etc) about 10¢ higher price than aver of metal & alloys.
† Silver : U S gov't price for domestic produced silver only.

put of other grades. This is due to the uncertain market for low grades of unstandardized products, both as to price and to ability to absorb at any price. Profit from such a mine is in producing the highest grade, the lower grades being produced and sold largely as unavoidable by-products.

Question of SIZE OF MARKET, available within a radius of feasible freight rates, is important, since the opening of a large new property in a restricted market area may demoralize existing prices. Facilities for sale of product demand serious consideration. Marketing a peculiar product may constitute a large item of cost; sometimes the market can be secured only through channels available on no other terms than practical surrender of control of the property itself. For preliminary use of those not in touch with sources of more detailed information, Table 4 has been prepared, largely from the U S gov't reports.

Valuation for tax depletion, being an effort to hold an even balance between rights of buyer and seller, is a problem in itself, in which estimation of future market price is a crucial point, perhaps requiring even more elaborate investigation than a physical appraisal (Sec 24).

Example I. Aver price of copper for 48 yr ending 1937 was 15¢ per lb on annual aver output of 1 010 000 000 lb. Minimum price (1932) was 6.3¢ on output of 540 000 000 lb. Aver for 1937 was 12¢, on output of 1 670 000 000 lb. In view of these facts, an engineer might hesitate to recommend purchase of an inoperative property, capable of producing copper only and unlikely to be able to maintain an output from best ore reserves for say a year, at gross cost of less than 6.3¢ per lb unless success of this or entirely similar property were so great as to well overbalance possibility of the copper market again dropping to 6.3¢. Again, such a property would be undesirable unless it could make good profit while mining its aver ore and selling at 15¢. Finally, the fact that in 1917, during the War, the aver price was 27¢, on an output of 1 890 000 000 lb, should be recalled in considering possibilities of a copper mine of long life; providing future governmental regulation allows war profits.

Example II. Aver price of barite for 48 yr ending 1937 was $5.89 per ton on aver annual output of 123 000 ton. Minimum price (1897) was $2.24 on output of 26 000 ton. Aver 1937 was $6.25 on output of 356 000 ton. An engineer might therefore hesitate to recommend purchase of a barites mine unlikely to be able to maintain an output from best ore reserves, for say a year, at a gross cost of less than $2.24, or which would fail to make good profit on aver ore at $5.89 per ton, unless this or entirely similar property were in highly successful operation at the time. In view of the small production of barites, of the physical and chemical qualities required by the trade in this mineral, and of the high relative transport cost, due to its low value per ton, the engineer should also hesitate to make recommendation before determining detail character and location of available markets. The fact that 228 000 ton were sold at $9.39 per ton in 1920 might have speculative interest were a deposit under consideration of sufficiently large indicated tonnage to insure unusually long life.

14. OPERATING SCALE AND PROFITS, CAPITAL REQUIREMENTS, AMORTIZATION

Scale of operation is determined, on the one hand, by the minimum rate at which the property can be worked at a low enough cost per unit to insure a profit. On the other hand, the maximum scale of operation is limited by the assured mineral and probable ultimate mineral resources from the exploitation profits of which the capital, interest, and ultimate profit must be secured; also by the capital available for development and equipment, and by available markets. These factors being determined as far as practicable, and estimates made of operating costs on the proposed scale of operations, the profit per

unit is estimated by deducting the cost of production from the assumed market price or prices (Art 12, 13). The profit per unit, multiplied by the proposed annual production (on the usual basis of 300 days actual operation per year), gives the estimated annual OPERATING PROFIT (Sec 21).

Capital requirements. Estimates should first include the probable cost of prospecting the property sufficiently to give a safe amount of assured mineral (Art 11). That is, there should be ASSURED MINERAL RESERVE sufficient to produce profits that will more than return the capital required to put the property into successful operation. Assured reserve should be so large that its extraction at the proposed rate can not exhaust it in a reasonable maximum length of time necessary to prove and block out additional reserves.

Sufficient assured reserves being secured, there should be ample capital to develop them to an extent which will insure regular production at the desired output. Capital must also be provided for EQUIPMENT necessary for proper handling of output to the point of sale as raw material, concentrate, metallurgical product, or whatever form conditions require. Milling plant, smeltery, employes' houses, etc, must be considered, and capital provided therefor when necessary (Art 2). There must be sufficient OPERATING CAPITAL to carry stocks of general and commissary supplies, mineral in process of treatment, and finished output prior to sale and settlement. In absence of more exact data, 3 months' cost of output may be allowed for these purposes. In estimating total capital requirements, the cost of securing the capital (underwriters' commission, brokers' charges, and incidental financial expenses) should be included. Under favorable conditions, such as an ownership associated with strong financial interests, this may not exceed 10%. Promoters' profits are usually included in the cost of the property.

Amortization of capital is its return with interest, at or before the time of exhaustion or "death" of the property. If the profit is to be genuine, total operating profits must include an ultimate profit over and above amortization.

Amortization of equipment is usually effected by annual or monthly depreciation or write-off on equipment capital account, which amount is charged to operating expense; 10% of the gross cost is a not unusual annual allowance on ordinary mine, mill, or smelter plant. If this charge is maintained as a surplus accumulating at 4% compound interest, funds will be on hand in a little over 9 yr for complete replacement of equipment.

Table 5. Amortization

Annual div rate	Years life required to yield ..% interest, and to furnish annual instalments which, if reinvested at 4%, will return original investment at end of period (See also Sec 45)					
%	5%	6%	7%	8%	9%	10%
6	41.0	....	....	....	....	....

27	4.3	4.5	4.7	4.9	5.1	5.4
28	4.1	4.3	4.5	4.7	4.9	5.1
29	3.9	4.1	4.3	4.5	4.7	4.9
30	3.8	3.9	4.1	4.3	4.5	4.7

Amortization of entire property is usually effected by disbursement of dividends. It is then the stockholders' responsibility to reinvest a sufficient proportion of the dividends to amortize the investment cost. Nevertheless, the engineer must make allowance for amortization in drawing conclusions as to value of the property. In cases where sufficient mineral values have been determined, and the price at which the product will be sold can be forecasted with sufficient likelihood to justify, amortization may be calculated by use of Table 5 (3). In cases where other uncertainties are sufficiently eliminated to justify, such as those dependent on assumed fixed conditions in making tax assignments, it should be noted, and allowance made for the fact, that this table continues the higher risk rate of interest on the entire amount throughout the entire period, notwithstanding that the sinking fund, presumably invested safely, is steadily growing and throughout the second half period constitutes the bulk of the investment (25, 26).

Example. A thoroughly proved gold placer deposit in successful operation by dredging at rate of 1 000 000 cu yd per year, at cost of 6¢ per cu yd, contained 10 000 000 cu yd, averaging 13¢ per cu yd recovery value. Annual operating profit was therefore $70 000 and the life 10 yr. Table 5 shows that an income having a 10-yr life will yield 5% per yr (besides a sufficient amortization

charge, accumulated at 4%), when the investment is such a sum that the annual dividend is between 13 and 14% thereon (in column 1, opposite to "10.3 to 9.4 yr" in column 2, will be found "13 to 14%"). To secure 10% return the dividend rate must be between 18 and 19%. Dividing $70 000 by 13, 14, 18, and 19 respectively, shows that the property will yield 5% net, besides amortisation, if between $500 000 and $538 000 is paid for it, or about 10%, at a cost between $369 000 and $389 000.

In absence of assured mineral reserves, the whole question of value is one of inference, and amortization tables have little application. But, when part of the property's value lies in assured mineral, it is often instructive to carry out the amortization idea as far as possible on the assured reserves, and then note the years of work, tons of ore, etc. required beyond the reserves to return the valuation placed upon the property with appropriate profit.

Example. A copper mine, having assured reserves of 750 000 tons ore yielding, at 14¢ copper, $2 per ton profit, is operating at rate of 150 000 ton per annum, and its securities sell in open market at a price aggregating $2 000 000. At the annual profit of $300 000, the yield is 15%. Assured life, 5 yr. Table 5 shows that a 15% dividend rate requires 8.6 yr to amortize the principal, if 5% per annum return is to be had, or 15 yr, if the risk is such that a net 10% return is required. The $2 000 000 market valuation of the property therefore assumes a life beyond the assured reserves of between 3.6 and 10 yr, a sufficient rise in the aver price of copper above 14¢, or a combination of the two. The additional ore required, independent of change in price of copper, would be 540 000 to 1 500 000 tons. At an aver ore yield of 2 000 tons per ft of depth, these added tonnages would involve the continuation of the deposit with average strength for a further depth of 270 and 750 ft, respectively.

For determination of present value of well-developed mines, where total sales value of product, costs of extraction and marketing, are known, the probable life and investment risk may be estimated with considerable confidence (Sec 45).

15. VALUATION OF MINES HAVING NO ASSURED MINERAL, OR IN WHICH VALUE OF ASSURED MINERAL IS UNPROVED

To value mines of this kind is simply an attempt to discount the future, and is therefore almost entirely a matter of personal judgment. A great variety of method and conclusion, according to temperament and viewpoint of the engineer, must be expected. But the engineer should not make this an excuse for failing to give his client the benefit of his best judgment on this vital question, and statements in Art 12 as to prospective values and quantities apply here with equal force. All possible information should be secured regarding the property in question, neighboring properties and their relative location, the district in general, and results secured elsewhere from apparently similar properties. The strength and character of outcrop; extent of, and values shown by underground development and drill records or cores; apparent tendency of values to pinch or swell, to become enriched or impoverished, or to assume a simpler or more complex character with depth or with horizontal extent; likelihood of finding a feasible treatment process, and the total values per ton in the mineral mass, whether known to be recoverable or not, should all have weight in reaching an opinion.

General geological conditions should be considered, as to whether they are favorable to the deposition of quantity and value, or the reverse; and also respecting their similarity to those of successful properties elsewhere. As to geographical location, see Art 2.

All these points having been studied and digested, the engineer should allow himself to be influenced by his general opinion, or his instinctive feeling in the matter. Analysis of reasons for this opinion should be worked out and recorded, to enable the engineer to explain and defend his position to others and steady his own resolve during periods of doubt and uncertainty in subsequent developments. But an instinctive sense of conviction, rightly developed by exhaustive study and restrained by realization of its limitations, is of great value to the client, and should be cultivated by the engineer as a source of strength rather than suppressed as a weakness.

Example I. An enrichment of a highly acid rock (locally known as quartz-porphyry) was exposed by underground workings, near the center of a property, to the extent of about 500 000 tons of ore. Property included an area covered by the porphyry rock, about 0.75 mile wide by 1.5 miles long, generally iron-stained at the surface. Presence of value similar to that of the proved ore was revealed at nearly every point where shafts of a few hundred ft depth or less had been sunk. Bottom level of the principal workings and the main shaft sunk below it showed distinct tendency to impoverishment with depth, and the workings as a whole showed an enriched zone about 150 ft thick, lying beneath about the same thickness of leached overburden. Though a small, dark-colored basic dike was noted in one side of the underground workings and at the surface, study of this dike in connection with showings of value elsewhere on the property where no dike could be found, discouraged the theory that the dike was the origin of values. Altogether, the indications pointed to the existence of a secondary enrichment zone of fluctuating value at varying depths beneath the entire porphyry area. The apparently flat-lying position of the values quite near the surface suggested cheap prospecting by systematic drilling from the surface, and the rock being both hard and badly shattered, power churn-drilling promised to be best. Judging by the thickness and depth

beneath the overburden of the exposed enrichment zone, probably millions of tons further reserves could be proved. But, the assured ore was too poor for profitable operation by any process then known, and none of the outlying shafts promised that further development would yield materially richer ore. The further objection had to be met that those who were treating elsewhere richer deposits of same character doubted the possibility of making a success of so low a grade. Altogether the property could be given no definite value. But, success had been achieved elsewhere on even poorer ore (though differently constituted mineralogically) by large-scale work employing extensive equipment and large capital outlay. The promise of vast tonnage provable by drilling, at a fraction of a cent per ton, was therefore an attractive feature. If successful treatment could be devised, there would be ample justification for venturing the comparatively small amount of money necessary to prove the tonnage required to justify capitalization for large-scale equipment. Balancing one consideration with another, the engineer was finally convinced that, in spite of great uncertainties, the chance of large profit was sufficiently good to make the property a highly attractive venture. The client was so advised, but the large capital which would ultimately be required was not available. The engineer, therefore, advised the client to devote available funds to investigating processes, to proving the practicability of cheap tonnage development by drilling, to meeting the considerable expense of maintenance of the property, to interesting heavy financial interests, and to maintaining a cash reserve which would give such independence of position as would secure satisfactory terms when final negotiations for the transfer of the property to strong hands became desirable. Some 8 years elapsed between the forming of a small company on this basis, and the beginning of regular dividends. But in half that time the client had realized many times his investment from sale of part of the securities received on transfer of the property to large financial interests, and, the property becoming a marked success, his remaining holdings were eventually valued at a much greater amount.

Example II. A gold placer property on a small stream was limited at each end across the stream by property lines, while outcrops and drill holes on the side hills showed that the bedrock cut off the gravel on each side. Records of churn-drill holes, made by an experienced placer prospector, showed yardage and values which should leave an operating profit of several times the cost of a dredging equipment. But, as no trained engineer was responsible for the drilling, the records were of uncertain value. Further, there were too few holes, and they had been placed too irregularly to be conclusive, even if correctly drilled and recorded. Value calculations could not therefore be considered conclusive, but indicative only. The likelihood that the ground was valuable for dredging was emphasized, however, by the fact that the valley below had been successfully dredged, while drift-mining had been done above. As the company had contracted with a leading builder for a well-designed dredge, which was nearing completion, the most direct and cheapest mode of checking the drill records was to await beginning of dredging operations. Meanwhile the property had no proved value, and the engineer felt the enterprise could scarcely be considered a good gamble, even at the cost of the dredge. The client (owner of a minority interest) was therefore advised to consider further provision of funds only on the basis of a very limited valuation of the property, and then only as a pure speculation and in case satisfactory assurance could be given of proper financing and operating of the company. These conditions could not be fulfilled and, as the engineer had advised was probable, a receivership and ultimate sale of the property took place. To avoid losing his original investment the client bid in the property at a fraction of the cost of the dredge. Sufficient value was ultimately proved to cover the client's outlay, plus a reasonable profit; but only a trifle of the original hopes of the enterprise were realized, and only those willing to contribute to the purchase at the receiver's sale avoided total loss.

16. CONDUCT OF EXAMINATIONS AND OUTFIT REQUIRED

Preliminaries. All information furnished by the client (which may range from a mere statement respecting location and supposed value of the property, to reports and maps by skilled engineers) is reviewed, to gain an idea of the scope and character of the examination, and the time and facilities required to make it. The extent of development of the property, especially that of the exposure of mineral values, largely determines the time and equipment for sampling, and the importance of sampling results in reaching a valuation.

Upon the location and accessibility from the engineer's headquarters depend the time and expense required to reach and return from the property. Technical periodicals and transactions, and books on economic geology, sometimes yield useful information, through their own or special mining indices. The relations of the client to the property are usually such that free access is taken for granted; if not, the limitations must be understood and the scope of the promised report restricted accordingly. If any considerable outlay is required to gain access to underground workings, the question of providing for this cost should be understood.

Ideal examination, regardless of time or money, would be one made wholly by the engineer personally, who would thereby become thoroughly familiar with all conditions affecting the problem. But reports must be made within a reasonable time, and are generally needed as quickly as possible. Moreover, a competent engineer is too expensive a man to devote time to unimportant details, and some assistance is always required, if only for clearing out old workings. In case of a large, operating property, the whole mineral exposure of which must be sampled, and its records and operations reviewed, a corps of assistants is necessary for preparing a reliable report with reasonable outlay of time and money.

Assistants must be selected with great care. Their integrity must be beyond suspicion, the capacities of each well understood, and none should be taxed with responsibility that he is not well able to carry.

An assistant should be given work that is new to him only under supervision of an experienced superior. Bright young technical graduates make excellent raw material to train for sampling, surveying, drafting, and similar work. But an inexperienced graduate should never be sent into the field alone, except to gather preliminary information, his field work being checked by an experienced man before any important decision is reached.

Sampling. As this is usually the most tedious part of the examination it should be begun promptly; though not until enough information has been gained (preferably by inspecting the mineral exposures) to determine if the cost of thorough sampling is justified.

If only one trained assistant is required, he usually does the sampling, thus allowing the engineer to devote his time to more general investigations. For extensive sampling the assistant may himself require trained assistance, or at least unskilled help. The latter is generally obtainable at or near the property, though it is sometimes desirable to bring it in from the outside to lessen possibility of salting (Art 9). But the chief sampler can alone usually retake enough samples to detect fraud, thus making it generally feasible to employ local labor.

Expert accountants sometimes assist to a thorough understanding and analysis of the mine accounts, though the engineer's knowledge of bookkeeping may be sufficient for him to understand and check the local bookkeeper's explanations, who can, when so checked, make analyses or segregations.

Legal assistance is sometimes required, in dealing with complicated legal situations arising in connection with titles, leases, or contracts, though the explanations of the owner's legal adviser are usually sufficiently clear and final to make unnecessary the expense of independent advice. If the engineer be unable to grasp the full purport of any important item, he should secure a competent attorney whose interest in the matter is identical with his own (Art 2).

Estimation of time and expense for making an examination and report of an unknown property is difficult. There is great diversity in scope of investigations, and in state of development of properties. Also, an engineer frequently requires much time to bring his own experience into line with the conditions, and to get himself into such a definite and well-thought-out position that he can submit a reliable and convincing report.

In general, the examination of an unfamiliar property, and a report thereon requiring careful consideration, can rarely be made in less than 10 days' time. Hence, as a minimum fee, it is customary to charge 10 times the daily rate which the engineer's standing commands. As time spent in the engineer's own office is subject to the interruption of his routine work which he has the advantage of being able to keep in hand, many engineers count only half to three-quarters time for office work.

Contingent fees, dependent on or proportional to certain eventualities, though just and desirable in cases where the engineer's interests are identical with those of his client, are undesirable in examination and report work, because the engineer can not maintain the position of impartiality so important in making valuations. But, if a client unprepared to make direct payment offers a satisfactory contingent fee, the engineer may accept such fee provided his report shows that he is not disinterested (Art 1).

Specific features to be noted in examining different classes of properties: ANALYSIS OF SAMPLES for other than the principal value sought is usually limited to a few composite samples, or to special samples the appearance of which suggests that more complete analysis might yield useful information. COAL. Volatile, fixed, and total carbon, moisture, heat value, coking quality, sulphur, and any impurities objectionable to probable metallurgical uses, should be determined (Sec 30, Art 15). Presence or absence of gas in the deposit, character of roof and floor rocks, water problems, character of overburden (particularly quicksands) through which shafts may have to be sunk, and the practicability of mining several seams simultaneously, if present, must be studied in their bearing on operation of the property. IRON AND MANGANESE. Determinations should be made of Fe, Mn, S, P (for Bessemer ore, P should not exceed 0.1% of the quantity of Fe present), SiO_2, and Al_2O_3; also, if present in any quantity, moisture, CO_2, CaO, MgO, Ti, Cu, Zn, etc. OTHER METALS. Precious metals, Cu, Zn, Pb, Sn, Ni, Co, Fe, Mn, As, Sb, S, SiO_2, CaO, MgO, and Al_2O_3 should be determined according to circumstances. If several economic metals are present, the possibility and cost of separation by concentration or smelting must be considered. Penalties imposed and bonuses offered by the smeltery where the ore will be treated usually regulate the necessity for earthy, ferrous, and zinc determinations. PRECIOUS METALS IN SOLID-ROCK FORMATION. Au, Ag, and the proportion of value recoverable by free milling, concentration, cyaniding, or direct smelting are the principal determinations. Many of the determinations listed above may be made for their indicative value regarding probable method of recovery (Sec 30, 31, 32, 33). PLACER DEPOSITS. Au and Pt fineness and the assay of concentrates of Sn or monazite should be determined according to character of deposit. Amount and head of water supply; elevation and situation of available dump room; character, depth, and slope of bedrock; quantity and disposition of boulders or buried timber, cost of removal of surface vegetation, climate and governmental restrictions, must all receive especial consideration in examining placers (Art 7, 9).

Outfit required varies greatly, but the following suggestions may be found useful:

General

Pocket aneroid barometer
Brunton pocket compass
50-ft "metallic" tape in leather case
Pocket lens
Prospector's pick
Telegraphic code
Drawing instruments, with pencils, paper, india and red ink and tracing linen
"Art gum," ink, and pencil erasers
Soft and indelible pencils
Red, blue, and white crayon pencils
Fountain pen, and ink in traveling bottle
Loose-leaf note books (quadrille-ruled sheets)
Ruled stationery for drafting reports
Triangular scale of 6 scales, 1 in = 20 to 60 ft
1-ft steel folding rule
Pocket adding machine
Photographic camera

For Sampling

6 by 12-in and 14 by 20-in sampling sacks
Twine for tying above
Sample envelopes, with flexible metal-strip mouth
Seal and sealing wax
6 by 6-ft canvas, ticking, or enameled cloth (for moisture samples) sampling sheet
Jones sample-splitting outfit
Large iron mortar with pestle and canvas cover, or collapsible mortar outfit for coal (Fig 3)
Galvanized iron screw-top cans or glass jars for moisture samples
Adhesive tape for above
Leather mail sack, with lock and keys
Whisk, clothes, or scrub brush
Single and double-hand hammers
Miner's pick
3/4-in moils, 6 to 18 in, diamond points
Gold pan and vanning plaque

Additions for Placer Sampling

100-ft steel tape on reel
Level and rod
Carpenter's pencils
Magnet
1 by 3/8-in bottles, with corks, for gold colors
Portable gold balance, sensitive to 0.5 mg
Mercury
Annealing cups and nitric acid
Alcohol and lamp
Gummed labels
Short-handle shovel
Galvanized-iron panning tubs
Retort stand with alcohol stove

17. WRITING OF REPORTS

Report forms. The form of a report depends largely upon circumstances (Art 1). One form is that in which an introduction, consisting of the mere formalities of submission, is followed by a summary and brief statement of conclusions, followed in turn by the details of facts, conclusions, and advice. This form places the gist of the situation immediately before the reader. A busy man gets the information he wants in the minimum time, and the interest of any reader is more promptly aroused than when the entire report must be read before its conclusions are revealed.

The older still used form leads up through description to conclusions. This is advantageous in a report which can not be brought to an unequivocal conclusion, and where a correct impression can be given only by the atmosphere created by detailed description. For convenience of reference, the subject matter is divided by headings, usually capitalized, underscored and centered on the line, with sub-headings at the side, also capitalized and underscored. Below is a simple form of introduction, giving desirable information as to date and duration of the examination. This is followed by headings which have been found useful under various conditions. These, and the article and paragraph headings of this section of the book, furnish suggestions for deciding on the best form for a specific case.

..............................Esq., President, New York, June...., 19...
..........................Copper Co.,
......................Broadway, New York

Dear Sir:

Pursuant to your request, I have carefully examined the............property, spending ....days, from..............to.................., on the ground, and herewith submit my report thereon.

Summary and conclusion.

Location of the property, names and positions of claims or of different blocks, areas, and titles.

History, including shipments, profits, and difficulties met.

Economic geology, topography, vegetation, climate, transportation facilities, claim and topographical maps.

Governmental conditions (when below standard), taxes, laws and illegitimate influences.

Sampling methods, checks, limits of accuracy, and assay maps.

Tests on character and extractable value of the mineral.

Assured mineral, calculations, and amount.

Prospects and limitations of the property.

Present equipment (photographs), mine development, underground maps, methods of working and of treatment.

Supply and cost of labor, water, power, fuel, timber, explosives and miscellaneous materials.

Operating costs, general conditions, and profits. Financial condition of the enterprise.

Market (for mine product) conditions, and assumptions.

Advice, respecting development, scale of operations, equipment, and capital required;

Estimated returns. Acknowledgments (of courtesies received and to assistants employed).

18. ESTIMATING STANDING TIMBER (By Prof C. H. Burnside)

Estimates of timber tracts are based on amount of standing timber, cost of logging and of transportation, and value of land after logging. Depending on the degree of accuracy required in an estimate of STAND in a belt of timber, the work of the CRUISER, or timber estimator, varies from a rapid preliminary inspection to an exhaustive and detailed tree count. PRELIMINARY COUNT is made by running once through each 40 acres ($^1/_{16}$ section), called a "forty," to size up the timber in a general way or estimate number of trees in any selected strip. TOTAL COUNT is made by running through each forty 8 to 12 times, and actually counting trees on either side of a compass line for a distance sufficient to cover the whole area (23).

Cost of "cruising" is from 10¢ to $1 per acre, depending on accuracy of estimate.

Rules observed by timber-cruisers are generally crude, varying with the individual, and with the proportions of different kinds of timber. Thus, in southern U S, much timber runs only 3 to 5 M ft per acre. It is fairly uniform in stand and without heavy undergrowth, making it possible for a cruiser to go through on horseback, counting an acre at intervals, taking the aver result, and multiplying by number of acres in the tract for total count. In the northwestern U S, much timber land is a succession of ridges and canyons; undergrowth is heavy, making cruising difficult; timber is not uniform in stand (10-acre spots carrying little timber may adjoin an acre having 300 M ft or more); also the trees vary greatly in size, scaling from 5 to 25 M ft per tree. Under these conditions, a cruiser must count every tree, or as nearly so as possible.

Methods of estimating the stand are: (*a*) Counting trees in selected strips or circles, computing the contents of the aver tree and multiplying by number of trees to obtain stand per area covered. To obtain total stand per 30 acres, multiply the stand per area covered by a factor depending on percentage of acreage actually estimated. (*b*) Determining contents of each individual tree in selected strips or circles, and multiplying the total by a factor as in method (*a*). (*c*) Roughly estimating entire acreage by much criss-crossing of an area between compass (practiced mostly by men of long experience).

(*a*) and (*b*) differ but slightly; in the one case the number of trees is multiplied by an aver tree. in the other the trees are estimated separately and added for the total. There is little difference between circle and strip methods of counting, but strip method is always used for total tree count.

Volume of individual trees is found from a volume table, based on an ideal tree of uniform taper. The table gives board measure contents of trees ranging from 12 to 90 in

Volume Table, Showing Contents of Logs of Uniform Taper (23)

	Butt diam, 4 to 6 ft above ground, in	Diam at top of 32-ft log or fractional log, in							No of logs	Aver taper, in	Volume, bd ft	
		1st	2d	3d	3 1/2	4th	4 1/2	5th			From scale of individual logs	Volumes for same aver taper

	23	20	18	15	...	14	12	...	4 1/2	2 1/2	1 563	1 596
Douglas Fir	21	18	15	11	...	...	...	...	3	3 1/3	831	789
	21	20	18	16	...	15	12	...	4	2	1 657	1 406
	40	29	27	24	...	20	...	...	4 1/2	5	3 656	4 596
	44	37	34	31	...	27	...	19	5	5	6 650	6 476
	50	44	38	34	...	29	...	24	5	5	8 762	9 398
		Diam at top of 16-ft logs										
		1st	2d	3d	4th	5th	6th	7th				
Yellow Pine	18	16	15	14	11	...	...	...	4	1 3/4	475	451
	18	17	16	14	13	11	10	...	6	1 2/3	670	556
	18	17	16	15	14	12	10	...	6	1 2/3	727	556
	32	30	29	28	25	23	...	...	5	2	2 662	2 466
	32	31	30	28	25	23	20	15	7	2 1/2	3 164	2 537
	36	35	33	33	32	29	25	...	6	2	4 298	3 718
	36	34	34	32	31	30	27	23	7	2	4 699	4 059
	36	33	32	31	31	31	27	26	8	2	4 908	4 335

or more in butt diam, and carrying a different number of logs and a varying taper for each diam.

Diam of standing trees is determined by a DIAMETER TAPE, length and taper being found by measurement. Due to natural variations, the sum of the scale of the individual logs does not usually correspond to the volume given in the table for the aver taper of the tree; a tree rarely has same taper for each log; trees of same diam vary greatly in length and taper; and top and butt logs usually have a much heavier taper than those in middle of the tree. Estimator must decide upon taper and number of logs in a tree.

Details. A "two times run" through a "forty" is made at intervals of 2 tallies or 660 ft, estimating or counting trees for a distance of 25 paces (about 66 ft) on each side of the compass line, and multiplying the amount of timber by 5 for the total. A "four times run" is made at intervals of 1 tally or 330 ft and multiplying amount of timber by 2.5 for the total. In an "eight times run" (intervals of 164 ft), the estimator sends a survey crew ahead to locate corners, set tally stakes along the section to keep the compass-man in alinement, and do the pacing, while he counts trees.

If two or more runs through a forty are made, the estimator gathers data for a map, covering such topographic details as will give general characteristics of the whole tract. Elevations for contours are based on barom readings. As cost of logging a tract is as important to know as the amount of timber on it, a good map is essential for solving logging problems.

A cruiser's report may vary from a simple sketch of the section divided into forties, and the total amount in bd ft inserted on each, to an elaborate form reporting for each forty the number of trees of each species, their total contents, aver length, diam, and contents per tree, and percentages of different grades, with brief comments on the different species and logging conditions, all compiled from field notes. For large tracts, the detailed reports on forties or sections are usually supplemented by a descriptive report on the tract as a whole, describing character of timber, fire hazard, topography and accessibility of the country, general plan of logging and facilities for transportation.

A buyer wishing general information as to character of a stand of timber does not care to spend much money, and so sends an estimator on a preliminary cruise. If the report is satisfactory, a more detailed estimate is made. Where stumpage is $3 or $4, or higher, the buyer will probably want a complete tree count. An owner wishing to put his timber on the market needs an estimate and description on which to base his price.

SECTION 26

AERIAL TRAMWAYS AND CABLEWAYS

BY

EDWARD B. DURHAM

MINING ENGINEER

Note.—Numbers in parentheses in text refer to Bibliography at end of this Section.

AERIAL TRAMWAYS AND CABLEWAYS

Definitions. An AERIAL TRAMWAY transports loads in carriers suspended from wire ropes forming the tracks, between fixed points, usually a long distance apart. Tramways are divided into 3 classes: (1) bi-cable (formerly called double rope), (*a*) continuous, (*b*) reversible. (2) twin-cable; (*a*) continuous; (*b*) reversible. (3) mono-cable (formerly called single-rope), continuous.

On continuous tramways, a series of loaded carriers travel in one direction on a track cable, and empty carriers return in the other direction. On reversible tramways, one carrier travels back and forth on a cable. Bi-cable tramways have a fixed track cable, along which the carriers are hauled by a traction rope. Twin-cable tramways are similar, except that carriers run on a pair of track cables. Mono-cable tramways have a single running rope to support and move the carriers. A CABLEWAY transports a load for a short distance, in a single carrier traveling back and forth on a single cable, or on multiple parallel cables, a hoisting operation being combined with the transfer of the load; the operation is intermittent.

GENERAL FORMULAS

1. CABLE FORMULAS

Catenary *vs* parabola. Theoretical curve taken by a cable of uniform weight when suspended from its ends is a catenary; it is the curve of the funicular polygon formed by a series of equal weights hung equidistant along the ARC. Its equation is complicated and difficult to apply.

A parabola is the curve of the funicular polygon formed by a series of equal weights hung equidistant along the CHORD between 2 supporting points. It nearly coincides with the catenary for the flat arcs occurring in tramways, its equations are simple, and results by its use are practically correct.

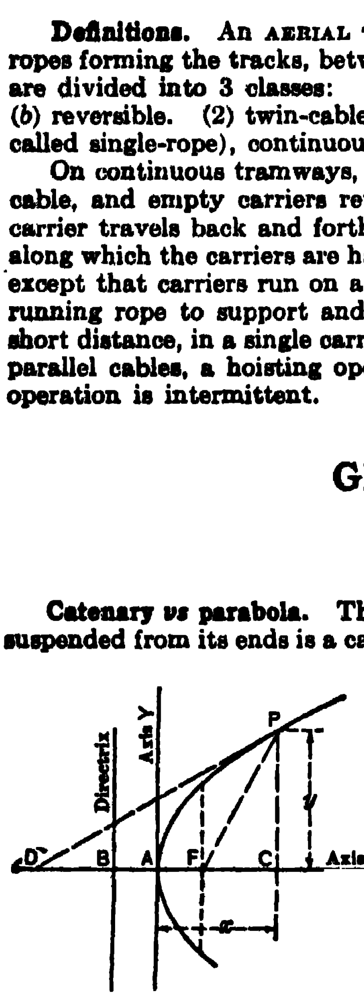

Fig 1. Parabola with Rectangular Axes

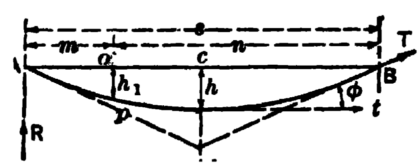

Fig 2. pty Cal Span

EQUATION OF PARABOLA (Fig 1) is: $y^2 = 2px$ (1)

Empty cable; level spans. In Fig 2, let: s = span, ft; h = deflection at center, ft; h_1 = deflection at any point of curve, as p, ft; t = tension in cable at center, lb = horizontal component of tension at any point; T = tension in cable at any point, lb; w = weight of cable per ft, lb; W = total weight of cable in span, lb = ws; R = total vertical reaction at a tower; for cable only, it is $\frac{1}{2} W = \frac{1}{2} ws$; m and n = sections into which point p divides span; ϕ = inclination of tangent to the curve at any point, as B.

Deflection at center. Take moments about point c of forces to left of center, then: $\frac{1}{2} W \frac{1}{2} s - \frac{1}{2} W \frac{1}{4} s = th$, or $\frac{1}{8} Ws = th$. But $W = ws$, hence, $h = ws^2 \div 8t$ (2)

Deflection at any point, as p. Take moments about point o of forces to left of it, then: $\frac{1}{2} wsm - wm \frac{1}{2} m = h_1 t$, but $wsm = wm(m + n)$, hence, $h_1 = wmn \div 2t$ (3)

Tension in cable at any point is: $T = t \div \cos\phi$ (4)

It is also equal to tension at any other point + or − the product of vert distance

between the 2 points and the wt of cable per ft. Thus, if V = vert distance between points B and p, the tension at p is: $T' = T - wV$ (5)

Bib 10a gives many cable formulas. Simplified working equations may be obtained by substituting numerical values for w and t in Eq 2 and 3; for with any one kind of cable w and t bear fairly constant ratio to each other. Thus, with locked-coil track cables, the wt of all sizes is practically 3.7 lb per ft per sq in of cross-section. The breaking strength of cast-steel grades is 121 000 lb per sq in, and with factor of safety of 3.5, the working tension is 34 600 lb per sq in. These values, substituted in Eq 2, give:

$$h = \frac{ws^2}{8t} = \frac{3.7s^2}{8 \times 34\,600} = 0.000\,012s^2 \qquad (6)$$

Table 1 gives wt and strength of cables used for track; by substituting the values for different cables in Eq 2 and subsequent formulas, a simplified equation suitable for any case is obtained.

Table 1. Weight and Strength of Track Cables

Diam, in	Locked-coil cables					Smooth-coil cables

2	10.00	316 000	90 300	430 000	123 000	8.40	370 000	82 200	436 000	97 000
2 1/4	12.50	......	......	560 000	160 000	10.36	466 000	103 600	532 000	118 000
2 1/2	15.20	......	......	690 000	197 000	13.10	570 000	126 700	670 000	149 000
2 3/4	18.30	......	......	840 000	240 000	......	......	......	......	......
3	22.20	......	......	1 000 000	286 000	......	......	......	......	......

The above weights and breaking strengths are given by Amer Steel and Wire Co (Bib 10a). The working strengths were calculated by author, using safety factor of 3.5 for locked-coil cable, and 4.5 for smooth-coil; these low factors are reasonable for reliable material like steel wire and where working stresses are nearly all tensile and can be determined with a high degree of accuracy. On tramways, it is customary to apply tension by means of weights, and hence overloading is improbable; also the cables are elastic and can absorb occasional shocks without injury. Where the tramway or cableway has a single span and track cable is anchored at both ends, there is a possibility of overloading; hence, it is advisable to increase the safety factors, but not above 4.5 and 6 respectively, for locked- and smooth-coil. On reversible tramways with a single heavy carrier, the cable can be treated as though counterweighted, even if anchored at both ends, because the slack will shift as the bucket travels. Track cables are also called track strand, and smooth-coil type, round-wire track strand. For aerial tramways, track cables have not exceeded 2 in diam (Art 7); for cableways all sizes are used (Art 23–27).

Slope of tangent to curve of empty cable. The tangent at end of span, when chord is horizontal, has a slope (Fig 3) of $\tan\phi = 2h \div \frac{1}{2}s = 4h \div s$ (7)

Substituting value of h from Eq 2: $\tan\phi = ws \div 2t$ (8)

but $ws \div 2$ is the reaction R, hence: $\tan\phi = R \div t$ (9)

In any one case, w and t are constant; hence Eq 8 can be simplified by substituting numerical values. Thus, for cast-steel locked-coil cable, w = 3.7 lb and t = 34 600 lb, giving $\tan\phi = 0.000054\,s$.

Concentrated loads. Let Fig 4 be the funicular polygon resulting from 3 concentrated loads, g_1, g_2, g_3, and a, b and c be their respective distances from right-hand end. Then the reaction at left-hand end is: $r_1 = \frac{g_1a}{s} + \frac{g_2b}{s} + \frac{g_3c}{s}$.

Taking moments about o gives: $r_1m = h_2t$, or $h_2 = r_1m \div t$ (10)

If wt of cable be included, moments about point o are:

$$R_1m - \tfrac{1}{2}\,wm^2 = Ht, \quad \text{or} \quad H = \frac{R_1m - \tfrac{1}{2}\,wm^2}{t} \tag{11}$$

In Eq 11, R_1 is reaction at left end, when both cable and concentrated loads are considered, and equals $\frac{g_1a}{s} + \frac{g_2b}{s} + \frac{g_3c}{s} + \tfrac{1}{2}\,ws$; and H is deflection at point o. Hence, deflection at any point for any loading equals moment, M, of all vert forces on one side of o, divided by the horiz tension, or $H = M \div t$ (12)

Experience shows that in spans carrying 3 or more equal loads, uniformly spaced, deflection at any point is practically the same as for a uniformly loaded cable of which the wt per ft

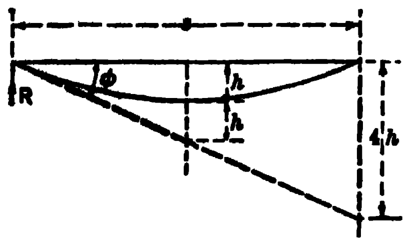

Fig 3. Tangent to an Empty Cable

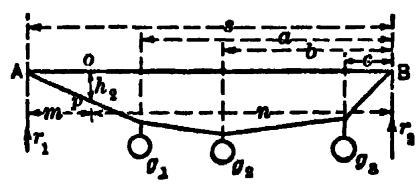

Fig 4. Funicular Polygon Due to Loads Only

is equal to the wt of cable plus that of one load divided by the spacing in ft. If value of R_1 be substituted in Eq 11:

$$H = \frac{R_1m - \tfrac{1}{2}\,wm^2}{t} = \frac{r_1m + \tfrac{1}{2}\,wsm - \tfrac{1}{2}\,wm^2}{t} = \frac{r_1m}{t} + \frac{\tfrac{1}{2}\,wm}{t}\,(s - m)$$

but $(s - m) = n$, whence $H = \frac{r_1m}{t} + \frac{wmn}{2t}$. Also $\frac{r_1m}{t} = h_2 =$ deflection at p due to concentrated loads (Eq 10), and $\frac{wmn}{2\,t} = h_1 =$ deflection at p due to cable (Eq 3). Hence, total deflection at any point is the sum of the deflection due to cable alone and that due to load alone.

Deflection due to one concentrated load. Three cases commonly occur: One load AT ANY POINT. Deflection at that point, by Eq 11, is:

$$H = (ws + 2\,g)\,\frac{mn}{2\,st} \tag{13}$$

One load AT CENTER. Deflection at center is found from Eq 13, by making $m = n = \tfrac{1}{2}\,s$, whence:

$$H = (ws + 2\,g)\,\frac{s}{8\,t} \tag{14}$$

One load AT DISTANCE y from one end. Deflection at point distant m from same end is found by applying Eq 11. The reaction R at opposite end of span for 1 load plus cable is $gy \div s + 0.5\,ws$. Taking moments at R gives: $th = Rn = 0.5\,wn^2$. Substituting above value of R, $H = (wms + 2gy)n \div 2\,st$.

$$H = (wms + 2\,gy)\,\frac{n}{2\,st} \tag{15}$$

Inclined Spans. Parabola with inclined axes. Let Fig 5 be such a parabola; then by analytical geometry:

$$y_1^2 = \frac{2\,p}{\sin^2\beta}\,x_1 \tag{16}$$

Empty cable. Let Fig 6 represent such a case, l being length of chord. Applying principle of moments:

Deflection at center, $$h = \frac{wls}{8t} = \frac{ws^2}{8t\cos\alpha} \qquad (17)$$

Deflection at any point, $$h_1 = \frac{wmn}{2t\cos\alpha} \qquad (18)$$

Cable carrying concentrated loads; chord inclined. Total deflection at any point is the sum of deflection due to cable alone and that due to loads alone. Deflection due to cable alone is given above. Deflection at any point due to loads alone equals moment

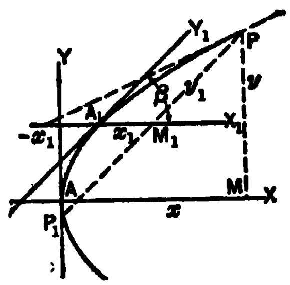

Fig 5. Parabola with Oblique Axes

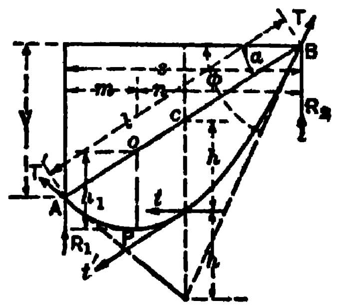

Fig 6. Empty Cable on an Inclined Span

of vert forces due to loads on one side of that point, divided by horiz tension (similar to Eq 10), thus:

Load at any point of an inclined span. Deflection at load is:

$$H = (wl + 2g)\frac{mn}{2ts} \qquad (19)$$

Load at center of an inclined span. Deflection at load is:

$$H = (wl + 2g)\frac{s}{8t} \qquad (20)$$

Load at distance y from one end of an inclined span. Deflection at a point distant m from same end, with moments taken about opposite end (see analysis for Eq 15):

$$H = (wml + 2gy)\frac{n}{2ts} \qquad (21)$$

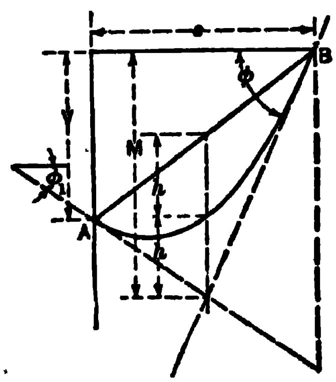

Fig 7. Tangent to an Empty Cable

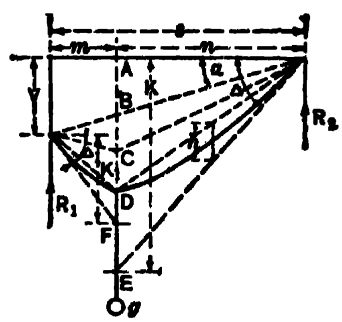

Fig 8. Tangent to a Loaded Cable

Slope of tangent to inclined empty cable. Let Fig 7 be inclined span. Then slopes of tangents to the two ends are:

$$\text{At } B,\ \tan\phi = \frac{M}{{}^1/_2\,s} = \frac{4h + V}{s} \qquad \text{At } A,\ \tan\phi_1 = \frac{M - V}{{}^1/_2\,s} = \frac{4h - V}{s}$$

Hence, slope of any tangent is: $\tan\phi = \dfrac{4h \pm V}{s}$, in which V = vert distance between ends of span, ft. (22)

Loaded cable. Let Fig 8 be an inclined span with concentrated load at some point. Slopes of tangents to the two ends are: $\tan\Delta = K \div n$ and $\tan\Delta_1 = K_1 \div m$. But K and K_1 are made up of a series of known parts. Thus, $K = AB + BC + CD + DE$, and

$$AB = \frac{V}{s}n;\quad BC = \frac{gmn}{st};\quad CD = \frac{wmn}{2t\cos\alpha};\quad DE = 4h = \frac{4wn^2}{8t\cos\alpha}$$

Substituting these in above, and simplifying:

$$\left.\begin{aligned} \tan\Delta &= \frac{gm}{st} + \frac{ws}{2\,t\cos\alpha} + \frac{V}{s} \\ \tan\Delta_1 &= \frac{gn}{st} + \frac{ws}{2\,t\cos\alpha} - \frac{V}{s} \end{aligned}\right\} \tag{23}$$

Length of parabolic curve. The length of a symmetrical parabolic curve, L, when the rise is small, is closely approximated by equation (Weisbach's "Theoretical Mechanics," trans by E. B. Coxe, p 299)

$$L = s + \frac{8h^2}{3s}, \quad \text{or} \quad h^2 = \frac{3}{8}s(L - s) \tag{24}$$

If chord be inclined, the length, for taut curves common in tramway practice, may be taken as equivalent to a symmetrical parabola having same chord length and same deflection *normal* to the chord. The normal deflection is nearly equal to: vert deflection $\times \cos\alpha$. Bib 10a treats of length of curve when stretch of cable is considered.

Horiz tension (t). In tramway construction, cables are stretched by tension applied to one end of span (usually by a weight), equal to working tension of cable. This tension is used in formulas for the value of t; it makes the actual horiz tension in cables a little less than that used in the calculations, and hence the sag will be greater than calculated. Owing to flatness of the curves, this error is not serious, when the chord is at a low angle. But on inclined spans it may make considerable difference; the error can be partly compensated by calling the applied tension t', and assuming that its direction is parallel to inclined chord; then the approx horiz tension will be $t = t' \cos\alpha$.

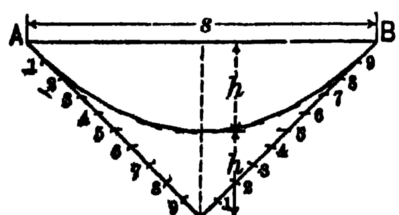

Fig 9. Plotting a Parabola, Axes Rectangular

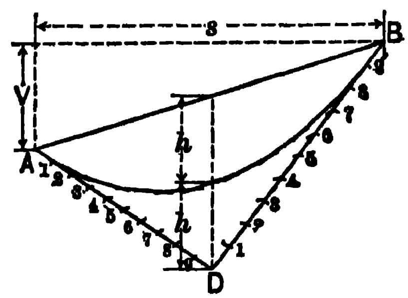

Fig 10. Plotting a Parabola, Axes Oblique

Plotting of parabolic curves may be done by points or by tangents. BY POINTS: Series of offsets is calculated by Eq 1 or 3, if chord be horis; or by Eq 16 or 18, if chord be inclined. These are plotted, and a curve is passed through their lower ends. BY TANGENTS: Chord of span and center deflection are plotted to desired scale, as in Fig 9 or 10 (same method applying whether chord is horis or inclined); deflection is prolonged to a total length of 2 h; lines drawn from ends of chord to this point are tangents to the curve. These tangents are then divided into same number of equal parts, numbered as shown. Lines are next drawn connecting corresponding numbers; these are tangents to the curve, and the curve can now be drawn tangent to them. By making a sufficient number of divisions in the two end tangents, the sides of the polygon formed by the tangents will be short and practically form the curve, as shown in Fig 9 and 10, where for clearness only the end tangents have been drawn.

2. OPERATING FORMULAS

Spacing of carriers. For a system operating a continuous series of carriers, let: t = time interval between carriers, sec; d = distance between carriers, ft; l = load in one carrier, lb; n = number of tons (2 000 lb) to be carried per hr; v = velocity of tramway, ft per min. Then, $n \times 2\,000 \div 3\,600$ = lb per sec to be carried by tramway, and this divided into l, gives time interval in sec, reducing to $t = 1.8\,l \div n$. (25)

Distance between carriers is, $d = tv \div 60$, reducing to $d = 0.03\,lv \div n$. (26)

Tension in traction rope. Tension in a rope holding any body at rest on an incline, neglecting friction, is $T = W \sin\alpha$. Friction of a body moving on an incline is, $F = f'W \cos\alpha$; in which: T = tension parallel to the plane, in same unit as W; W = total weight of bodies on the plane, preferably in lb; α = inclination of plane; f' = coeffic of rolling friction = 0.02 with plain bearings for sheaves and carriage wheels, and 0.01 for ball or roller bearings; F = total friction, in same unit as W.

When the body extends whole length of incline, as a rope lying on it, then total weight is $W = wL$, where: w = wt per ft, in same unit as W, preferably in lb; L = inclined length

of the plane, ft. Substituting this value of W in general equations for T and F above, gives:

$$T = wL \sin \alpha = wV \tag{27}$$

$$F = f'wL \cos \alpha = f'wH \tag{28}$$

in which: V = vert distance between ends of plane, ft; H = horiz length of plane, ft.

Tension in traction rope of a double-rope tramway, or in endless rope of a single-rope tramway, at its upper end, taking friction into account, will be: $T = wV \pm f'wH$ (29)

Sign of last term is $+$ when rope is being pulled up the incline and $-$ when it is moving down. If rope be empty, w is the wt per ft of rope alone; but if carriers be attached, w must be increased by wt of the carriers including their load, if any, uniformly distributed over whole length of incline, or else the effect of carriers must be calculated separately and added to value of T. Tension T is further increased by pull exerted by tension weight applied to the floating sheave; half the pull on this sheave being added to traction rope tension on each side of tramway.

3. TRANSMISSION OF POWER BY BAND DRIVES

This discussion is applicable to any type of band or rope drive, or to band brakes where tension is known.

In a band drive, tension on slack side must bear a certain relation to tension on taut side, to develop sufficient friction to prevent slipping. The formula for this relation, from analytical mechanics, is: $T = Se^{f\pi n}$ (30)

in which T = tension on taut side; S = tension on slack side, both in same unit, preferably lb; e = base of Napierian logarithms = 2.71828; π = 3.1416; f = coeffic of friction (values given in Table 2); n = number of half laps on drum (number of turns of 180° each).

The useful effect, or force transmitted by the drive, is the difference between tensions on the two sides, that is, $T - S$. If S be subtracted from both sides of Eq 30, this becomes, on reducing: $T - S = S\,(e^{f\pi n} - 1)$ (31)

which is an expression for force transmitted by a band drive, and is useful in determining S for a given drive when force to be transmitted is known. Table 3 gives values for $e^{f\pi n}$ for a number of combinations, for saving time in applying Eq 30 and 31.

Most calculations for tramway drives and brakes are based on the coeffic of friction for wet ropes, as this often occurs; neither rope nor brake should ever be greasy.

Grip sheave, as in Fig 29, has a series of jaws about its circumference which are tightened by the rope's press; these multiply the press between rope and sheave by the ratio of lever arms of the jaws, and hence proportionately increase the friction. For a grip sheave with iron or steel jaws, having leverage of 1 : 3, the value of $e^{f\pi n} = 2.228$, and where the leverage is 1 : $3^1/_2$, $e^{f\pi n} = 2.5$, in both cases with rope for which $f = 0.085$.

BI-CABLE TRAMWAYS

4. GENERAL CONSIDERATIONS

Elements. A bi-cable tramway consists of: 1, two track cables stretched at required tension; 2, an endless traction rope for moving the loads; 3, numerous carriers for the loads, each fitted with carriage or trolley to run on track cable and a clamp or grip for seizing traction rope; 4, a station at each end to operate or control the traction rope and provide places for loading and unloading carriers; 5, intermediate towers for supporting track cable and traction rope.

In operation, each load is placed in a carrier while standing on a track in loading terminal; the carrier is then attached to traction rope, and hauled to discharge terminal; there it is released from traction rope and contents are discharged. Empty carrier is then attached to traction rope on return side and is hauled back to loading terminal.

Capacity. Economic limits of capac for ordinary bi-cable tramways are approx 10 and 100 ton per hr. If less than 10 ton per hr, it is more economical to operate tramway fewer hours or on alternate days, than to reduce carrying capac.

Demand for tramways for traffic exceeding 100 tons per hr has recently developed special heavy equipment and structures, permitting construction of lines carrying up to 300 tons per hr.

Length. It is seldom wise to use bi-cable tramways for distances less than 1 000 ft, because terminal machinery costs as much as for a longer line and so makes first cost excessive. Max limit, under favorable conditions, is about 4 miles; the resulting 8 miles of traction rope is as long as can be operated successfully; the tension in traction rope becomes excessive; an exceptional case occurred on the Benguet tramway, which is 49 500 ft long (Art 17). For very long distances, a series of tandem tramways can be built, and the carriers switched from one to another; but each division is practically an independent tramway. Thus, a tramway at Chilecito, Argentine, 21 miles long (Art 17) has 8 divisions. In any tramway, the track cables are divided into sections of 3 000 to 5 000 ft each, one end of each section being anchored and tension being applied to the other end; each section of cable may be made up of as many pieces as desired, provided the couplings do not come close to tower saddles. As the carriers pass through anchorage and tension stations without interruption, lengths of cables limit neither operation nor possible length of line or division.

Loads. Net weights of 500 and 2 000 lb are the usual lower and upper limits for loads on ordinary tramways; below 500 lb there is no saving in cost of carriers, and for over 2 000 lb the wear on cables is great. The time interval between carriers is conveniently about $^1/_2$ min. Then 2 000 lb every $^1/_2$ min = 120 tons per hr, and is near the maximum capac of bi-cable tramways, using two-wheel carriages. In recent practice, larger and stronger track cables permit use of higher cable tensions, and 4-wheel carriages are used to keep the wheel load down. Net loads to 4 000 lb are carried where the necessity for large tonnage warrants the extra cost of plant (Art 6a).

5. TRAMWAY SURVEYS

Survey of proposed route, with surface elevations, must be made and a profile of center-line must be plotted before a tramway of any type can be designed. At summits, or wherever sudden changes in profile occur, elevations should be determined at intervals of 25 or 50 ft. The stations staked out may be numbered 1, 2, 3, etc, for distances of 100, 200, 300, etc, ft from the origin, as in R R surveying; intermediate distances are noted as + ft from preceding station. In very rough country, distances and elevations of important points on summits may be determined by stadia measurements, and the position of additional points on each side by taping and leveling from the stadia points. In any case, the data collected must be such that an accurate profile can be plotted.

Location line of tramway should generally be straight, as this is the shortest distance between terminals, and cheapest to build and operate. An exception occurs where tramway passes over a ridge, with a sharp summit in profile; then, for a large tonnage, or where the summit is high or slopes are steep, it is advisable to search for a lower pass, even if off the direct line; a second profile is made from loading terminal straight to this pass and thence straight to discharge terminal, making a horiz angle between the lines at the pass. It may be found, on laying out the two routes, that the one with the angle is the better. If the ground has a steep cross slope, say over 15° (or 1:4), cross-sections should be made at intervals, so as to describe the conditions.

Additional data. Besides profile of center-line, the survey should include plan of site of both terminals, with contours; and show position of all buildings to which tramway must be connected. These plans should cover an area considerably larger than the proposed terminal, say 50 ft on each side of center-line and 300 ft along it. Similar plans should be made of sites along the route where intermediate stations are likely to be located, in order to place all conditions before the designer. Relation of plans and cross-sections to points on profile must be given by reference marks on each, and permanent marks left on the ground so that the line can be located when construction is begun. It is important to preserve survey points near terminals, and if these are likely to be destroyed by excavation for the structure, other reference points must be set. Survey should be plotted by profile, cross-sections, and plans, before leaving the locality, to insure that all necessary data have been secured; but survey notes giving distance to, and elev of, each point should be sent in with the plots, so that the latter can be redrawn, if desired, without having to scale the surveyor's drawings.

6. DESIGN OF BI-CABLE TRAMWAYS

Proportioning of interrelated parts of tramways depends on many variables and conditions. Values in Table 4 apply to lines with easy grades, and are useful for preliminary layouts. For conditions which increase difficulty of design, see Art 6*a*.

Table 4. Relations of Cable Sizes, Loads, Etc, to Tonnage

Tons per hr	Diam of cast-steel Cables, in		Loads			Gage, ft	Carriage
	Loaded side	Empty side	Wt of material, lb	Wt of carrier, lb	Total load, lb		
5 to 10	1	7/8	500	300	800	6	Light
15 to 20	1 1/8	7/8	700	400	1 100	6	"
25 to 30	1 1/4	7/8	900	425	1 325	6 or 8*	Heavy
40 to 50	1 3/8	7/8	1 200	450	1 650	8	"
60 to 75	1 1/2	1	1 600	500	2 100	8	Extra heavy
80 to 100	1 5/8	1	2 000	550	2 550	8 or 10*	"

* Wide gages are needed for long lines, where driving machinery must be large.

These combinations are based upon the fact that the size of load for a given tonnage determines the number of carriers on the line; if load be small, the cost of rolling stock is increased, due to the number of carriers, since part of cost of each unit is constant; if load be large, the size of track cable increases in proportion to the individual weight carried, although the loads may be few in number. An empirical rule sometimes used to determine SIZE OF CAST-STEEL TRACK CABLE is to permit a gross wt of carrier = to 1 200 lb per sq in of cross sec of cable on small sizes, and increase permissible load to 1 400 lb per sq in of section on larger cables, assuming sectional area equals that of solid bar of same diam. The GAGE (distance apart of track cables) may be 6 ft for small carriers, but must be 8 ft for large ones, and may need to be 10 ft to suit bulky materials.

Tramway speeds must be high to carry large tonnage without increasing weight of moving parts, nor the stresses due to their weight, but when speed is too high it is difficult to handle the carriers at terminals. The practical speed is about 8 ft per sec, with 10 ft per sec as max with favorable conditions and careful designing.

Let Fig 11 be a typical profile on which is to be built a tramway to carry 60 000 lb broken ore per hr, weighing 100 lb per cu ft. By Table 4, the cables will be 1 1/4 and 7/8-in diam. Let carrier capac be 800 lb, and gage 8 ft. If speed be taken at 480 ft per min, the spacing of carriers will be (Eq 25 and 26): time interval $t = 1.8\ l + n = 1.8 \times 800 + 30 = 48$ sec, and distance apart $d = tv + 60 = 48 \times 480 + 60 = 384$ ft. An 8-cu ft bucket weighs 420 lb, making gross weight of one loaded carrier = 420 + 800 = 1 220 lb.

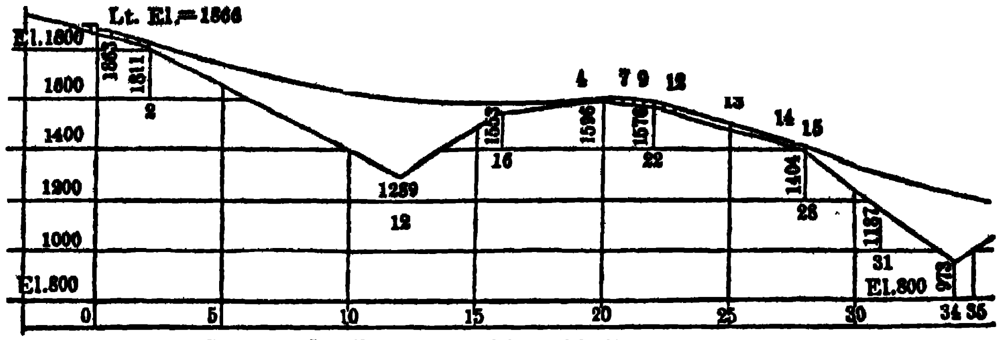

Fig 11. Profile of Typical Bi-cable Tramway

Locating the line. The profile is plotted to a natural scale, say 1 in = 40 ft on "Plate A" profile paper, 20 in wide, ruled 4 by 20 lines to the inch. If difference of elev between ends of line be great, several strips may be joined together to get required width. If line is too long to be operated as one division the junction points are determined and each division is laid out as a separate line; later, the junction stations are designed (Art 16).

By inspecting the profile, points where a rope stretched from one terminal to the other would first touch the ground can be seen; in Fig 11, these will be at Sta 21 and 50. The profile is then tacked to a long table, exposing one portion of the line, say from loading terminal to the first high point; and the terminal structure is plotted in outline to fit roughly the conditions imposed (Art 16). A pin is set in the terminal at point where cable leaves the horiz rail, another pin is set at the minimum height of tower at the ridge (say 12 ft if snow does not lie there over 3 ft deep); a silk thread is looped over one pin, passed around the other and led over the edge of the table where the spool's weight (a hitch having been taken in thread to prevent unwinding) draws it tight. If the profile paper be ruled in green, and red thread used, there will be no confusion with black ink or pencil lines that may be added. The thread represents a chord, from which the cable curve can be plotted by laying off deflections at as many points as necessary. If it develops that the chord is not in best place, it is shifted by moving the pins. It can be subdivided into shorter chords by holding it with intermediate pins. Tramways are usually laid out for the heavy cable; the light one carries only the empty carriers and will fit same supports as the loaded one, though sometimes it may be necessary to lay it out for separate study.

Towers. The location and height of towers must be such that: *a*, track cable will lie firmly in the saddles under all conditions of loading; *b*, angle made by cable over any saddle at a crest will not be excessive. These requirements are expressed by EMPIRICAL RULES: 1. The tops of towers are brought up to a CONSTRUCTION CURVE, the tension of which is 1.5 times the working tension of track cable. 2. The deflection angle α, Fig 12, made by empty cable over any saddle, shall not exceed 2° 52′; that is, an angle the tangent of which is 0.05. As these angles are conveniently laid out by their tangents, they are referred to as deflections of 0.05 or 5%. But, the tower at end of a long span should have no deflection over it when cable is empty. Angle α is the deflection between chords only for short spans; on others, it is the deflection between tangents to adjacent empty cable curves.

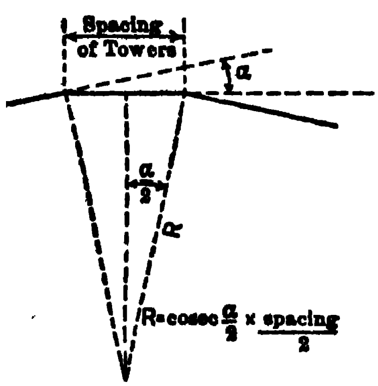

Fig 12. Derivation of Table 5

After preliminary layout is finished, different points on the line are studied separately (Art 6a), the position of cable is determined mathematically and the design modified to fit the specific conditions.

Construction curve has a tension 1.5 times that of the working curve, hence its equation for cast-steel cables is:

$$h = \frac{ws^2}{8t} = \frac{3.7\,s^2}{8 \times 34\,600 \times 1.5} = 0.000\,009\,s^2 \qquad (32)$$

in which 3.7 = wt per sq in of steel in cable 12 in long, and 34 600 is working tension per sq in of steel (Eq 6).

To plot construction curve, points are located at intervals by deflections from the chord, as marked by the thread, and construction curve is then drawn through them, by wooden curves. These curves should be 18–24 in long, made by laying out deflections from a chord for a number of points, by Eq 3, using proper constants, and must be con-

structed on same scale as the plot. The towers are then plotted in outline at convenient points, with their tops at the construction curve and the curve of the cable at working tension (with or without loads) is drawn in between them, thus forming a slight angle at every tower.

On long spans, the loaded position of the cable should be calculated and plotted, and its relation to towers and ground investigated. If there are 3 or more loads on a span,

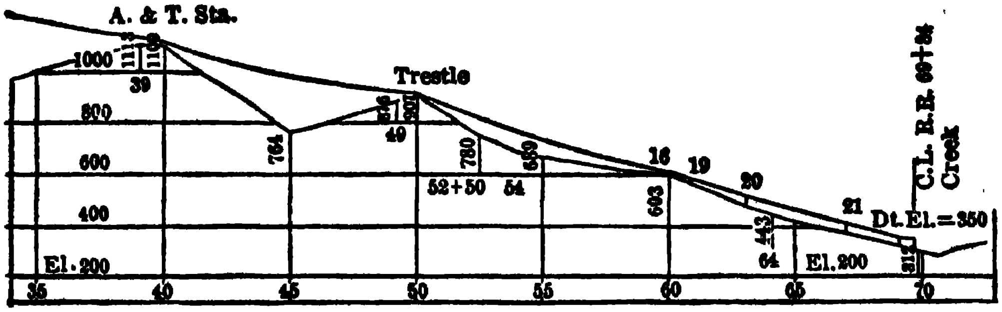

Fig 11. Profile of Typical Bi-cable Tramway—*Continued*

their effect is practically the same as an equivalent load uniformly distributed; hence the wt per ft w, in equation giving the deflection, will be:

$$w = wt\ cable\ (lb\ per\ ft) + \frac{gross\ wt\ of\ carrier\ (lb)}{spacing\ (ft)} + wt\ of\ traction\ rope\ (lb\ per\ ft) \qquad (33)$$

In Eq 33, spacing is found by Eq 26, and the traction rope, for preliminary determination, may be taken as 0.75-in diam, weighing 0.89 lb per ft. With only 1 or 2 loads on a span, the deflection at load points is found from Eq 11. Having determined deflection at one or more points, a smooth curve connecting them with the end points can be drawn. If spans are inclined, the formulas for deflections of inclined spans must be used (Art 1).

Application of rule 1 for locating towers is shown in Fig 11, from Sta 50 to the discharge terminal. A pin is set 15 ft above the ground on profile at Sta 50, another at end of rail in the terminal, and the thread is stretched. As the construction curve would strike surface at Sta 60, a pin is placed here about 10 ft above ground, giving 2 chords. From Sta 60 to terminal, the chord is not far above ground; hence the construction curve is drawn and towers 20 and 21 are place under it, to divide the space about equally and avoid a tower in the hollow.

Exceptions are sometimes made to the rule requiring towers to reach up to the construction curve: 1, if spans are long, causing a great difference in sag between empty and loaded conditions of cable, involving sharp bends over the towers; 2, if the line crosses a ravine, where it could not be operated without towers, but where the towers would be unduly high if brought up to construction curve. In both cases, the tops of towers are placed along a slacker curve, and the empty cable is prevented from lifting out of saddles by steel plates bent over the cable and fastened to saddles. The curve through tops of towers should be high enough to cause cable to bear in the saddle when line is loaded, and so relieve the hold-down straps. When this construction is used, the position of traction rope must be investigated, as it may be taut enough to lift and foul track cable or tower saddles, if there are no buckets on the span to hold it in normal position. Designing on basis of loaded cable is further discussed in Art 6*a*, under Broad Valleys.

Construction at crests is a difficult problem. The principal wear on track cable occurs near towers, and this is aggravated at crests by the downward pressure due to pull of traction rope, added to weight of carrier. Downward pressure is minimized by making the curve over the crest as easy as possible, by introducing a series of towers at short intervals and distributing the bend among them.

Illustration of this occurs at Sta 60, Fig 11. A pin having been set at Sta 60, a tower is placed equidistant on each side of it; the one on upper side is so placed that the cable will make a 5% deflection over it when span is loaded, and the end tower on lower side is brought up to curve of the empty cable, with no deflection. Total deflection angle between tangents to these two curves is 8°. A deflection of 5% per tower corresponds to an angle of 2° 52′, which, divided into 8°, indicates that 3 towers are needed. A fourth tower, No 19, is added and brought up to construction curve drawn from No 18, to take the bend due to a loaded carrier in the span from No 19 to No 20. The profile makes it convenient to place the towers 40 ft apart.

The location of towers at a crest is expedited by using a set of circular curves, finding by trial the one that fits between tangents to the two cables and is best suited to the profile, and then building the towers up to this curve. If the towers are lined on a circular arc, and an equal deflection occurs at each, they will be spaced at equal chord-lengths along the arc, the radius of which can be calculated for any chord. Radius of the curve through

towers, for different deflections and tower spacings, is given in Table 5, the data on which it is based being shown in Fig 12.

Table 5. Radius of Curve Through Towers (All dimensions in feet)

Deflection	Tangent	Angle α	Cosec $\frac{1}{2}\alpha$	Spacing of towers, measured on the curve									
				10	20	30	40	50	60	70	80	90	100

At crest at Sta 21, a similar group of towers occurs, and Fig 13 gives graphic solution of problem. A point A, at Sta 21 and El 1 600, is taken as a trial point and a chord drawn to Tower No 3. It is

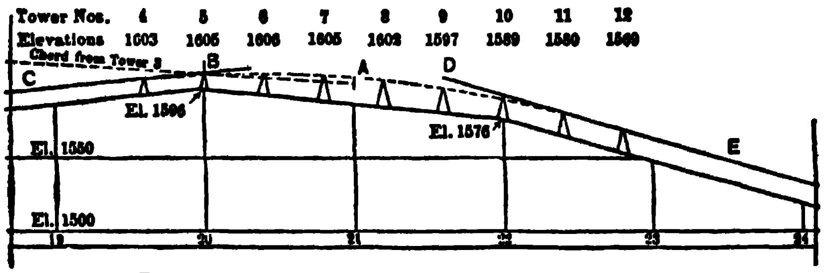

Fig 13. Details of Construction at Sta 21, Fig 11

evident that a curve drawn to this chord will strike the ground, hence Sta 20 is a more suitable terminus for the chord. A point B is therefore set at Sta 20 and El 1 605, and a new chord drawn to Tower No 3, giving a span from Sta 2 to Sta 20 = 1 800 ft horizontally. Next, the center deflection of loaded cable is computed and the tangent B to C is constructed. On the right of summit it is evident that the cable will follow slope of ground to Sta 28, hence a line DE is drawn parallel to and 15 ft above ground. A trial of several circular curves shows that one of 20-in radius (which, at scale of 1 in = 40 ft, corresponds to 800 ft radius), laid tangent to the lines BC and DE, conforms to the profile. By Table 5, the 800-ft curve corresponds to towers 40 ft apart, for deflections of 5% on each. This arc is then drawn in, towers are set near tangent points, with a distance between them equal to a multiple of 40 ft, and other towers are plotted up to the curve with a spacing of 40 ft, thus giving 9 towers for the vert curve.

Tramway trestle is a structure with a series of saddles mounted at intervals of 5–20 ft, with a slight deflection of cable at each saddle, and is used on a summit where a group of towers would be objectionable.

Fig 14 shows an application of this construction, for conditions at Sta 50 (Fig 11). The figure also gives, for comparison, the graphic solution for a series of towers, similar to arrangement at Sta 21.

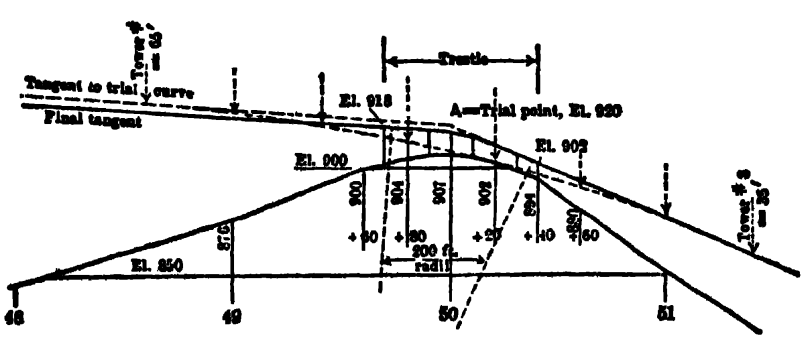

Fig 14. Details of Construction at Sta 50, Fig 11

A trial point A is set at Sta 50 and El 920 and, as the spans are long, the tangents to loaded cables are drawn on both sides, AB and AC. A curve of 800-ft radius is drawn tangent to these lines, and towers are spaced 40 ft apart, giving the 8 towers, shown by dotted lines and inverted arrows; but these are undesirable, owing to their heights (upper one being 65 ft high) and to necessity of cutting the summit of ridge. Next a trestle with saddles 10 ft apart and a deflection of 5% on each is

investigated. Under these conditions, the saddles will lie on a curve of 200-ft radius (Table 5). This curve, placed tangent to the lines *AB* and *AC*, is unnecessarily high at the left, hence line *AB* is lowered, which moves point of intersection of tangents to the right. The structure adopted is shown by full lines.

In making final design of a trestle, the elevs of end points are scaled from profile, the inclinations of tangents to loaded cables are computed and the difference is the angle of deflection between the two tangents; this divided by the angle corresponding to desired deflection, gives number of saddles required. From this the slope of chord from saddle to saddle is found and the elev of each saddle calculated to nearest 0.1 ft. A similar process may be used to calculate elev of individual towers of a group, after locations of end towers have been determined by scaling.

Rail trestles are similar to type just described and have the same application, but a rail is added to take the rolling load and relieve the cable (Art 13).

Track cables are tightened by a weight or some tension device at one end, the other end being anchored (Art 11). On short lines, the anchorage is at one terminal and the tension is applied at the other. A section from 3 000–5 000 ft is as long as can be controlled from one tension point, hence long lines must be divided into sections of approx 4 000 ft. Exact lengths of sections are controlled by choosing, along the line, suitable sites for stations. It is customary to place anchorage at the high end and apply tension at low end of section; then the wt of cable aids in working the slack down to the tension weight, and erection is also facilitated. Intermediate stations are necessary for long lines (Art 12). The typical tramway (Fig 11), being nearly 7 000 ft long, requires one intermediate tension station, placed on the ridge near Sta 40. It is constructed as a combined anchorage and tension station (see end Art 12).

6a. MORE COMPLICATED PROBLEMS OF DESIGN

When a tramway is to carry heavy individual loads, or large tonnage, or the difference in elev between ends is great, serious problems are presented. Heavy loads require a large cable, or a carriage with more than 2 wheels, or both, to distribute rolling load and reduce bending stresses in the cable. Large tonnage or great difference in elev creates heavy traction stress (computed by Eq 29), which requires rope of large size or high tensile strength. The vert component (Fig 18) of a heavy rope stress augments the rolling load, which in turn injures the cable. Hence, when an unusually strong traction rope is needed, say over 0.75 in of cast-steel grade, it should be taken as a danger signal and the design carefully reconsidered. Heavy rolling loads also affect the design of structures and machinery, increasing bending stresses in saddle beams on towers and stations, and in the members of rail trestles (Art 13).

Determination of rolling load. A profile to scale of 1 in = 40 ft (or 1 to 500 metric measure) is generally convenient. Humps in the line can be located, and these replotted to twice the above scale for detailed study; choosing first those points, near upper end, where tension is greatest and conditions likely to be most severe. As the exact position of the cable can not be plotted in the early stages of design (some conditions being unknown), an approximation must be made.

For a given make or type of tramway certain mechanical parts have fixed and known dimensions, viz: the distance at carrier of traction rope below the carriage and distance of traction rope carrying sheaves or rollers below the grip. On these bases, a diagram is drawn to scale of 1 in = 20 ft (or 1 : 250 metric), with locus of tower saddles as an arc, the path of grip or clip as a similar arc, and a third arc representing the locus of traction rope rollers. These arcs are concentric, and their distances apart are determined by the above mechanical features. Fig 14*a* shows such a set of curves (exaggerated). For any position of a carrier, lines drawn from its grip tangent to the roller curve will be chords of the traction rope, as lifted by a passing carrier. This is true unless the curve is so sharp that the chord of the traction rope to next carrier does not touch a roller, when a different construction will be needed, as in Fig 14*b*, discussed later. With traction rope chords drawn to roller arc (Fig 14*a*), a parallelogram of forces is laid out on them, and the vert component determined. If the traction rope stress is laid off as 100, the vert component is a percentage, which, multiplied by the actual tension in the rope (Eq 29) gives the vert stress due to tension. This can also be found analytically (see calculation below Fig 14*a*). Total rolling load is the sum of: wt of carrier and its load, if any, and vert stress found from the chords.

Radius of arc over saddle for any case should be the one best suited to shape of the crest, taking into account the sharpness of the ridge and breadth of the hill, and be as large as possible without making the ends too high from ground. Sometimes on a sharp ridge a cut or even a tunnel is needed to allow flattening of curves. Spacing of towers to fit the saddle arc is found from Table 5 for a desired deflection angle over individual saddles.

When radius of saddle arc can not be increased enough to reduce the rolling load to a desired amount, a rail structure can be built over the crest in place of several towers, thus carrying the load on solid track instead of on the cable. Such a structure often costs no more than a group of towers; sometimes it can be combined with an anchorage or a tension station, at little added cost. The rail must be long enough at each end to keep carriers off the cable, so as to prevent heavy vert stresses on cable when carriers are near the crest. See Fig 14*b*, where carrier *P* on tangent to the summit curve has a heavy vert stress due to traction rope tension, which, if on the cable, would cause serious bending. If the rail is extended down the tangent, so that a carrier, as *Q*, is on the

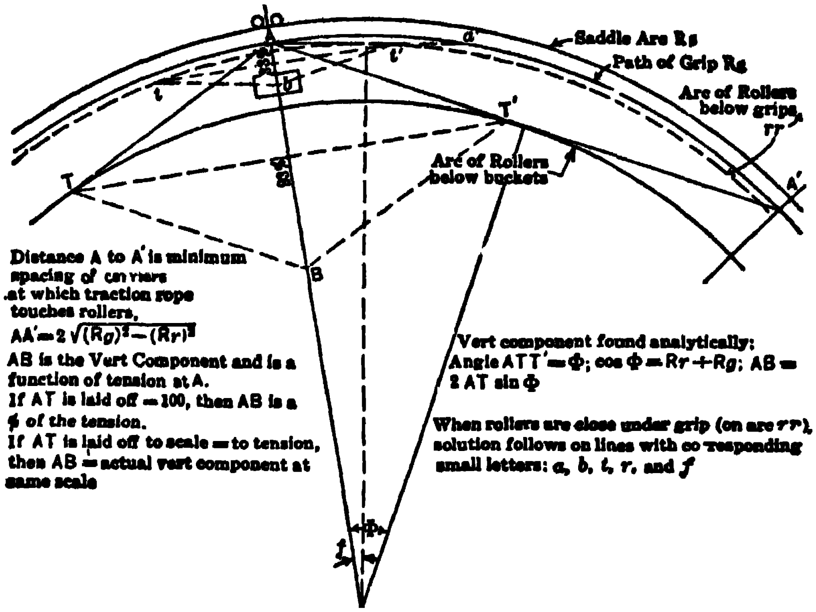

Fig 14*a*. Stress Diagram of Vertical Component

rail, the rolling load does not come on the cable. Use of supporting sheaves for the traction rope, close under grip or clip, makes the vert stresses much smaller than when rollers are below bucket. Fig 14*a* gives solutions of these stresses for the two types of construction.

When saddle arc has a large radius, is short, or carriers are close together, the traction rope may be supported by the carriers, not touching the rollers; this often occurs where traction rope rollers are below the buckets, but less frequently when rollers are close under the grips. When traction rope does not touch rollers, the position of next carrier on each side is plotted, and a force diagram plotted on the chords drawn between grips, as for carrier at *N* (Fig 14*b*). Note that the diagram would be the same if chords were drawn between the points on cable where the carriers stand, instead of from grip to grip.

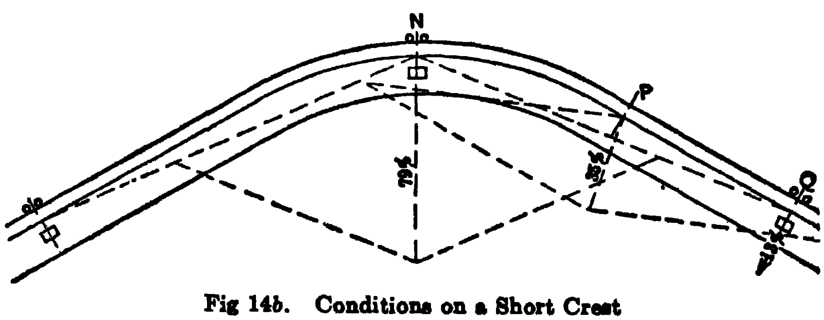

Fig 14*b*. Conditions on a Short Crest

Permissible rolling loads. Table 4, showing net loads that can be carried on cast-steel cables of different sizes, is useful in beginning to study a problem. The total rolling load must be considered; it consists of net load of material carried + wt of carrier + vert component of the traction rope tension; and should not exceed 1 200 lb per sq in of cable section, when a 2-wheeled carriage is used. The metallic area of cable is found by dividing the wt of cable per ft (Table 1) by 3.7, and the working tension is 34 600 lb per sq in of area.

Bending of the cable under the traveling load decreases with increased tension. Where a cable had been injured, investigations indicate that a ratio of rolling load to horiz cable tension was too great, and that a ratio $W \div t = 0.035$ is about the limit of load that can be carried without undue wear. This ratio corresponds to a deflection angle, between the tangents to the cable on the two sides of the load, equal to 2°, with carriages having two

10-in wheels, 18-in centers. If the ratio exceeds 0.035, a larger track cable, or one of stronger wire, may be used; either will increase value of t by permitting the use of higher tension in the cable and so decrease the deflection angle at the load. If the tension can not be so increased, the design of the carriage may be altered by using four 12-in wheels on 20-in centers, mounted in an equalising frame. The load can then be doubled and still give a deflection angle under each pair of wheels not exceeding 2°; that is, the total deflection angle for a 4-wheeled carriage may reach 4°, the tangent of which is nearly 0.07.

Where the gross load is too great for the cable at a few points, and a larger cable throughout is not warranted, the deflection angle under a load can sometimes be decreased by building a section of the tramway with a larger cable, thus permitting a higher local tension, with the same effect as reducing the rolling load. This device can also be used on a long span, to reduce sag of the track cable.

Angle over towers. In Art 6 it was stated that the deflection angle of the empty cable over towers should not exceed 2° 52′, or a change of direction of 5%; this rule is applicable to many lines using fixed saddles, especially for capacities up to 60 tons per hr. But conditions may occur, especially if duty is high, where the rule is not applicable, as the difference between loaded and empty position of cable on long spans is so great, that the loaded position of cable must control the design.

Example. If a span is 1 000 ft long, empty cable weighs 3 lb per ft, total uniformly distributed wt of loaded cable is 9 lb per ft and cable tension 24 000 lb; then, from Eq 8, the slope of the empty cable at the end tower will be 6.25% and slope of loaded cable 18.75%. If the tower at end of span is set with relation to the next one, so that there is no angle over it when cable is empty, there will still be a 12.5% deflection when span is loaded. No construction will permit so great a change in position of cable. In such case, the towers at ends of the span must be so set that there is an upward deflection on end tower when cable is empty; then, when loads come on the span, the cable will sag and deflect downward over that saddle. Thus, if the empty cable had a deflection of 6.25% acting upward, the final deflection when span was loaded would be 12.5 − 6.25 = 6.25% downward. To hold the cable in the saddle when it is empty, the saddle must then have a strap (hold-down saddle), and movable points to permit the passing carriers to leave and return to the cable. In trying to reduce the angle over a tower at the end of a long span, the position of cable is determined by gravity and can not be altered, and to get an easy approach the positions of towers back of the end tower are the only conditions susceptible of change.

For the heavy lines discussed in this Art, saddles are preferably of the rocking type, some in use have arcs 10° long, with radii of 15 ft for $^7/_8$–$1^3/_8$-in cables and 25 ft for 1.5–2-in cables, supplemented by arcs of smaller radius at each end. They may be used where the cable deflection over them is as much as 8°, or 14%. When a load approaches such a saddle, the depression of the cable rocks the saddle toward the load and, after passing over it, the depression of the cable rocks it in the opposite direction. The rocking saddle is essential where tower spacing is long, as the deflection angle between tangents to the cable is then large; if it exceeds 8°, a double tower with 2 saddles for each cable may be used.

To determine type of saddle and construction needed at any location, the exact slope of the track cables must be found. The worst condition is when a load approaches or leaves a saddle and is a short distance from it; this distance varies with the saddle design and length of carriage, but may be assumed as 6 ft for a general study; the positions of the other loads are determined by the load spacing. The inclination of the cable at a saddle is the algebraic sum of: (1) inclination of the chord found from equation $\tan \alpha = V \div s$ (Fig 7), which may be up or down; (2) inclination of the empty cable with respect to its chord, from Eq 8, is $\tan \beta = ws \div 2t$; (3) inclination of the funicular polygon due to the loads; thus, in Fig 4 (from Eq 9) at the end A, $\tan \phi = r \div t$, where r, the reaction at opposite end B is due to the concentrated loads.

When one load is close to a saddle, the next one on opposite side will be nearly a load spacing away and the others will be multiples of the load spacing from it. Deflection angle of the cable over the saddle can be determined from the inclination of the 2 cable tangents, and with the rocking saddles described above would be limited to 8°. The deflection can be figured in percentage by adding the tangents, as they are practically proportional to the angles when the angles are small; the limiting deflection would then be 14%. If the next saddle, on the side opposite the one where the load is close to the saddle, is less than a load spacing away, the inclination on that side will be due to the chord and the empty cable only; this condition may occur where towers are closely spaced, or where 2 saddles are mounted on a double tower.

Broad valleys present another case where construction must be based on the loaded cable, especially if the valley is too deep to use ordinary towers, or is shallow enough for the loaded cable to touch the ground on a clear span. Loaded cable deflection would then be computed for a point in the valley where a tower could be built, using a tension

25% or more greater than the working tension. If a tower is built up to this position of cable, the empty cable must be held down on it, but the loaded cable will bear upon it with only a moderate angle. Several trials may be necessary before a solution is found. In such case, the traction rope must remain below the track cable, so as not to foul, nor have a lifting action that will raise an empty carrier off the cable. The position of traction rope is determined from its wt per ft and its tension at this point. It may be possible to hold it down at towers by rollers placed above the grip.

Example. Suppose the valley is 3 000 ft wide, and chord is horiz; empty cable weighs 3 lb per ft, loaded cable has a total uniformly distributed wt of 9 lb per ft and cable tension is 24 000 lb. Then, by Eq 2, the deflection of empty cable at center of span is 140 ft, and end slope is 18.67%; when loaded, deflection is 420 ft and end slope is 56%. For a construction curve at 1.25 times the working tension, deflection will be 336 ft, and topography may be such that a tower can be built up to the cable at this point. The end slopes of this construction curve will be 45%. Assuming that the surface on the flanks of valley has about this slope, towers can be placed under the cable at both ends of the 3 000-ft span, and so reduce the half spans to say 1 000 or 1 200 ft from the flank towers to tower in mid-valley. The flank towers will probably need hold-down saddles. Several trials will be necessary before final solution is found, as the introduction of towers changes conditions. The tower in the center of valley will also need a device for holding down the cables. Sometimes hold-down saddles can be used; otherwise a short rail station should be built. An anchor or tension station, if needed, may be located in the valley and so hold down the cables. Where the traction rope does not naturally hang below the cable, it may be possible to hold it down by sheaves above the grip, but care must then be taken not to produce an upward stress that will lift an empty carrier off the cable. If the traction rope can not be held below the cable, the valley tower must be raised to hold the cable above the curve of traction rope.

Anchored spans, having a take-up to produce tension in the track cables, are sometimes feasible. They require more judgment in erecting and in keeping the proper tension in cables than where weights are used, but this construction is usually cheaper than weighting, as the structures can be lower than those used with weights and the equipment is cheaper. The tension in cable is produced at one end of a section by a wire rope tackle, or a turn buckle, or rods with long threads, forming part of the permanent equipment.

On Riblet tramways, cable tension is nearly always produced by wire rope tackle between end of cable and an anchorage. The tackle blocks have sheaves set tandem between 2 long steel plates; the sheaves in each block are of different diam, the one nearest the connection being the largest; this places the sheaves and ropes in one plane, but the ropes clear each other due to the different sheave diameters. The pull on the loose end of the tackle rope is obtained by winding it on a drum driven through worm gearing operated by hand. The fixed tackle block is attached to the drum frame, and the whole is anchored to a block of concrete or masonry.

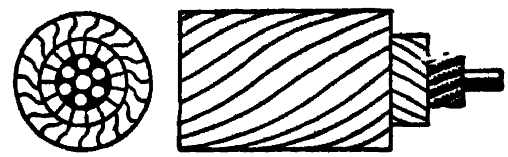
In erecting a line with anchored spans, tension should be applied to empty cable to bring it a little higher than the computed position of the loaded cable when fully loaded, say with a center deflection 75% of that of loaded cable. Then, when loads are added and cable stretches, it will occupy approx the calculated position. The layout of tramway with anchored spans should be such that a concentration of loads on a long span (due to conditions in loading or stripping the line with buckets, or accidental uneven spacing during operation, causing the span to sag and pull up adjacent spans) does not lift the empty cable off of its saddles. This also occurs in a reversible tramway with anchored cables (Art 20, 21), where there is a single heavy carrier. In such tramways the slack of the cable will move from span to span with the carrier, and adjacent spans will be taut. Bib 10a gives examples of anchored spans and calculations of effect of stretch of cable.

A condition identical with an anchored span is obtained by placing blocking under the tension wt, after the cables have been loaded. This holds cable in same position as if anchored, and prevents it from lifting when unloaded. The wt affords a safeguard, however, in that it can lift if the span is overloaded. This relief is absent from an anchored span; when load is increased the cable stretches somewhat, which increases the sag and counteracts some of the increased stresses of moderate overloading. Anchored spans and blocked weights require careful design. The operating conditions are easily misunderstood, and tightening of the cable, as it stretches and becomes slack, is neglected; hence, such spans should be used cautiously, and only under skilled supervision.

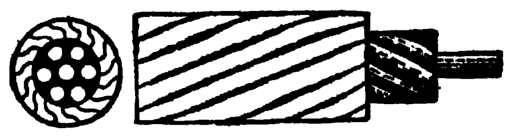
7. TRACK CABLES

Track cables for all types of aerial tramways are usually smooth-coil or locked-coil cables. They are made of large wires (Fig 15) in order to have long life under the surface wear of the carrier wheels. Ordinary haulage ropes, with 6 strands of 7 wires each, may be used on light tramways, where low first cost is desired; but usually the small wires wear so quickly that they are uneconomical. See Sec 12.

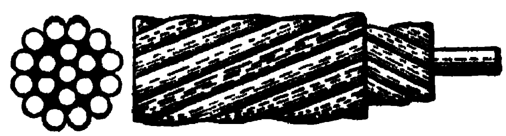
Locked-coil cables have a smooth exterior, the shape of outer wires resembling an angular oblique figure 8, so that they interlock. This locking holds one broken wire, but if several break near each other the outer layer will unravel. The center of a locked-coil cable is a 7-wire strand, and is surrounded by key and locked wires. In small sizes the key wires are omitted (Fig 15 *b*); larger cables (Fig 15 *a*), have one layer of key wires; very large ones, over 2 in diam (used on cableways), have 2 layers of key wires. For ordinary tramways, the cables are of C S wire, but for heavy capac lines the wire is of a special grade. For example, if conditions require a 2-in C S cable (Table 1), a stronger cable can be had in the 1.75-in size of special steel, making a saving of 23% in wt. A 2-in cable is considered as large as can be economically used, because couplings would be so large in diam as to require very wide carriage wheels to travel over them, which would increase the size of other equipment.



(*a*) Locked-coil Cable, 1 1/8–2 in diam



(*b*) Locked-coil Cable, 7/8 and 1 in diam



(*c*) Smooth-coil Cable

Fig 15. Track Cables

Smooth-coil cables, entirely of round wires, are not so smooth as locked-coil cables, but become fairly smooth by wear. As the wires do not interlock, a broken wire is apt to work out and repairs must be made promptly by applying a sleeve-like clamp, permitting carriage wheels to pass. They are easier and cheaper to make than the L-C. As they are of high tensile strength wire, their wt (Table 1) and cost are reduced; but they must be replaced oftener than L-C cables. One center wire is surrounded by 2 to 5 layers of wire, all of same size laid in opposite directions. The number of wires may thus be from 19 to 91; their diam, 0.15–0.22.

Couplings. Length of a piece of cable is limited by length of wire that can be manufactured. Sections required for long tramways are joined by couplings to form a continuous cable from anchorage to tension station. Each coupling (Fig 16) is in halves, one of which is wedged to end of each section, the halves then being connected by a plug having right- and left-hand threads. Couplings are as small in diam as consistent with strength, and the carrier wheels are wide enough to pass over them. At the ends, the cables are attached to sockets similar to that used for couplings, and designed so they can turn when cable is rotated. Couplings should not come within 15 ft of a tower, or within 10 ft of each other, so that the cable will be free to sag as a carrier passes over a coupling, and not receive sharp bends.

Attaching couplings and sockets. Cable is seized with wire for several inches from end to prevent distortion; then sawed off square; a clamp is put on beyond where fitting will come; the seizing is removed and wires are cleaned with gasolene. Cable is inserted in small end of the taper hole in fitting, the rows of wires are separated by annular wedges driven between them, spaces between wires are filled with slender steel wedges and any small spaces remaining are filled with slim shoe pegs. This wedging grips each wire and makes a solid steel knob on end of cable which prevents it from pulling through the taper. Wedges and thimbles may be driven with a hammer and punches, but a screw press is quicker and better. With a press, the fitting is placed on cable as above, thimbles and wedges are inserted and driven part way down; then the fitting is placed in the press, the entire set of wedges forced home, and the bulged end of cable pushed firmly into the taper fitting.

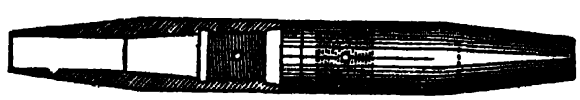


Fig 16. Coupling for Track Cables

Rotation of track cable. Every week or so the cable should be turned through 1/8 of a revolution. This distributes wear over its entire surface, prevents flattening of cable and displacement of wires. The turning should be in such direction as to tighten the outer wires of cable; thus, if wires have a left-hand lay (Fig 15), the cable should be rotated to the right, or clockwise.

Maximum wear on a track cable occurs in a length extending about 5 ft on each side of a summit saddle. Directly over the saddle the rolling pressure is greatest, due to pull of traction rope combined with wt of carrier; just off the saddle the cable gets a reversed bend between carrier wheels and saddle, especially on the side where loaded carriers approach the tower. The downward pull of traction rope can be reduced by proper location of towers and traction-rope rollers (Art 10), and bending minimized by stretching cable as taut as its strength will permit.

Cables are oiled about once a month with a heavy oil, to prevent rusting, to provide internal lubrication, and reduce friction of carriers. Oiling may be done by men riding slowly over the line in a carrier and slushing oil on cable with a handful of waste; or with a mechanical oiler, hauled over the line like a carrier. Saddle grooves should be greased to facilitate rotation of the cables, and to permit them to slide so as to maintain their tension.

To repair a cable the tension is taken off the end, tackle attached to each side of break, the blocks are drawn together, and break is cut out. If break is short, half a coupling is wedged to each end, and they are united with the right- and left-thread plug; if worn part is long, a new piece of cable is inserted. Inserted piece should never be less than 10 ft long, or wires will break at ends of couplings, due to stiffening of cable by the couplings.

8. ROLLING STOCK

Each piece of rolling stock (carrier) consists of: carriage, container, hanger, and clamp or grip for attaching to traction rope.

Carriage runs on track cable; its wheels, 8–12 in diam, are mounted in a frame with a connection for the hanger supporting the container. For heavy loads, carriages have 4 wheels; they are practically 2 ordinary carriages, connected by a swivelled equalizing frame, from which the load is suspended. This distributes the load and reduces wear of the cable due to bending.

Container for bulk material is a bucket; for other materials it may be a tank, platform, or cage. For timber, the hangers terminate in hooks, to which timbers are attached by slings; these are used in pairs, one at each end of load. Sometimes workmen are transported by a tramway during certain hours of the day. Long buckets, each holding 2 men, are best. One man sits in each end with his legs between those of the other man.

Hanger is of bar steel, with C-I or steel parts to facilitate connection with carriage and container, and hold clamp for traction rope. Its form is largely governed by the parts to which it connects.

Clamp for traction rope may be a GRIP, which can be applied to or released from the rope at terminals, thus allowing carrier to be shunted to loading or discharge point; or it may be a CLIP, permanently attached to both carrier and traction rope.

Grips differ in design and often in principle on each make of tramway, and are shown in maker's catalogs. Devices used to obtain gripping pressure on traction rope are: (1) Levers and toggles. The latter, by passing a center closes and locks the grip, as in the Webber grip (Maker 1, Art 29) extensively used in the past; obsolete for new work. Its motion was prescribed and it would not grip the rope where its size varied beyond the rope's compressibility. (2) Springs. By cushioning one jaw, grip can take ropes of varying size; levers are used to compress the spring and produce initial press; holding power depends on strength of spring and its leverage on grip jaw. Used formerly in modified Webber grip, and now in Wico grip (Maker 1, Art 29). (3) Screws. Grip jaws are brought together by a screw as in a machinist's vise; the gripping force is large and jaws will seize ropes of considerable difference in diam and are locked wherever the screw stops turning. This type was originated by Otto in Germany, and in slightly different detail is now made by Makers No 8, 3, 9 (Art 29). (4) Wedges. A slim sliding wedge is used to force jaws together on the rope; the taper being less than coef of friction there is no tendency for grip to release. They will hold on ropes whose diam varies due to stretch or wear. Made by 2 and 9 (Art 29). (5) Gravity. Wt of container, acting through levers, gives the holding force on traction ropes. The closing motion stops when jaws have seized the rope; this permits gripping of ropes of varying sizes. The grip is usually attached to hanger below the carriage (under-hung grip); for special purposes it may be built into the carriage (over-head grip). Made by 5, 6, 7 (Art 29).

Most grips can be attached by hand, but are usually closed by an attacher; they are always released automatically when carrier enters terminal. A grip depending on the weight of container for its holding force requires a special system of rails for lifting the container, in order to open grip preparatory to inserting traction rope on outgoing side, and a similar device on incoming side to open grip and release traction rope.

Some grips occupy most of the space, not needed for clearance, between carriage and carrier, so that the rollers supporting traction rope at towers must be placed below the carriers. This construction is good on most lines. As the carrier is free to swing sidewise through considerable range, guards are often used to fend the rope onto the rollers. Other grips allow supporting sheaves to be placed close under their jaws, so that the traction rope is lifted but little as carrier passes the sheave. This requires carriers to be guided, to prevent colliding with the sheave, and to make the rope drop back on sheave after grip has passed. Guides are objectionable when applied to every tower, but to have the sheave close under the grip is advantageous in passing over crests, as it reduces the downward press. Guides can be easily constructed on summit structures. (See discussion regarding Fig 18, Art 10.)

Clip is a U-shaped band of steel, bent around traction rope and permanently clamped to it by bolts. As clip can not be released from rope while tramway is in operation, terminals must be so arranged that carriers can pass around end sheaves; the buckets are loaded while in motion by an automatic loader, and dumped while in motion by a tripper. Tramways with clips are obsolete. Disadvantages: wear on traction rope due to gripping is concentrated at clips; the non-stop feature makes terminals inflexible; speed of the line is limited by centrifugal force developed by carriers passing around sheaves.

Dimensions of 3 sizes of ore carrier accompany Fig. 17. In a preliminary design these may be used for several sizes of buckets smaller and larger than those noted. The distance *A* differs considerably; its minimum is about 3.5 ft, when the traction rope is carried on rollers below carriers. *A* must be increased to clear sheaves supporting traction rope if close under the grips, to admit special latches and tripping mechanism, for clearance in terminals, and for loading. Distance from track cable to grip is kept constant on each system, at about 2 ft, so grip will pass under the cable saddle and end of its supporting beam.

Dimensions

	Capacity of bucket, cu ft		
	5	10	20
A	3′–6″ with traction rope roller below carriers; 5′–0″ with traction rope sheave under grips		
B	1′– 3″	1′–10″	2′–5″
C	2′– 7″	2′–11″	3′–2″
D	1′–11″	2′– 3″	3′–0″
E	1′– 5″	1′– 9″	2′–3″
Weight, lb	300	420	55

Above are approximately applicable to buckets of 4 to 6, 7 to 15, 16 to 25 cu ft, respectively.

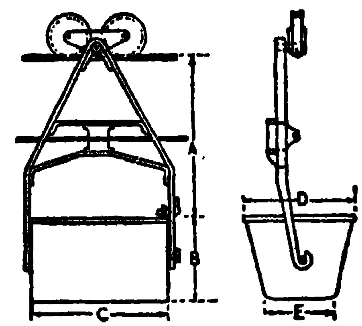

Fig 17. Ore Carrier

9. TRACTION ROPE

This is usually Lang lay, of as large wires as consistent with flexibility and to offer max wearing surface. For sizes of 0.75 in diam and less, there are 6 strands of 7 wires each, all of same diam, laid about a hemp center. For larger diam, the strands have 19 wires; 1 center and 9 outer wires of about 25% of diam of strand, and an intermediate layer of 9 wires half the diam of outer ones; this combines flexibility with good wearing surface. For moderate tensions the wire is of cast steel, to make a rope of such diam that the gripping surface is ample. For higher tensions (ropes over 0.75 in diam), plow-steel is used, to keep down size and wt and give the flexibility due to smaller wires. Factor of safety, 5. See also Sec 12.

Lubrication. Traction rope should be oiled frequently, to lubricate the interior. Lubricant must be carefully chosen, so as not to reduce holding force of grips. A thin oil may be used in abundance, to penetrate the interior, the surplus being wiped off to leave surface dry. It can be applied mechanically by an oiler on the outgoing empty side of a terminal. Some operators prefer a thick sticky lubricant, which works well into the interior. Admixture of linseed or other drying oils in the lubricant is advantageous, in causing exterior surface to harden, and enabling grips to take a firm hold.

10. TOWERS

Stresses in towers have 3 sources: 1. Downward press on saddles, due to vert component of tension in track cables, wt of loaded carriers, and vert component of tension in traction rope. 2. Racking motion parallel to line of tramway, due to changes in direction of press from the cable when a load approaches and leaves the tower. 3. Side press, due to wind.

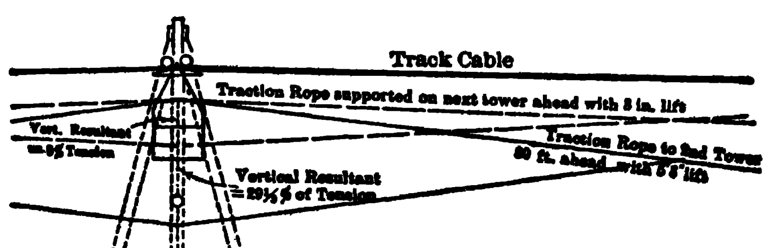

Fig 18. Stresses in Saddle Beams; Towers 40 ft Apart; Cable Deflected 5% on Each

1. Downward press on saddles is often so great that their supporting beams must be of oak or steel to resist bending stresses and crushing by the saddles; steel is preferable. At towers along the line, downward press from traction rope can be determined only when exact conditions are known, as the next point of support for traction rope is generally the next carrier on each side, and the positions

of these depend on their spacing and the sag of the track cable under them. For mode of determining vert stresses, see Art 6 a. Fig 18 shows the vert stresses in percentages of the tension for a single tower. The full lines show the vert stresses when traction rope is supported on rollers below the carriers, and dotted lines show stresses when traction rope is supported on rollers 8 in below its position when in the grip. In practice a vert resultant of 29.5% (Fig 18) would be prohibitive, unless traction rope tension is very small.

2. Racking. The problem of supporting the saddle beams and providing rigidity against racking is made difficult by necessity of maintaining a clear passage for the carriers.

3. Wind. Tower base is spread parallel to center line of tramway, so resultant of press of cables on saddle falls well within base, even when cables are moderately inclined; hence will usually resist overturning by wind parallel to line. High towers may be narrower in other directions and should be investigated for resistance to wind at right angles to line; they may need to be guyed.

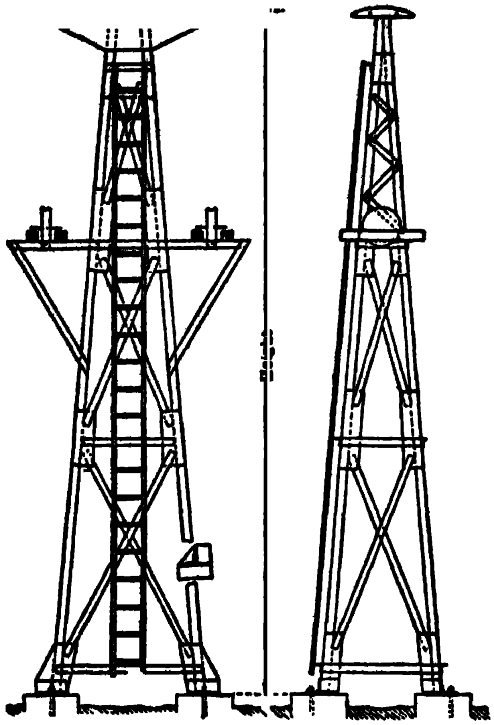

Fig 19. Tramway Tower: Pyramid Type in Steel

Material. Steel with concrete or masonry foundations is best for permanent plants and where wood is costly. Riblet uses steel fabricated near tramway site and pre-cast concrete blocks for foundations (11). Wood is usually framed at the point nearest tramway site to which timber can be delivered; main posts are 6 by 6 to 8 by 8 in; rarely 10 by 10; saddle beams are usually 8 or 10-in steel channels In remote districts, towers have been of round timber with hewed bearing surfaces, but timber can usually be whipsawed or ripped in a portable saw mill; squared timber reduces cost of framing, distributing and erecting. Foundations should be concrete or masonry, but are often of such material as is procurable: logs, cribs with or without rock filling, or piers of stone laid up dry; such foundations will not resist up-lifting stresses and many towers must be guyed. Concrete and masonry towers are sometimes used, especially when tramway serves a cement plant; they are bulky, and attractive designs have not been worked out.

Pyramid tower (Fig 19) is economical of materials. When of steel, a rigid head can be designed with shapes and plates securely fastened to the angle posts. When made of wood, the small area at top of posts makes it almost impossible to attach saddle beams so that they will not rack and work loose. In this type, whatever material is used, clearances between a large carrier and the side of a wooden tower are too small; the base

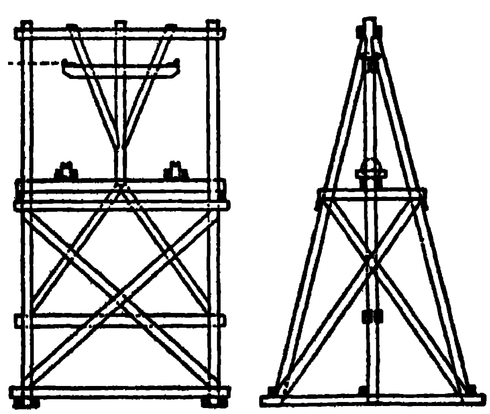

Fig 20. Tramway Tower: Through Type

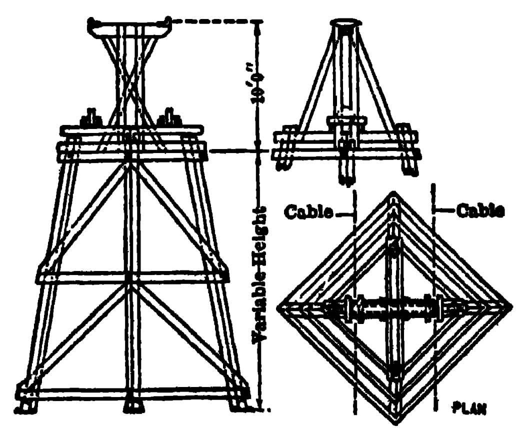

Fig 21. Tramway Tower: Composite Type

also is small and provision must be made for wind stresses, and on steep lines for cases where resultant of cable stresses falls outside the base.

Through tower (Fig 20) is rigid and efficient, but contains about 100 bd ft of timber per ft of height up to 60 ft, which is nearly double the amount for pyramid towers. Sometimes, on light lines, the outside center posts are omitted below roller deck, especially on high towers.

Composite tower (Fig 21) has a top identical for all towers, the base being varied to give desired height. Base stands with its diagonal on center line, hence its long dimension is in line with main stresses. Its top is rigid against racking. Framing is simpler than it seems in a drawing. These towers contain less timber than those of through type.

Side-hill tower (Fig 22) is of through type and designed for steep lines to ensure that line of press shall fall within base, and slope of inclined side is made to suit direction of press.

The principle of the through tower can be used for steel towers with good results.

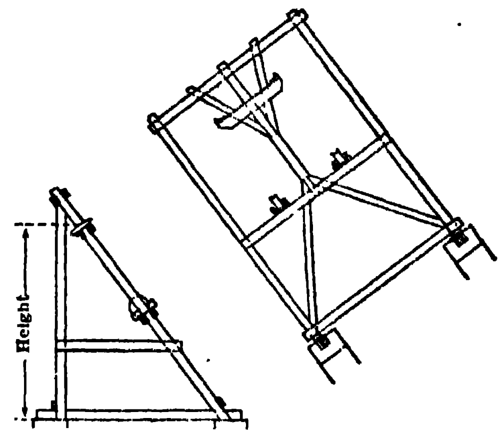

Fig 22. Tramway Tower: Side-hill Type

11. ANCHORAGE AND TENSION OF TRACK CABLES

Track cables must be taut enough to support the load and minimize bending under the carriage wheels, both on spans and when carriers approach tower saddles.

Tension weights to keep cables taut are wooden boxes filled with stone or scrap iron, or are moulded concrete blocks. It would be desirable to weigh the tension wt, but, this being usually impracticable, the wt of the box is computed and added to that of its contents, taken as 100 lb per cu ft for broken stone or 350 lb for packed scrap iron; concrete blocks are taken to weigh 140 lb per cu ft. Form and dimensions of weight are influenced by the allotted space. A tension wt can keep taut 3 000 to 5 000 ft of cable depending on profile of line and the care with which saddle grooves are kept clean and well greased. The weight usually equals the working tension of the cable, unless the slope is so great that the added wt of cable would overstrain the upper end; then the tension wt should be reduced.

Anchorage at opposite end of cable from tension point must be designed to cover fact that slope of line may increase tension due to the wt alone. Sometimes the cables terminate in station framework. For steel construction this is simplest; for timber it is often difficult to design the structure to take these stresses, and it is usually economical to deflect cables to the center, carry them through station and attach them directly to a masonry anchorage. See terminal stations (Fig 33, 34), also Fig 23.

The anchorage block must be a monolith, equal in wt to the vert component of the tension, allowing 140 lb as wt per cu ft of masonry or concrete, and the front must have sufficient area to give a bearing resistance against the earth equal to horiz component of tension. Horiz resistance of aver earth may be taken as 1 000 lb per sq ft for a deep block, but on a down-hill slope the anchorage must be carried into the hill by a tunnel. For an anchorage in rock, a T-shaped trench is excavated and the anchorage bars set in it, the space around them being filled with concrete. Metal parts of the anchorage must be designed for required tension, and also to allow the cable to be turned (Art 7) while under tension. Anchorage bars must be enclosed in masonry to a point above water level, and extend above dampness before coupling to cables, to avoid injury to the wires from rust.

12. INTERMEDIATE STATIONS

These are needed to apply working tension to track cables which are too long for terminal apparatus to be effective throughout (see end of Art 6). There are 3 types: Double-anchorage; double-tension; anchorage and tension. In all, the track cables are deflected to center of structure, out of the way of carriers, and pass downward to anchorage or to tension weights. Space between sections of track cable is bridged by rails, to allow carriers to pass through without being detached from traction rope.

When both pairs of cables are in place and under full tension, the pull of those on one side of station will counteract the pull on other side, but the structures must be so designed as to be secure if cables on either side are released while the others remain under tension, a condition which may occur during erection, while making repairs, or in case of accident. These stations are similar on all tramways, but must be designed to suit conditions on each profile. They may be of wood or steel; if steel, the bents can be simplified and all posts placed between the cables, somewhat like the steel tower, Fig 19, or wooden summit station, Fig 26. Cable sockets are designed to allow cables to be turned (Art 7)

Double-anchorage stations can be as low as profile conditions will permit, provided there is ample clearance for carriers above the ground. Where there is no snow, they

need not be over 10 ft high. Fig 23 shows essential features, with cables anchored to the structure. It is preferable, however, to continue the cables to masonry anchor blocks set in the ground, as shown in terminal, Fig 33.

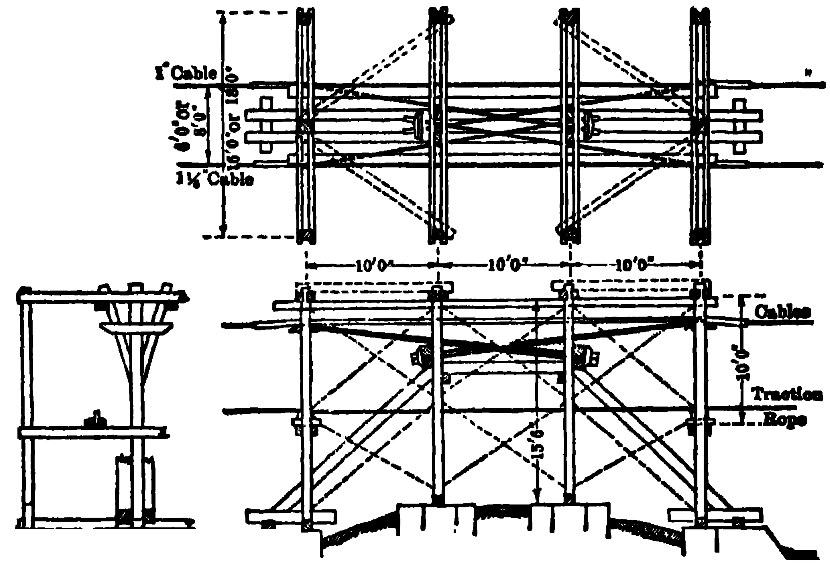

Fig 23. Double-anchorage Station

Double-tension stations must be built high enough to allow tension weights a vertical motion of 6 to 8 ft, and still have their tops below path of carriers. Even with squat weights, this makes stations 20 to 30 ft high to the rail (Fig 24).

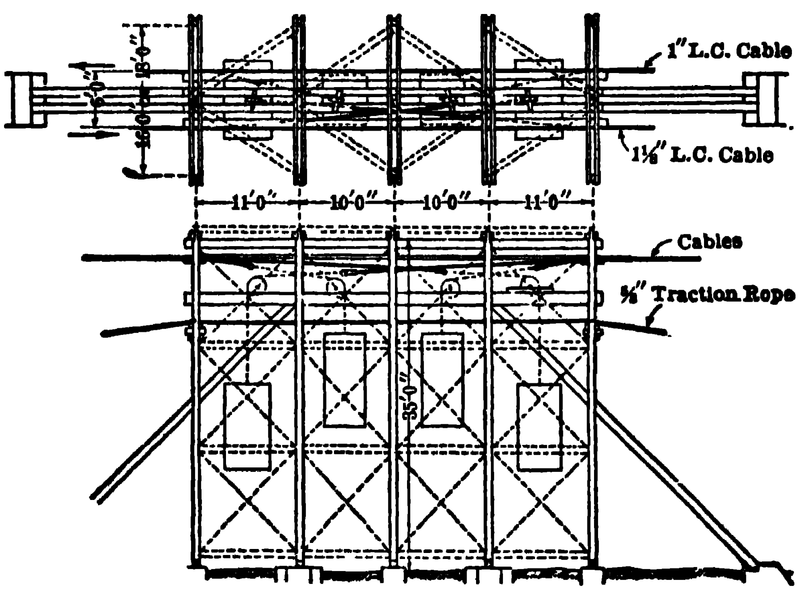

Fig 24. Double-tension Station

Tension weights are attached to chains or wire rope, passing over sheaves on short axles, resting in bearings. Horis pull is transferred to main beams by gains in the timbers, into which the bearings fit. Main beams support the vertical load and transfer horis stresses to inclined braces, which in turn transfer them to foundations. Inclined braces may develop an upward thrust when design is such that the full tension box does not come on end of inclined brace, or when all cables are not under tension. These upward forces are resisted by giving the foundations a mass equal to the uplift, and bolting the posts to them. Tension stations may be no higher than anchorage stations when take-up tackle replaces floating weights (see end of Art 6*a*).

Anchorage-and-tension stations provide for anchoring the cables of one section and applying tension to those of the other. They are practically half of a double-tension station, combined with half of a double-anchorage station of same height.

13. ANGLE AND SUMMIT STATIONS

Angle stations are required for horiz deflections. Main cables are terminated, traction rope passes through and is deflected by sheaves; carriers are detached from incoming traction rope, run over a rail bridging gap between cables, and reattached to outgoing traction rope. Fig 25 shows a simple station, with both pairs of cables anchored; in it, the carriers detach automatically, but 2 men are required to reattach them to traction

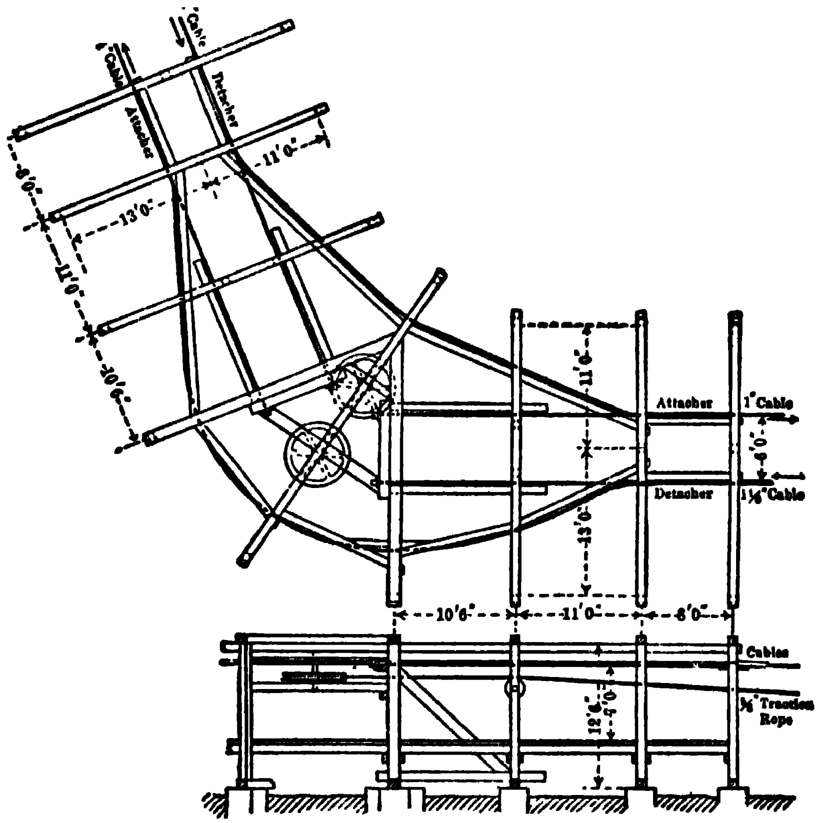

Fig 25. Angle Station

rope. Occasionally, angle stations are designed so that carriers detach and reattach automatically, or are arranged so that they make the turn without being released. Either arrangement complicates details and adds to first cost of the tramway, but reduces operating expenses by saving attendants at angle station. See end of Art 16 for similar problems. An angle station may be introduced at a junction, between two divisions of a tramway, without increasing first cost or operating expense (Art 17).

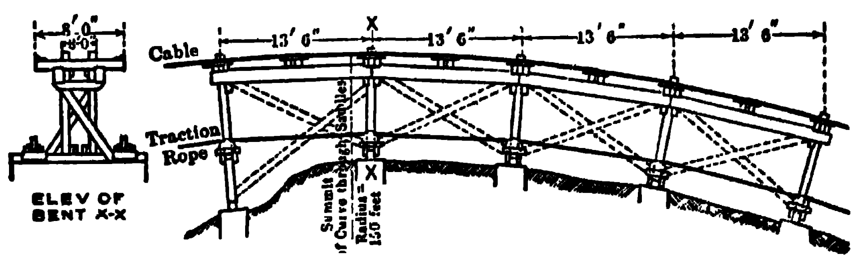

Fig 26. Summit Station, Traction Rope under Carrier

Summit trestles are introduced at crests in a line to save erection of a group of towers (see near end of Art 6), and carry a series of saddles with a slight bend of rope on each (Fig 26); they have limited application; a rail station (see below) being preferable.

Rail stations are similar in purpose to summit trestles with saddles. The main cables are carried through the station, but rails are mounted above them, on which the carriers run, and so relieve cable wear. Each end of the rail has a point, to lead the carriage from cable

to rail and let it down from rail to cable (Art 16, par 3). Rail stations are used where rolling press is heavy, due to heavy loads, limited space for structure, heavy tension in traction rope, or where conditions prevent a reduction of vert component.

Traction rope, in both forms of summit station, is supported at a uniform distance below the track. The larger the radius of track cable, or rail, the less will be the deflection of traction rope at the grip, and consequently both press and wear of carrier wheels on the track are reduced. Fig 26 shows a trestle with saddles set on an arc of 150-ft radius, with rollers below the carriers. Downward stresses due to traction rope could be reduced for this trestle by increasing the radius of the curve through the saddles; or, if the design of grips and carriers permit, by supporting the rope on rollers close under the grips (Art 6*a*). Vert stresses are found by similar methods to those in Fig 14 *a*, *b*, 18.

14. POWER REQUIRED OR DEVELOPED BY TRAMWAY

Tensions. Given: wt of individual load = l; wt of empty carrier = e; spacing of carriers = d; wt per ft of traction rope = r. Then the weights per ft of uniformly distributed load corresponding to wt of carriers plus wt per ft of traction rope, are:

For loaded side, $w_l = \dfrac{l + e}{d} + r$ (34); for empty side, $w_e = \dfrac{e}{d} + r$ (35)

If w be the total uniformly distributed wt per ft for any case, then tension in traction rope at upper end of line (Eq 29) is $t = wV \pm wf'H$. If load is descending, the sign of last term is minus; if ascending, plus. Total tension equals the tension thus found plus that put into the rope by tension wt applied to a sliding sheave. The tension added to each rope by tension wt = t_w.

Power. Let gross tension on taut side = T; and gross tension on slack side = S. Then $(T - S)$ is the force to be applied to move the traction rope, or to be opposed to traction rope, to restrain it. This force multiplied by veloc of rope in ft per min (v) gives the work done on or by the traction rope per min; hence, power required or developed (omitting friction of terminal machinery) is

$$\text{H p} = \frac{(T - S)\,v}{33\,000} \tag{36}$$

Friction losses. Power thus computed will be increased when power is required, or decreased when power is developed, by friction of driving machinery at terminals. If friction coeff of this machinery be 0.33 $^1/_3$% of its wt, the power to overcome friction will be

$$\text{Friction h p} = \frac{0.00\,^1/_3\,Wv}{33\,000} = 0.000\,000\,1Wv \tag{37}$$

in which W = wt of moving terminal machinery in lb, and v = veloc of rope in ft per min. Combining Eq 36 and 37, gives total power of tramway as

$$\text{H p} = \left(\frac{T - S}{33\,000} \pm 0.000\,000\,1\,W\right)v \tag{38}$$

Inertia. At instant of starting, inertia of the line is to be overcome, and moving resistance is higher than when running. To insure sufficient starting power, the following empirical rule may be used: in determining the power developed by a gravity line in starting, divide wt of individual load l by 2; or for the power required to start a power-driven line, multiply l by 2, before substituting in Eq 34.

Return freight may be carried on a tramway. This at times increases tension on slack side, a condition which must be recognized in power calculations. On a gravity line considerable up freight can be carried when line is running at full capac of descending loads, but when there is little descending material, driving machinery must be supplied, for use at such times.

To solve Eq 36 and 38, T and S must be known. But when a drive is first investigated, these factors are unknown, since each is composed of the stresses due to loads, plus half the tension wt, the amount of which has not yet been determined; but, as half the tension wt is applied to each side, the value of $(T - S)$ will be equal to the difference of the stresses on the two sides due to the loads, as determined by Eq 29, without considering tension wt.

Tension weight. A sheave which will furnish friction necessary to drive or restrain the traction rope is found by Eq 31, by substituting the value of $(T - S)$ as above and the value of f and n suitable for the friction surface, and number of half laps under consideration, and then solving for S, the tension on slack side. If S be less than the tension

for this side as found by Eq 29, no tension wt need be applied by sliding sheave to provide the necessary friction. If S be greater than the tension on empty side, the deficiency must be supplied by a tension wt equal to twice this difference, applied to a sliding sheave. Trial calculations may indicate several possible types of drive with their respective tension weights, and the merits of each can be considered. If S be less than the tension produced by loads on slack side, a sliding sheave is needed simply to take up slack in traction rope, and the wt applied need be sufficient only to keep the rope taut near sheave. If the resulting tension, after tension wt is added, is greater than necessary, it shows that the power sheave is capable of doing more than is required. Having found the wt to be applied to sliding sheave, T is found by adding t_w to tension on taut side, due to the loads as found by Eq 29. This is the stress that finally determines size of traction rope required.

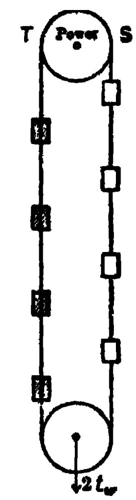

Fig 27. Power Machinery at Upper End

Application of these principles to the typical tramway, Fig 11, illustrates method of computation. Fixed data for this line are: wt of load = l = 800 lb; wt of carrier = e = 420 lb; spacing of carriers = d = 384 ft; wt of traction rope = r = 0.89 lb per ft; horiz length of tramway = 6 900 ft; difference in elev of ends of tramway = 1 866 − 350 = 1 516 ft. As carriage wheels have plain bearings, f' = 0.02.

Let Fig 27 represent CONTROLLING MACHINERY AT UPPER END, the most probable arrangement for this tramway. Calculation of forces developed by descending loads and required for ascending loads, to accompany the figure, is as follows:

LOADED CARRIERS DESCENDING (By Eq 29, $t = wV \pm wf'H$)

Loaded side; descending.	Empty side; ascending.
$w = w_l = \frac{l+e}{d} + r = \frac{1\,220}{384} + 0.89 = 4.07$	$w = w_e = \frac{e}{d} + r = \frac{420}{384} + 0.89 = 1.98$
$t_l = 4.07 \times 1\,516 - 4.07 \times 6\,900 \times 0.02 = 6\,170 - 562 = 5\,608$	$t_e = 1.98 \times 1\,516 + 1.98 \times 6\,900 \times 0.02 = 3\,002 + 273 = 3\,275$

$$(T - S) = t_l - t_e = 5\,608 - 3\,275 = 2\,333 \text{ lb} = \text{force developed.}$$

LOADED CARRIERS ASCENDING (By Eq 29, $t = wV \pm wf'H$)

Empty side; descending.	Loaded side; ascending.
$= w_e = \frac{e}{d} + r = 1.98$	$w = w_l = \frac{l+e}{d} + r = 4.07$
$t_e = 1.98 \times 1\,516 - 1.98 \times 6\,900 \times 0.02 = 3\,002 - 273 = 2\,729$	$t_l = 4.07 \times 1\,516 + 4.07 \times 6\,900 \times 0.02 = 6\,170 + 562 = 6\,732$

$$(T - S) = t_l - t_e = 6\,732 - 2\,729 = 4\,003 \text{ lb} = \text{force required.}$$

In above case, for descending loads, $(T - S) = 2\,333$ lb. For a gravity line, controlled by hand brakes, a pair of plain sheaves might be used (stresses being too great for wood filling). This assumption gives $f = 0.085$ and $n = 2$; hence from Table 3, $e^{f\pi n} = 1.706$, which substituted in Eq 31 gives $(T - S) = S(e^{f\pi n} - 1)$, or $2\,333 = S(1.706 - 1)$; hence $S = 2\,333 \div 0.706 = 3\,300$ lb. This practically equals value of t_e; hence t_w might be zero if there is to be no margin of power. For a power margin of 25%, new value of S is 4 125; substituting this in the expression $S = t_e + t_w$ gives $t_w = 4\,125 - 3\,275 = 850$ lb; hence tension wt should be 1 700 lb, which is reasonable.

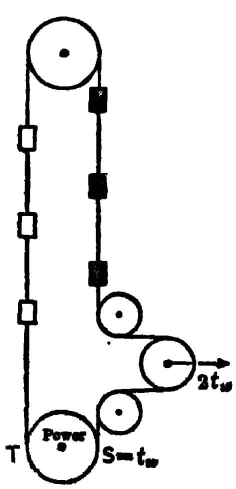

Fig 28. Power Machinery at Lower End

To haul the same loads up the line, a grip sheave with steel jaws (Fig 29) would be necessary to develop required pull. Let the jaws have a ratio of 1 : 3; then $f = 3 \times 0.085$, $n = 1$ and $e^{f\pi n} = 2.228$ (Art 3). Substituting these values in Eq 31 gives $(T - S) = S(e^{f\pi n} - 1)$, or $4\,003 = S(2.228 - 1)$ and $S = 4\,003 \div 1.228 = 3\,250$ lb, which is greater than t_e. Hence, with no margin of power, a tension wt of $2(3\,250 - 2\,729) = 1\,042$ lb is essential for power purposes. It is well, however, to add 25% and make up the increased tension on slack side by adding to the tension wt.

Another combination occurs with CONTROLLING MACHINERY AT LOWER END of tramway (Fig 28). Then the tension in slack side due to loading will be zero, and the only tension on slack side of driving sheave will be that given by tension wt attached to sliding sheave; that is, $S = t_w$. Tension on taut side will be $T = (w_l - w_e)V \pm (w_l + w_e)f'H + t_w$; the plus sign being for ascending loads, the minus for descending. From these equations the force to control movement of loads $(T - S)$ can be determined. For ascending loads, power is always required, but for descending loads there are two combinations: (1) on a steep slope, first term may be the larger and the value

of $(T - S)$ positive, indicating that force is developed; (2) on a gentle slope, second term may be the larger and $(T - S)$ negative, indicating that force is required to pull the loads down. With large powers, either required or developed, it is not practicable to place power machinery at lower end, because all tension on slack side must be obtained artificially, and by so doing tension on loaded side is increased prohibitively. Value of $(T - S)$ is substituted in Eq 31, together with trial values of f and n, and the value of S is determined. Since $S = t_w$ for this arrangement of driving machinery, the required tension wt is known at once.

15. POWER MACHINERY

Rope drives on plain sheaves may have one or several half laps on the sheaves. A C-I sheave with a single groove, giving a half lap on the sheave, makes a satisfactory drive, but the pull exerted is small. Two or more grooves in a C-I sheave, where the grooves are positively connected, is objectionable, because the rope in first groove has more tension; hence this groove wears faster and becomes of smaller diam than the others, producing a differential stress of large but unknown amount. Multiple-groove drives are satisfactory if the grooves can slip or creep to compensate for this differential stress. Elliptical-grooved sheaves with several laps about them, as used on capstans, are not applicable to tramways, as the rotation of the rope down the slope in one direction will twist it and give trouble by tilting empty carriers.

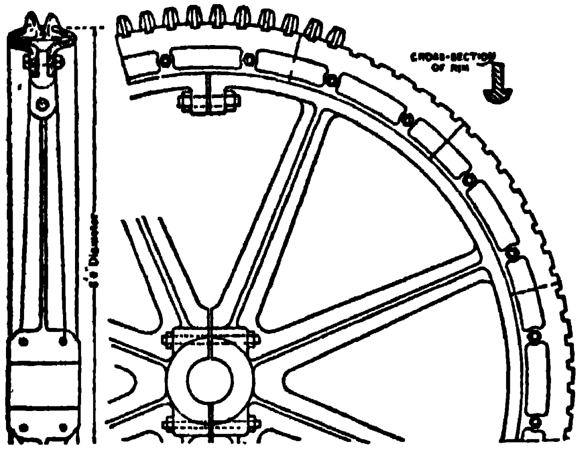

Fig 29. Hallidie Grip Sheave

Wood-filled sheaves can be used for transmission of considerable power, where $(T - S)$ is large, but actual tensions are small. If tensions are heavy, the wood will be cut out. RUBBER AND LEATHER-FILLED SHEAVES give max friction for rope drives, but are easily cut and not applicable to tramways.

Grip sheaves give a strong hold on rope for a single half lap on sheave, and do not produce differential stresses in rope. The Hallidie pattern (Fig 29) is well adapted to transmit considerable power, and does not injure traction rope. The jaws multiply the rope press by 3 or 4, increasing the friction. This increases f in Eq 30, 31 by same amount, whence the power transmitted by a single grip sheave is equivalent to that of a 3 or 4-grooved iron sheave. The grip sheave costs about the same as the multi-grooved sheave and its idler.

Band brakes may be used with machinery running constantly in one direction. The force absorbed by the brake is $(T - S)$ and ratio of T to S is given by Eq 30. Brake should be so arranged that the greater tension T will come at fixed end; then S is the pull exerted on other end in applying the brake. If the conditions are reversed, the max stress comes on movable end and the brake tends to release itself. The bands are about $^1/_8$ in thick, lined with blocks of maple to increase friction. Frequently operated brakes must not absorb too much power per unit of area, or they get excessively hot and destroy the blocks. A good rule is to allow 72 sq in of brake surface for each hp absorbed.

Automatic speed regulators for gravity lines save brakeman's wages and the tramway runs smoothly; on power-driven lines they assure constant speed. The best controller is an elec motor, belted or geared to the tramway drive sheave. It furnishes operating power when conditions prevent the tramway from running by gravity, and turns current back into the power line when being driven by the tramway. It will run about 5% under speed when acting as a motor, and 5% over speed when generating current. Current may be either d c or a c. If a c, the motor may be of constant-speed type to say 30 h p; above that, the variable-speed type avoids excessive line loads or starting shocks. Motor should have an ELECTRIC BRAKE capable of stopping the line if current fails; without a brake, the line would run away when the motor ceases to offer resistance. Hand brakes are also required, to shut down and hold the line, or for use when the motor is not acting. The starting device should admit current to the elec brake and release the brake when it connects the motor to power line. A d-c motor can be made to generate current under any line condition, but an induction motor acts as a generator only when connected to a line supplied with current by a separate a-c generator. Current turned back into the line can be utilized elsewhere.

Other automatic regulators having limited application: (*a*) hydraulic controllers, offering resistance by pumping water or oil against a pressure, which is automatically changed in proportion to the power absorbed; (b) fans running at high speed in the air, with blades arranged to swing out, like governor balls, thus acting with longer radius and more resistance as speed increases. They can be adjusted to keep tramway speed constant; (*c*) water may be pumped or air compressed to absorb surplus power; the water or air can be utilized or run to waste; (*d*) where mill or other machinery is adjacent, a tramway can be connected to the line shaft; the governor for the mill machinery then controls tramway speed and power generated by the tramway aids in driving the mill.

Brakes may be operated by levers, handwheels and screws, or combination of the two. Levers are quicker to operate, but not so powerful as handwheel and screw. The operating stand may be on the terminal floor or on an elevated platform. When brakes are operated by levers, the latter can be extended by rods to any point.

Power-driven tramway. When using less than 20 h p, connection to the vert shaft is conveniently made by bevel gears placed either at top or bottom end of shaft. With a gear ratio of 1:5, the horiz shaft runs at convenient speed for belting to motor or engine. When power exceeds 20 h p, torsion in vert shaft is considerable. This is avoided by bolting brake wheel to one side of main sheave and a spur gear to the other side and driving latter by a pinion mounted on a parallel vert shaft, the latter being driven through bevel gears from a horiz shaft. On heavy drives the sheave will usually be a grip sheave. Bevel gearing may be avoided by deflecting traction rope over a pair of vert sheaves, and causing it to pass under main driving sheave mounted on a horiz shaft. Sheave is bolted to a spur gear, driven by a pinion on a parallel shaft to which motor or regulator is geared. As the ropes tend to lift main sheave, the downward press of the shaft in its bearings is reduced. When the traction rope tension is sufficient to lift the driving sheave, with any gear or brake wheel attached to it, the bearings should be inverted, with lubricating grease well below the shaft, like a R R car wheel, the bearings being placed on under side of supporting beam. The connection between motor and tramway sheave may include a belt drive (not as reliable as gearing). Silent-chain drives and speed reducing gears have also been used. A machine-moulded spur gear attached to main sheave, followed by cut gears with rawhide pinion on motor, give a good drive at reduced cost.

Gravity lines. Where power is absorbed by automatic regulator, or utilized for any purpose, connection to main sheave is made by gearing, as above, for power driving.

Tension sheave at lower end may slide in a horiz or slightly inclined plane (Fig 32), or the rope may be deflected so as to make it travel vertically (Fig 40), or in any other direction.

16. TERMINAL AND JUNCTION STATIONS

Purposes. Every terminal station must be designed for 3 distinct functions: 1. To secure track cables. 2. To operate traction rope. 3. To transfer carriers from cables to rail, lead them to loading or discharging point, and return them to the cable.

1. **Cables are secured** in same manner as at anchorage and tension stations (Art 12), with changes in details to suit conditions.

2. **Traction rope is operated** by power drive, or controlled by a brake system at one end, usually the upper, and is tightened by passing over a sliding sheave, usually placed at lower end. Occasionally power machinery and tightener are at same end. Type and arrangement of controlling and tension mechanism depend on local conditions, and are subject to considerable modification (Art 14 and 15).

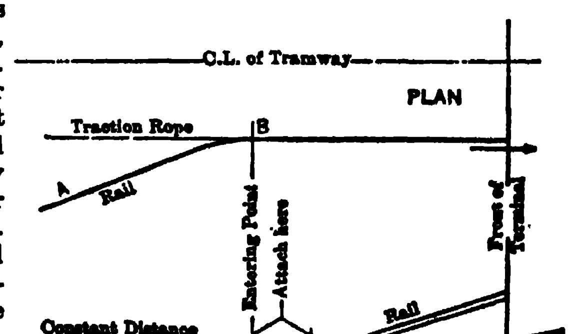

Fig 30. Attaching Point for Grips Opening Sidewise (Dotted lines show alternative position of rail and traction rope)

Manner of deflecting and guiding traction rope in terminals is influenced by the process of getting the rope into or out of the grip, and of attaching or detaching carriers. For a grip OPENING AT SIDE, the rope must be brought through a point where it will be opposite the grip jaws at the instant that grip comes into the vert plane through the rope, as the carrier moves toward rope in running along rail. Thus, in Fig 30, the carrier moves along rail from *A* to *B*, the grip travels in horiz plane *abc*, and when carrier reaches *B*, the traction rope must be at *b* so as to enter the grip, which is then closed, after which the carrier supports the rope. A second case, where rail and traction rope slope downward, is shown by dotted lines. In detaching, these operations are reversed.

For a grip OPENING DOWNWARD, the carrier moves so as to bring grip into plane of rope, but somewhat above it, then advances toward inclined rope, or is lowered onto rope, if it is horiz, until it bears in the grip when jaws are closed. Thus, in Fig 31, carrier moves from *A* to *B*, with grip above rope, then advances until point *C* is reached, when rope will be in jaws of grip, which can be closed. In detaching, the process is reversed. If grip jaws OPEN UPWARD, the grip will pass under the rope before taking it.

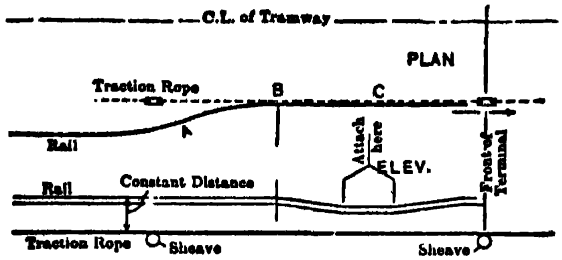

Fig 31. Attaching Point for Grips Opening Downward

3. Transfer of carriers, from cables to rail, or vice versa, must be done as smoothly as possible, to prevent lunging of carriers and hammering of cable where carrier leaves the rail. Lunging of the carrier is reduced by accelerating it on entering the attacher, to approx speed of traction rope. Experience shows that wear on cable is least when carriers run on to cable outside the terminal saddle, where cable is free to deflect when load comes on it. This requires a terminal point movable vertically. When carriers take the cable at a rigidly supported point, the cable is hammered and the wires are displaced and worn.

At terminal saddle, rail is placed parallel with track cable, but back of terminal point the rail is curved vertically so as to change from the inclination of cable to the horiz before reaching point

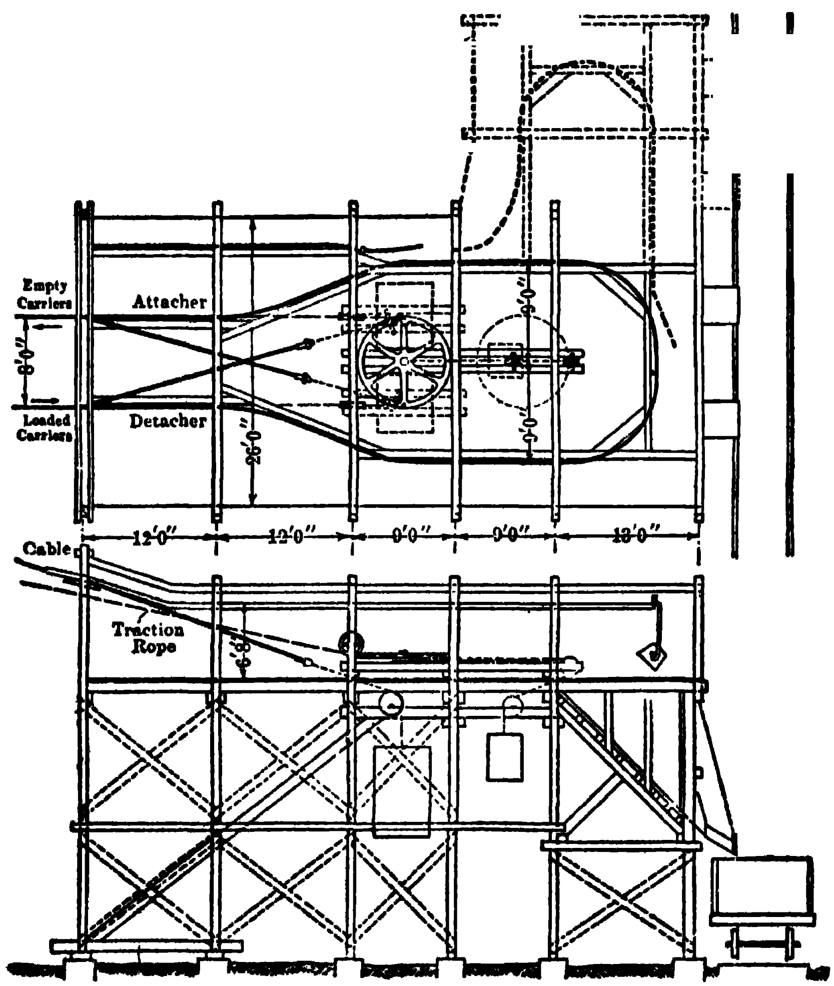

Fig 32. Discharge Terminal for Sidewise-opening Grip

where grip is released from traction rope. Where cables slope downward from a terminal, rails are bent on convex vertical curves at the front of a terminal, resembling a rail station at a crest, until they are parallel to slope of cables; the curved rail saves cable from downward press of carriage, and reduces wear on cable. When cables leave a terminal on an upward slope, the rails are bent on concave curves, and provision must be made for holding traction rope down, to make it change its direction without lifting carriers off rail.

Back of detaching point, the rail is bent horizontally on easy curves so that the incoming bucket, running at high speed, will take curves smoothly. On outgoing side, the curve leading to attaching point may be a little sharper, as the carriers are pushed by hand or move by gravity and travel at a slower speed. The rail must form a loop large enough for carriers to clear the terminal machinery and the framing used for its support. Rail can be extended by switches and loops into as elaborate a system as desired, to reach loading and discharge points (see dotted rails in plan of Fig 32). Rail

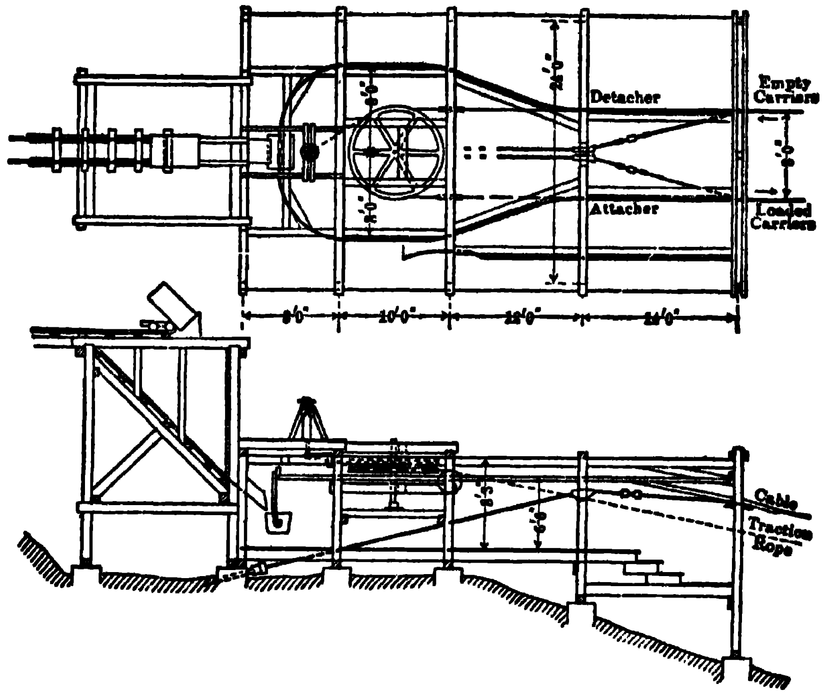

Fig 33. Loading Terminal for Sidewise-opening Grip

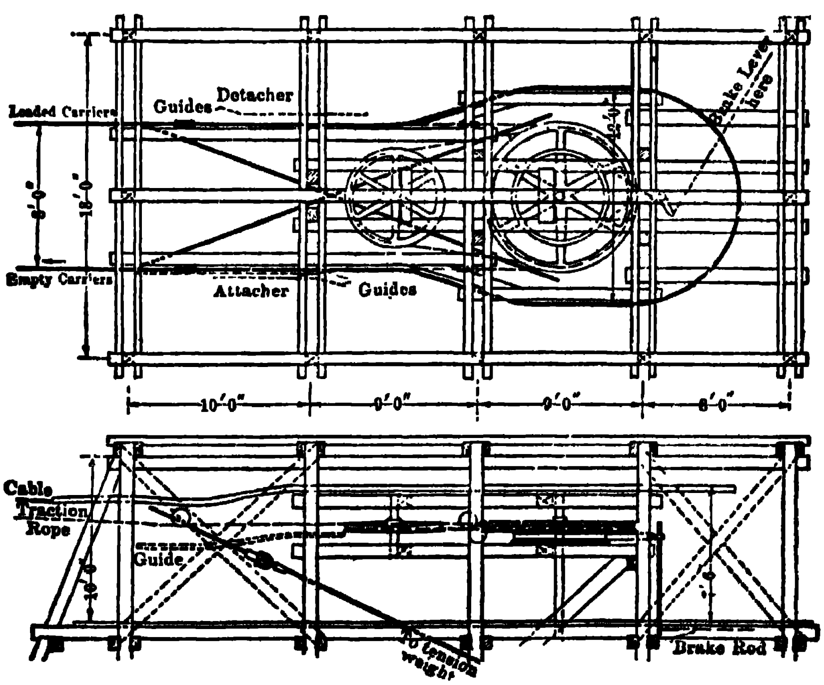

Fig 34. Terminal for Downward-opening Grip

is often graded, so that parts of the run can be made by gravity. At a loading terminal for bulk materials, carriers are filled from bin chutes, and at discharge end are run over pockets into which they are dumped. Fig 32 and 33 show typical arrangements of terminals for tramways with grips opening at side, with horiz curves to release traction rope from grip. Fig 34 shows a terminal for grips opening downward. In this the horiz curves are not necessary for gripp'ng operations, but are required for the carriers to clear the center posts.

Quarry loading terminals may be designed to transfer buckets from tramway hangers to flat cars, for conveyance to quarry face. Larger rocks than those that will pass through bin gates, or material too sticky to handle in chutes, can thus be loaded directly into buckets. The loaded cars are hauled back to tramway terminal and the buckets replaced in hangers (tramway makers 1–8, Art 29). Buckets can be transferred from hangers to cars by running the car track under tramway rail and grading track or rail so that the hanger hooks or unhooks from the bucket as required, when car and hanger are moved along together.

Transfer by a mechanical lift (maker 5, Art 29); see *The Engineer*, London, Oct 9, 1936. At loading terminal of a tramway transporting clay to brick works at Reading, England, buckets are hauled to the pit on cars and filled by an excavator. The cars have a platform movable vertically about 6 in by a lever. To transfer an empty bucket to a car standing beneath it, the operator raises the platform under the bucket and lifts it out of the hooks on tramway hanger. After loading, the platform is lowered so that the bucket trunnions again ride in the hanger hooks (Maker 6, Art 29).

Underground tramways and terminals. Where entrance to mine is by tunnel, with its mouth in steeply sloping ground, the rear part of the loading terminal has been built in an underground chamber below the tunnel, with an ore pocket at tunnel level.

At San Francisco del Oro mine, Mex, a bi-cable tramway extends 4 715 ft from discharge terminal at mill to a point where tramway makes a deflection angle of 67°, enters an adit, 3.5 m high by 4 m wide, and runs underground 3 000 ft to a terminal from which loops extend to 2 loading points at bottoms of old stopes lined with concrete to form storage bins. At one loading point the

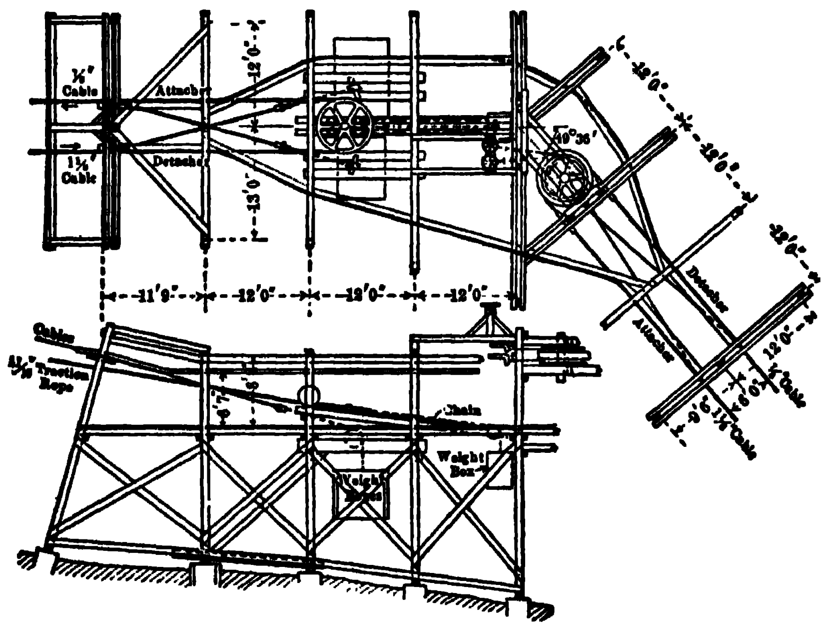

Fig 35. Junction Station

rails are hung from bottom of the bin; at the other, supported from the floor. From the terminal, the track cables are carried on rocking saddles, 30 m apart, resting on hangers suspended from 8-in channels concreted into hitches in the adit walls. The traction rope, free for full length of adit, is supported entirely by the buckets. Tramway cables are locked-coil, 1.5 and 7/8 in; carriers weigh 200 kg and hold 800 to 1 000 kg of ore, giving a capac of 100 to 125 metric tons per hr. Traction rope is 5/8 in, plow steel; speed, 150 m per min. Buckets are filled by hand-operated chutes and coast to the terminal, where they are dispatched at proper intervals, travel to the angle station where they detach; then coast through structure and re-attach automatically. From mill terminal, buckets coast to bin, where a tripper is set, dump load, and run to return side. For a round trip, a bucket is handled by a loader and a dispatcher at each end terminal. Cost of operating the above and a feeder tramway for more than a year was 2.3¢ U S cur per metric ton per km; covering labor, power, supplies and rope replacements (14). Maker 1, Art 29.

Automatic discharge terminals can be built to return carriers without detaching them from the rope and without attendance. They contain a horis tail sheave, usually 12 ft diam, around which the traction rope travels and, parallel with it, a curved rail on which the carriers run. At the terminal, buckets leave cable and run on a rail, dumping in transit either when on terminal loop or when on cable outside of terminal; the carriers, preferably empty, pass around the loop and run off the rail onto the return cable. This eliminates labor at the terminal, but requires a large diam sheave, to which the speed of travel for whole line must be proportioned, to keep down the centrifugal action of the carriers in making the end turn. Tramway speed is 300 ft per min with 12-ft sheave and 500 ft with 16-ft sheave. Loading terminals are of the usual type (Fig 33, 34), including

release of the carrier grips. **Angle stations** can be designed so that carriers will pass around them at low speed without being detached from the rope; but more carriers are needed than for the ordinary tramway, thus increasing direct stresses on the line. The grips must be designed to pass around the sheaves. These conditions increase first cost, but decrease operating costs. Makers No 1–8, Art 29.

Junction stations are practically 2 terminals placed back to back where divisions of a long tramway meet. An angle may occur between center-lines of the divisions without increasing cost of operation, and with only a slight complication of design. Fig 35 shows a junction station at an angle, which contains the driving machinery for one division and the tension sheave for traction rope of the other. The cables from one right-hand division are deflected and anchored; those from the other being stretched by tension weights.

17. TRAMWAY INSTALLATIONS

Ordinary tramways. Until about 1920, bi-cable tramways had capacities under 100 tons per hr; net loads seldom exceeded 2 000 lb; carriages had two 8-in, or 10-in wheels; many are still being built. Following examples are illustrative; see also Bib 13.

Argentine Government tramway, built about 1910, connects a mining field in Mejicana Mts with smelter and RR at Chilecito. Length, 34.3 km (21 miles); fall, 3 528 m (11 600 ft). As there are 8 divisions, each with its own drive and traction rope, the line consists of 8 indeoendent tandem tramways, connected by junction stations; at these the buckets, detached from incoming traction rope of one division, coast on rails to outgoing rope of the next and are there attached automatically. At several junctions the line makes horiz angles. Control machinery for divisions is at junction stations, each division being subdivided into sections by suitable anchorage and tension stations for the track cables. Country is rugged, requiring rail trestles on crests, and long spans over ravines (2 of 258 m and 540 m); through one sharp crest is a tunnel 150 m long, 4.5 m wide, by 4 m high. All structures are steel. Capac of line, 40 tons per hr of ore down from mine, and 4 tons per hr up freight. Buckets hold 1 125 lb ore; speed, 510 ft per min. Track cables are both locked- and smooth-coil, 35–30 mm diam on loaded side and 26–20 mm on empty side (approx 1 3/8–1 3/16 in and 1–0.75 in). Cables are stressed by weights hung on wire ropes passing over sheaves. Cables oiled by traveling oiler (Maker 7, Art 29) (15). See Bib.

Spanish Peak lumber tramway transports lumber from saw mill in forest to planing mill at Gray's Flat, Calif. Length, a little over 5 miles. From loading terminal line rises 1 200 ft in 3 miles and then drops 2 100 ft to discharge terminal. Loads consisted of packages of lumber not over 16 by 32 in by 32 ft, containing 300–600 bd-ft, weighing about 1 250 lb; hung by chain slings from a carrier near each end. Nominal capac, 10 000 bd-ft per hr, about 15 tons. Loads were sent out every 3 min, spaced 1 242 ft apart. Lang-lay traction rope, 5/8 in diam, runs normally at 414 ft per min. Cables are locked-coil, 1 1/8 and 7/8 in. Running normally, line develops about 10 hp, but requires 20 hp when loading up empty line. It is controlled by two 24-in Pelton water wheels opposing each other; a governor admits water to forward-turning wheel when tramway slows down 5% below normal, and to reverse wheel when speed exceeds 5% above normal.

Tramway was built in 1916 by maker I (Art 29); in 14 years carried over 150 million bd-ft of lumber; idle 5 years and put to use again in 1935, by Meadow Valley Lumber Co, Quincy, Calif (16).

Consol Coal Co, W Va, installed a 3 400-ft bi-cable tramway for mine waste disposal. The first half passed over a summit and across a ravine with a clear span of 1 700 ft, from which buckets were dumped. Tramway operated by 1 man at loading terminal; the empty buckets detach automatically, coast to loading chute, and are filled from an air-operated under-cut rotary gate. Loaded buckets coast to an automatic dispatcher which released them at intervals to coast into an attacher, gripping them to traction rope. On the long span, the rotating self-righting buckets passed through a frame which dumped them automatically; they then went to outer terminal, passed around a horiz sheave without detaching and returned to loading terminal, which contains driving and traction rope tension machinery. Outer terminal contained return sheave and tension weight for track cables. Buckets, hung from 4-wheel carriages, held 0.75 cu yd (2 000 lb). Traction rope, 7/8-in; driven 350 ft per min by 75-hp motor. Track cables, locked-coil, 1.5 and 1 1/8-in; tensions, 62 000 and 34 000 lb (Maker 1, Art 29) (17). Line had capac when built of 30 cu yd per hr, to be increased to 50 cu yd by adding more buckets and reducing the spacing from 525 to 315 ft, with 54 sec time interval.

Benguet Consol Mining Co, Philippine Is, has a 49 500-ft tramway with fall of 873 ft, in a straight line, driven by power as one unit; 0.75-in endless traction rope is nearly 19 miles long; buckets, 6 cu ft; capac of line 15 tons per hr; 8 spans are 2 770–5 180 ft long. Flat profile, grade in favor of loads and light tonnage, give a low traction-rope tension (Maker 1, Art 29).

Riblet Tramway Co has built bi-cable tramways containing unique features. NORTHERN PERÚ MINING Co has 4 interconnected tramways, connecting 3 mines with mill and smelter, so that ores, concentrates, smelter products and supplies can be sent to any point without reloading buckets. The system, 30 miles long, was put in operation in 1927. One division, 9 000 ft long, feeding smelter with coal and ores, has capac of 50 tons per hr; the others, 15 tons per hr. Track cables are 1 1/8 and 1 in plow-steel smooth-coil, and 1 3/8 and 1 1/8-in cast-steel locked-coil. Steepest incline, 35°; longest span, 4 351 ft. Traction ropes, all 0.75-in plow-steel Lang lay have speed of 500–550 ft per min; 10 motors, totaling 510 hp, start the line, but when running only 7 are needed, with total capac of 410 hp (11, 12). In BOLIVIA, a 6.5-mile tramway starts at mine at elev of

14 000 ft, crosses summit of Andes at 16 000 ft and ends at concentrator at 9 000 ft. One span of 3 000 ft crosses a chasm so rugged that a 7-mile detour is required (11). At GLORIETTA, N Mex, a tramway with capac of 80 ton per hr, has 2 divisions at an angle; junction station contains the controls for both; 1 span is of 4 000 ft. HYDER, Alaska, tramway is 11 miles long, in 1 unit. Unusual features: (1) a continuous traction rope; (2) 3 angles in the line, all deflecting in same direction; combined deflection, 171°, so that the direction of travel at the ends is nearly reversed. Line has speed of 600 ft per min; was designed for capac of 15 tons per hr, which has been greatly increased (12a).

Heavy-duty tramways. Since 1920, there has been demand for tramways of larger capac; an important recent application is in hauling aggregate for concrete at dam sites, the concrete being carried and deposited by cableways (Art 26). Bi-cable lines with capac to 300 tons per hr, have been built to carry 4 000-lb loads suspended from carriages with four 12-in wheels. FOR RAPID LOADING, a measuring hopper holding 1 bucket load, may be filled by a chute with under-cut arc gate; or, if material is coarse, by pan conveyer or vibrating feeder; hopper discharges quickly into the buckets, which can be dispatched at rate of 3 or 4 per min.

A typical plant was used on the PARDEE DAM, for water supply for San Francisco Bay cities. Length of line, 18 255 ft, total rise, 389 ft. One summit was 456 ft above loading terminal; near discharge terminal a river was crossed by a span of 1 320 ft. Carriers were 32-cu ft end-dump buckets, holding 3 000 lb, hung from 4-wheel carriages; speed, 470 ft per min; spacing, 192 ft; time interval, 24.5 sec; capac, 220 tons per hr. Track cables, locked-coil, 1 $^5/_8$ and 1 $^1/_8$ in, except for river span, where they were 1.75 and 1 $^3/_8$-in Cables of first division, anchored at loading terminal and the angle station, were stressed by concrete weights at a double-tension station about the middle of the section. Cables of second division, anchored at the angle station and a double-anchorage station, were stressed at a tension station near the middle. The river span, with larger cables, was stressed independently from discharge terminal. All structures of wood. Traction rope, $^7/_8$-in; that for the first division was driven from angle station; for second division, from discharge terminal; each drive comprised a grip sheave and spur gear, driven by a 125-hp motor. Traction-rope slack was taken up by floating sheaves at ends of each division. At loading terminal, empty buckets detached from rope coasted to the loading chute, were filled in 4 or 5 sec, and coasted to the dispatcher, which held the bucket until the one ahead had traveled the length of the spacing; then released it to coast down grade to acquire the traction-rope speed; the attacher closed the grip and the bucket departed. At the angle station, empty and loaded buckets, detached from traction rope, coasted on rails between the divisions, and took the out-going rope of the other division. At discharge terminal, buckets coasted across the bins, dumped while in motion by trippers, rounded the loop, gripped the outgoing rope, and began their return trip. All operations were automatic, supervised by 1 man (18) (Maker 1, Art 29). At CONCHAS DAM, N Mex, a bi-cable tramway was built in 1937–8 to transport concrete aggregate. Region rather flat, favoring a truck road, yet contractor decided low cost of tramway operation more than offset its greater cost. Line crossed river with 1 085-ft span. High winds are common, but caused only slight delays to operations. To prevent freezing of wet aggregate in zero weather, steam was forced into load at lower terminal, preventing freezing in transit. The line was unloaded at night during cold weather; the bucket loads being reduced 1.5 cu ft successively until all were empty. Operating crew per shift: foreman, 4 men at terminals, and a lineman. Details of tramway are: length, 9 963 ft; rise, 235 ft; capac, 224 tons per hr; 36-cu ft end-dump buckets, with 4-wheeled carriages, were spaced 264 ft; net load, 3 600 lb. Track cables, 1 $^5/_8$-in and 1-in locked-coil. Traction rope, $^7/_8$-in 6 by 19 Lang lay plow steel; speed, 550 ft per min; interval between buckets, 28.8 sec. Driven from lower terminal by 150 hp motor. At discharge terminal buckets turn around a 16-ft sheave without detaching (Maker 1, Art 29) (19). For details of other dam construction, see Bib 20–22.

Heavy-duty tramways have recently (before 1938) been built by Maker I (Art 29) as follows. U. S. GYPSUM Co, Alabaster, Mich. Line 6 800 ft long to dock in Lake Huron, to carry 260 tons per hr, with provision to increase capac to 300 tons, is carried on 8 towers 750 ft apart, built on cribs in lake. PENNSYLVANIA-DIXIE CEMENT Co, 1 mile long to carry 250 tons per hr. Buckets loaded and dumped automatically after line is started. One man oversees operation. CANYON COAL & COKE Co, Morgantown, W Va. Line 3 412 ft long transports 200 tons coal per hr in 62-cu ft end-dump buckets, hung from 4-wheel carriages. Having a fall of 150 ft, line runs by gravity, and develops 20 hp, which is absorbed by a 25-hp induction motor. Cables, locked-coil, are anchored at both terminals; stressed by weights at a double-tension station on the Cheat River, whence they make a clear span of 1 500 ft to discharge point and thence to anchorage. Buckets are loaded at a chute with air-operated under-cut arc gate, and are automatically attached to traction rope, hauled over the line and back to loading terminal where they coast to loading chute. Enroute they are dumped at the discharge point and returned around a tail sheave. Line speed, 450 ft per min; spacing of buckets, 195 ft = 26 sec time interval. Operated by 1 man, with another available for relief and chores at loading terminal (23).

18. COST OF EQUIPMENT AND OPERATION

Cost of a tramway comprises: 1. First cost of machinery. 2. Freight to the tramway site. 3. Cost of timber and foundation materials. 4. Distributing machinery and material along the line. 5. Framing and erection. 6. Installing machinery, including

cables, saddles, terminals, etc. 7. Superintendence and contingencies. If structures are of steel, cost of fabricated steel replaces cost of timber and its framing in items 3 and 5 above. Attempts to give costs are almost futile, as conditions and prices vary greatly, but the following discussion (repeated from 2nd Ed) will aid in estimating by indicating the items to be considered. See also the 1938 costs given below.

1. **First cost of machinery** for a bi-cable tramway of grip type, for aver conditions and ordinary equipment, in 1926, was approx as follows:

Table 6. Price and Weight of Machinery

	Capac, tons per hr	Cables, diam, in	Carriers, capac, cu ft	Spacing of carriers, ft	Price per ft	Wt per ft, lb
Line machinery, including tower equipment, cables, ropes and carriers. Towers taken as 250 ft apart; line speed, 500 ft per min	10	1 and 7/8	5	750	$1.60	8.0
	20	1 1/8 and 7/8	6	450	2.00	10.0
	50	1 3/8 and 7/8	12	360	2.40	12.0
	100	1 5/8 and 1	20	300	3 20	16.0

	Price	Wt, lb
Machinery for 2 terminals, including all metal-work, but no motor or automatic regulator	$4 000 to $6 000	24 000 to 36 000
Intermediate station machinery	$1 667	10 000

Motors, with solenoid brake, controller, transformer, oil switch, 500 r p m and 1 000–1 200 v, cost per h p; 25 h p, $50; 50 h p, $32; 100 h p, $24; 150 h p, $20.

2. **Freight** by R R, boat or team from maker's factory can be estimated from above weights and prevailing traffic rates. Hauling by motor truck on highway costs roughly 5–10¢ per ton per mile.

3. **Timber and foundation materials** are usually obtained locally. Timber needed: 2-in planks, 6–12 in wide; timbers 3 by 6 to 10 by 10 in; a few beams and struts, for terminals and intermediate stations, 10 by 12 to 12 by 16 in. No timber need be over 30 ft long. Foundations should be of masonry or concrete.

Average conditions require an intermediate station every 4 000 ft, which may be assumed to contain same material as an anchorage and tension station.

Table 7. Quantities of Materials in Structures

	Timber, ft B M	Foundations, cu yd
Loading terminal, no bins	10 000	50
Loading bin	8 000	10
Discharge terminal, no bins	15 000	50
Tower	80 per ft of height	Under 20 ft high = 4
Average height, 30 ft	2 400	Min = 6
Intermediate station:		
Double anchorage station	8 000	25
Double tension station	16 000	45
Anchorage and tension station	12 000	35

4. **Cost of distribution** is a local matter. Wt of machinery and quantity of timber are stated above. Length of haul to destination depends on topography, and these data, with local charge for hauling, form basis for estimate; roughly, say 50¢ per ton mile, from freight terminus to last points accessible to motor trucks or wagons.

5. **Cost of framing and erecting timber** depends on local wages and quality of labor. An approx figure is $50 per 1 000 ft B M for terminals, bins, intermediate stations and towers. Foundations, including excavation, approx $15–$20, per cu yd. STEEL STRUCTURES and towers cost in 1921–22, f o b factory, 3.5–4.5¢ per lb fabricated ready for erection.

6. **Cost of installation** varies greatly. Rough estimate is: for heavy cables, 3.5¢ per lb; light cables and traction rope, 5¢ per lb; machinery, 1.5¢ per lb. These figures include cost of distribution of machinery along the line, by dragging or sledding from end of truck or wagon haul.

7. **Superintendence and contingencies** may be figured as 20% of TOTAL ESTIMATED COST. If a quotation is obtained on the machinery, the allowance for this item may be put at 30% on the REMAINING ITEMS of the estimate.

On a 4-mile tramway in Tenn, erected 1903, in rolling country, where all parts of the line were accessible for teams, and discharge terminal was near the R R, costs per 1 000 lb were very low (see accompanying table).

Material	Unloading at R R and haul	Installing	Total cost per 1 000 lb
Cables	$2.76	$3.64	$6.40
Traction rope	Unloaded, pulled through towers, spliced and installed in one operation		7.00
Machinery	$1.02	$2.22	3.24

In general, cost of timber, framing and erecting the structures and installing machinery, on lines carrying 40 tons per hr and over, is a little under the price of machinery; on lines of less than 40 tons

per hr, a little over that price. Conditions under which tramways are built are so variable that it is difficult to specify averages; hence all the above prices must be taken as approx, and may easily be changed 25% by local conditions.

Quantities of material in structures, weights and costs of equipment and cost of erecting in 1927, were discussed and conclusions tabulated by Carstarphen (7).

In 1938, a tramway engineer for an important maker furnished following figures. Tramway costs: lumber, per M bd-ft erected, \$80–\$100; structural steel, per ton (2 000 lb) erected, \$160–\$200; installing cables and machinery, per ton, \$60–\$70. Quantities of concrete in foundations: 25 to 30-ft towers (higher towers take more), 4 cu yd; anchorage and tension stations (min), 25–30 cu yd; terminals (min), 30–40 cu yd. For costs of construction and operation of tramways, see Bib 8a, 12a, 19, 24.

Cost of operating consists of labor, repairs, interest on investment and a sinking fund allowance.

Operating labor for a line carrying 50 ton per hr or less will be: 1 brakeman, 1 laborer at each terminal and an oiler half time if line is not over 2 miles long. On heavier lines, 2 laborers may be required in each terminal and the oiler would work full time. Oiler should travel over the line daily, inspecting machinery, tightening loose parts and making petty repairs; when his whole time is given, he may be the line foreman. Automatic regulators, or a power drive, will save the brakeman; on light lines, loader may act as brakeman; sometimes buckets can be dumped automatically and all labor at discharge terminal be dispensed with.

Repairs for first 2 or 3 yr will be light, due mostly to accidents; in 4th and 5th yr, all parts will show wear, and renewals may amount to 2% per yr on first cost; after 5 yr, repairs may be 5% per yr on first cost.

Carstarphen discusses comparative costs of hauling by truck and by aerial tramway, and concludes that only on short hauls (say 1 mile) and moderate tonnage (as 100 tons per day) are trucks cheaper than tramways (24).

OTHER TYPES OF TRAMWAYS

19. TWIN-CABLE TRAMWAYS

These, invented by W. C. Lawson, have carriers running on parallel track cables on same level. Carriers have 2 or more sheave-wheels on each side and are hauled by a single traction rope (Maker 3, Art 29); they resemble a system of cars running on rails and hauled by a wire rope. If tramway is continuous, there are 2 pairs of track cables, one pair over the other; loaded carriers travel on the upper cables and empties return on the lower. At each end, traction rope passes around a vert sheave 6 or 8 ft diam, and carriers leave track cables and travel on rails, which are curved at the ends to parallel the sheave circumference, and having a radius about 18 in greater than the sheave radius.

In passing from upper to lower pair of cables, carriers are inverted for discharging; they return inverted to starting point and are righted in passing around the vert sheave at that end. As carriers are permanently attached to traction rope by clamps or sockets, they are filled while in motion by a mechanical loader, automatically drawing material from bin and measuring proper load. Speed of ropes must be slow enough to permit loading without spilling, and maintain a moderate centrifugal force at the curved ends. Fig 36, 37 show diagrams of terminals of typical automatic tramways (Interstate Equipment Corp).

Carriers may be attached to traction rope by grips; by detaching them, loading of other than bulk material is facilitated; but this eliminates some automatic features, and few lines have been thus designed. By detaching, return cables may be on same level and to one side of outgoing cables; carriers then return right side up, and may be used to haul back freight.

Towers are open through the center at their tops, and track cables are supported on rocking saddles attached to insides of tower posts, the carriers passing through towers and between saddles. Traction rope is supported on wide-faced sheaves, a little below clearance line of carriers.

Horiz angles can be turned by ending cables at a structure with curved track rails on which carriers travel and are hauled by traction rope as in a rope haulage system on the ground. After leaving the curve, carriers again run onto the cables. The curve must have a radius of 57 ft or more. As curve is horiz, the line speed must be reduced, or radius of curve must be large enough to prevent excessive centrifugal force.

Carriers for bulk material are usually shallow rectangular steel cars, of 10-60 cu ft capac for different hourly tonnages and weights per cu ft of load. In dumping, a baffle plate causes the material to flow instead of being dropped; this prevents breakage in case of coal.

Track cables are either locked- or smooth-coil, 0.5-1 5/8 in in diam, and are stressed as on bi-cable tramways (Fig 15 and Table 1). On short lines, the stressing devices are at

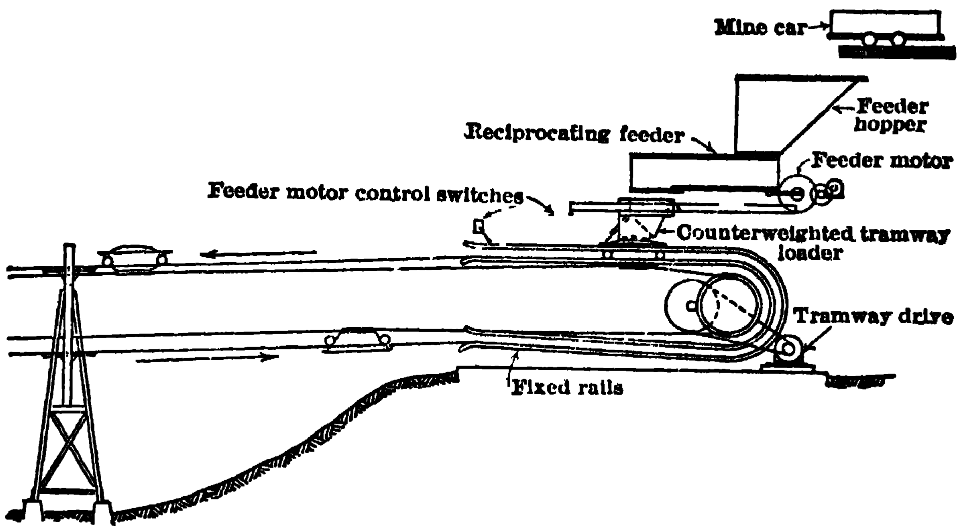

Fig 36. Loading Terminal, Automatic Tramway

one end; on long lines, the cables are anchored or stressed at intervals of 2 000-3 000 ft, to preserve the desired tension.

Traction ropes are 6 by 19 hoisting rope, their size and grade depending on working conditions; 0.5 in to 1 in are common; safety factor of 5 should be used. The rope is made up of lengths equal to spacing of carriers with sockets on both ends of each length; sockets are then attached to bottoms of carriers by pins, and tension is applied by equipping an occasional carrier with special splicing devices. The splice carriers are spaced not more than 5 000 ft apart, and have means for holding the traction rope in any position

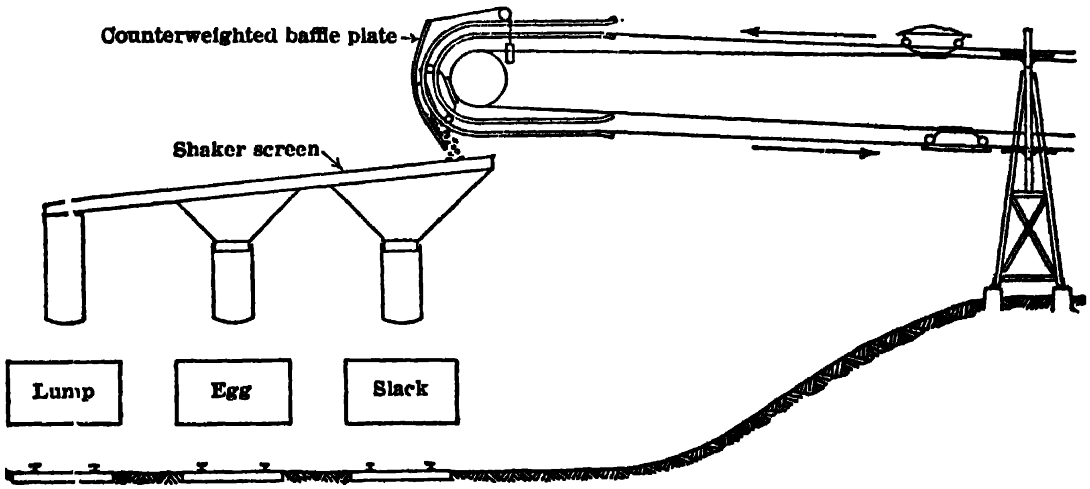

Fig 37. Discharge Terminal, Automatic Tramway

after being stressed to desired tension. When the rope stretches, the slack is taken up at a splice. When carriers are attached to traction rope by grips, traction rope is endless and slack can be taken up at a terminal by a sliding tension sheave. If loads cause very heavy tension in traction rope, it may be necessary to divide the tramway into sections, each dumping its loads into the bin of the following section.

Capacity. Lines have been built to carry 300 tons coal per hr, using 60-cu ft carriers running on 0.5-in locked-coil cables. Speed of travel directly influences capac: it is usually about 400 ft per min (Table 8).

Table 8. Recent Twin-cable Installations

	Horiz length, ft	Material	Capac, tons per hr	Fall, ft	Carriers, cu ft	Speed per min, ft	Traction rope, in	Track cable,* type & diam
Cold Spring Mining Co, Cold Spring, Va	13 000	Mine run kaolin	30	650	9	380	5/8	SC 5/8 & 1/2

* SC = smooth-coil. LC = locked-coil.

20. REVERSIBLE TRAMWAYS

These, sometimes called " jig-back " or " to-and-fro " tramways, consist of: 1. One or two track cables. 2. Traction rope for carriers. 3. One carrier on each track cable, moved to and fro by traction rope. 4. Station at each end for operating machinery, and filling or dumping carriers. 5. Sometimes intermediate towers are used to support track cable and traction rope, but are disadvantageous, as they limit speed to 1 000 ft per min, while without them carriers may be run at 2 000 ft per min. Carriers dump automatically at discharge terminal; the machinery is then reversed and carrier returns on same cable. One man fills the carrier and operates the line. Made by all tramway builders.

Limitation. Cost of erection and operation is low, but capac is limited by the reciprocating movement. With ordinary construction this limit occurs, with a 2-cable system, when product of tonnage per hr multiplied by distance in ft approximates 50 000; that is, a tramway 1 000 ft long can handle 50 tons per hr. With special construction much larger tonnages are carried. With a single track-cable, capac is a little less than half the above.

Sizes of carrier and cable are governed by same conditions as other bi-cable tramways; the load must not cause excessive bending in the cable (Art 6, 6a), but, as loads pass at longer intervals than on a continuous tramway and therefore cable receives fewer bends per hr, heavier loads may be used, subjecting cable to more bending than on a continuous tramway. When loads must be heavy to secure tonnage, carriages may have 4 wheels. For a cheap plant, the track cables may be smooth coil, or, for temporary use, standard 7-wire strand rope.

Track cables are seldom weighted, but are made taut by turnbuckles or wire-rope tackles. The cable tension is judged by deflection of empty cable at center of span. For a single span with anchored cable and single heavy load, see discussion at Fig 45, Art 27.

Carriers, when there are 2 track cables with 1 carrier on each, are clamped to traction rope so that one will be at loading terminal when the other is at discharge terminal; thus one is loading while the other is discharging. If there are no intermediate towers, the carrier hangers can be extended down from both sides of carriage, thus preventing carriers from jumping off the cable, and permitting higher speeds. At each end, in any case, carriers stop just before terminal saddles are reached, for loading and discharging. When loads are descending, the system will often operate by gravity like a gravity inclined plane. A reversible tramway may be operated with 1 track cable and 1 carrier. This is practically half a double system, and always requires power.

At loading terminal, when there are 2 track cables, they are sometimes brought close together, one above the other, so that a carrier on either cable can be loaded from one chute. Between the terminals the cables are far enough apart to permit carriers to pass each other. They may be brought close together again at the outer end.

Installations. The principle of reversible tramways can be utilized to transport very light loads to loads of several tons. In general, this tramway is the simplest and cheapest for moderate distances. Tonnage per hr is limited by long time interval between loads,

due to the intermittent action, and by size of the load. The time is fixed; size of load is the only variable, and when increased, the size of cable and strength of construction must be increased also, and an economic limit is reached if more than 100 tons per hr are carried.

Table 8a. Typical Installations of Reversible Tramways

Capac, tons per hr	Material	Length	Net load, lb	Loads per hr, cap + wt	Time interval, min	Loading time, min	Speed, ft per min
25	Coal waste	755	2 500	20	3.0	0.5	650
25	Coal	1 200	2 700	18.5	3.25	0.5	873
40	Coal waste	1 320	4 000	20	3.0	0.5	1 056
75	Coal waste	440	4 200	35.7	1.68	0.4	687
90	Coal waste	1 250	6 000	30	2.0	0.5	1 667
100	Coal	1 600	6 667	30	2.0	0.4	2 000
100	Coal	1 600	8 000	25	2.4	0.4	1 600

21. DESIGN OF REVERSIBLE TRAMWAYS

Fig 38 is a profile of a typical reversible tramway, with cables anchored at both ends; 1 tower; horiz length, 610 ft; fall, 228 ft. Assume line is of double-cable type, to carry 20 tons per hr, aver 30 loads per hr. This requires a load every 2 min. Allowing 0.5 min for loading, running time per load, is 1.5 min. On the steep grade shown (37.4%), the inclined length of 651 ft, divided by time of 1.5 min, gives running speed of 434 ft per min, which is reasonable for this length of line. Net wt of load is capac per hr + number of loads, or 1 333 lb. Assume nearest size bucket is 15 cu ft, and that it might be loaded with 1 500 lb. Its empty wt (Table 9) is 500 lb. Assume traction rope weighs 0.75 lb per ft.

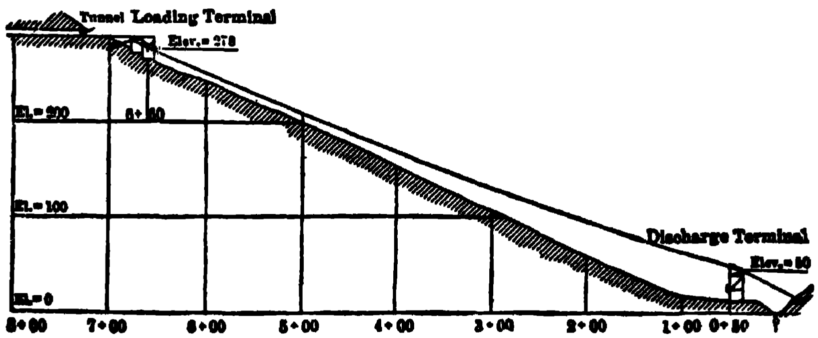

Fig 38. Profile of a Double Reversible Tramway

Track cables. Having chosen a load suitable for desired tonnage at a speed practicable for the length of line, the gross load = wt of carrier + net load + wt of traction rope hanging on carrier. As these can be closely determined and are not subject to increase, the size of track cable can be based on a load of 1 500 lb for each sq in of section for cast steel cable; then $W + t = 1\,500 + 34\,600 = 0.0435$; this is 25% more than is allowable for continuous tramways (Art 6, 6a), but this work is intermittent. Then, gross load + 1 500 = cross-sec of cable; this multiplied by 3.7 = wt per ft of whatever type of track is used, and by Table 1, the size of suitable track is found. If a light-weight rope is desired, one of higher grade steel but equal strength may be used. In this example, load is 2 250 lb; hence, $2\,250 + 1\,500 \times 3.7 = 5.55$ lb per ft of cable, which corresponds to 1.5 in C S locked- or $1\,^5/_8$ in smooth-coil cable.

Table 9. Weight of Rotating Buckets for Reversible Tramways

Capacity of bucket, cu ft......	6 to 8	10 to 15	18 to 20
Weight of empty bucket, lb...	400	500	700

Larger buckets, for coal, weigh about 30 lb per cu ft capac.

Path of load must be investigated. When cable is weighted, the position of loaded cable at different points is determined by Eq 13 or 19, but, when stretched by turnbuckle or tackle, and not weighted, position of loaded cable must be determined by method used for cableways (Art 27, Fig 45), because cable has fixed length, and tension is neither constant nor fully known.

Max stress in traction rope occurs when loaded carrier is on steepest part of line, which will probably be when it is at the top. Its size is determined by: Tension = (*wt loaded carrier* $\times$ *sine inclination of cable*) + wV + tw; in which wV comes from Eq 27,

and t_w = tension due to wt applied to sliding sheave. If the sheaves are large, the wear on rope will be mostly on its surface, and a 7-wire strand rope is suitable; for small sheaves, 19-wire strand should be used.

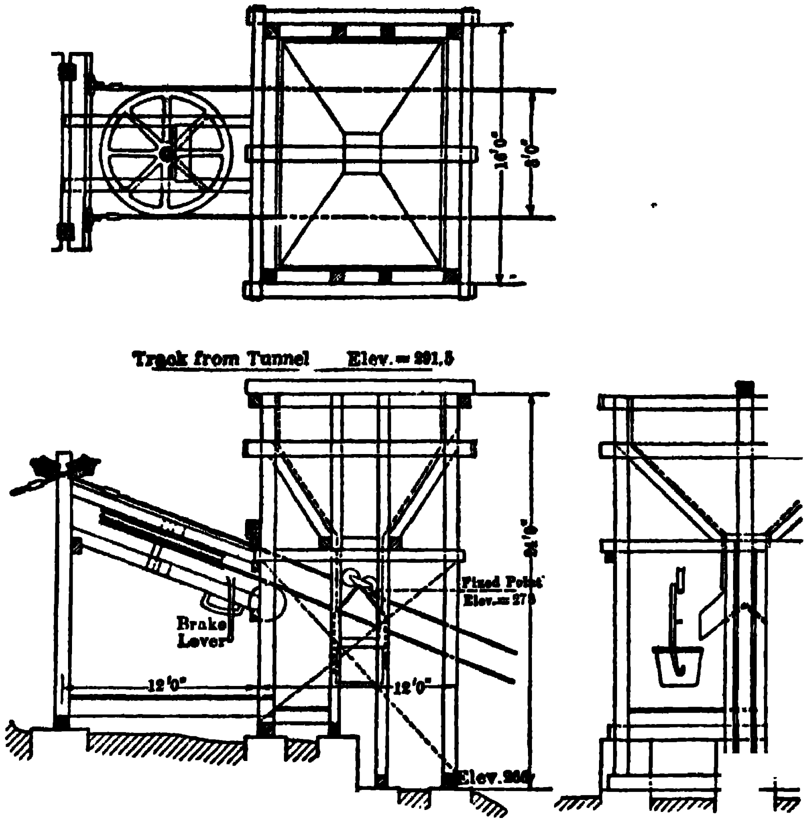

Fig 39. Loading Terminal, Double Reversible Tramway

On gravity lines, relation of operating force to resistance must be investigated at all points, with especial attention to conditions at discharge end, for there the slope of cable is flat and little power is generated, while the other carrier is climbing steepest part of its track and offers max resistance. Momentum of carriers may complete the trip after loaded carrier has ceased to generate power, but this should be counted on with caution, as it requires a skillful operator to run loaded carrier with sufficient speed to take it into its terminal and stop without undue shock. On flat inclines, or with a heavy carrier and slack cable, the lowest point in path of carrier may be at a distance from the discharge terminal, and momentum of carrier may not be sufficient to complete the trip. In such circumstances, this type of tramway should not be installed, or power should be provided to complete the trip of carriers; or, a large track cable should be used, so it can be stressed at higher tension and give a track more nearly approaching the chord.

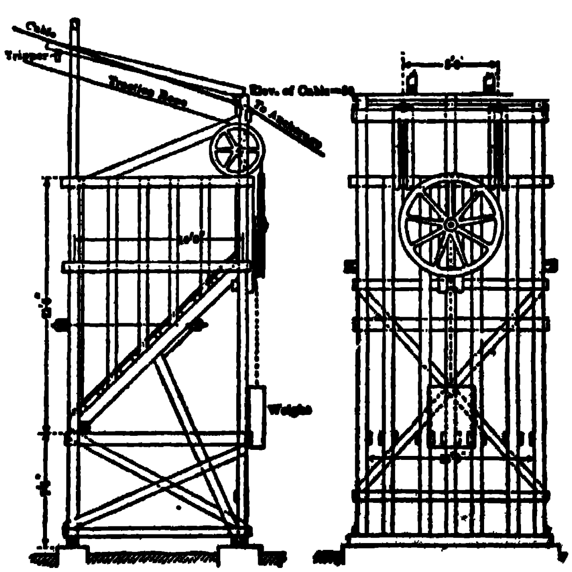

Fig 40. Discharge Terminal, Double Reversible Tramway

Controlling machinery may be either brakes or a power drive. The drive must provide for stopping and for running in either direction.

Shifting belts are satisfactory for this reversing mechanism. They wear well, are simple and easily repaired. Band brakes may be double, with bands applied in opposite directions, so that one

will be efficient, whatever the direction of rotation, and the most advantageous one will be used for main control, while the other is left set throughout run. Power calculations are analogous to those in Art 14. Fig 39, 40 show typical terminals.

22. REVERSIBLE TWIN-CABLE TRAMWAYS

These may have either a single or a double pair of cables (Art 19). Twin track cables permit heavy loads. Carriers for bulk material are usually steel cars, with sloping bottoms, swinging end doors, and 2 or more wheels on each side, traction rope being attached near the wheel line; they dump into a bin at discharge terminal, or are dumped along the line (Art 25). Use of end doors gives a gradual discharge and avoids the upward snap of the cable caused by sudden dropping of the load.

Lines are in use with carriers to 125 cu ft capac, traveling at 1 500 ft per min over towers on pairs of 1 $^5/_8$-in locked-coil track cables and hauled by a 0.75-in 6 by 19 plow-steel rope (Maker 3, Art 29).

A heavy twin-cable type of single reversible tramway was built across the American River, Calif (13). Span, 2 600 ft, with approx horiz chord; four 2-in cables, 2 on each side of a cradle, carried a standard-gage freight car, which loaded with lumber weighed 58 000 lb. The cradle had 8 wheels on each cable, and was hauled at 1 500 ft per min by an endless rope (Maker 1, Art 29).

23. MONO-CABLE TRAMWAYS

These are also called ropeways and single-rope tramways. They comprise: (1) a single endless rope running around large sheaves at each terminal and over small supporting sheaves at towers; (2) carriers suspended at intervals from running rope; (3) terminal machinery for driving the rope and loading and unloading carriers. They are of 2 forms: (*a*) carriers permanently attached to running rope by clips; (*b*) carriers suspended from running rope by "box-heads" (see below) which ride on the rope and are detached at the terminals for loading and unloading.

Clip type. The clip consists either of a thin steel strap encircling the rope, or a steel forging inserted in the rope by slightly separating the strands. Due to this permanent connection, the carriers must be loaded while in motion; where they are small, this may be done manually with scoop shovels, but usually by a mechanical loader; at discharge end, the carrier latch is tripped automatically and load is dropped. One man attends to loading, and operates the control, if this is at the loading end.

The control, by brakes or a power drive, is attached to a grip-sheave at upper end (Fig 28). At lower end, the rope passes around a plain sheave with means for applying tension to the rope. These terminal sheaves are horiz and usually 8 ft diam; carriers passing around them develop centrifugal force, which is kept low by limiting speed to 180 ft per min. Towers have a sheave, 24-in diam at each end of top cross timber, on which the running rope travels. Where downward press of rope is heavy 2 or more sheaves mounted on a rocking beam are used to reduce bending of the running rope. To hold the rope down, sheaves can be placed above the running rope, but, as this adds a load to the rope, bending stresses should be small, and avoided if possible.

Angles in the line are made by deflecting the rope around sheaves of the same diam as terminal sheaves, but without releasing clips from the rope; the sheaves being arranged so that the carrier hanger never comes between it and the rope; the clip projects outward from the sheaves at all times. The rope on the convex side of the angle can be deflected by a single sheave, but that on the inside requires 2 sheaves; these are placed beyond the angle point and at different elevations, so carriers can pass over the other ropes.

Junctions between 2 tramways, where the running ropes turn around terminal sheaves, are made by the carriers of one line dumping into bins, from which the material is reloaded into carriers of the second line. The structure has practically 2 terminals, one above the other. The 2 lines may be at an angle without materially affecting the construction. Fig 41 shows the profile of a short line, and Fig 42, a general standard terminal; with slight changes, it can be adapted to nearly all conditions at loading or discharge end of line, or at junctions.

Limitation. These tramways give good service to a capac of 15 tons per hr, a length of 2 miles, and a difference in elev of 2 500 ft. For greater capac, length, or inclination, running rope becomes heavy and wear is excessive. The limited field for this type has resulted in its being dropped by makers in the U S, although for a light line it is cheaper, in both first cost and operation, than any other tramway. They are still made by English firms 4, 5, 6 (Art 29).

Box-head type of tramway. A box-like casting, a few inches square and 10–20 in long, rides on the running rope and from it the carrier is suspended. There are 2 designs: (1) with a lug at each end, having corrugated V-shaped grooves in their lower ends to increase friction and prevent length-wise slipping (Makers 4 and 5, Art 29); (2) with a grip operated by wt of the carrier; one style (Maker 6) has a tong-like action which closes the jaws about the upper two-thirds of the running rope and gives a positive hold. Another (Maker 8) has a pair of rollers at each end of the box-head, the axes of which are parallel to the rope; the rollers are grooved to match the strands of the rope, each pair being contained in a chamber with tapering sides. When the box-head is set on the rope, the

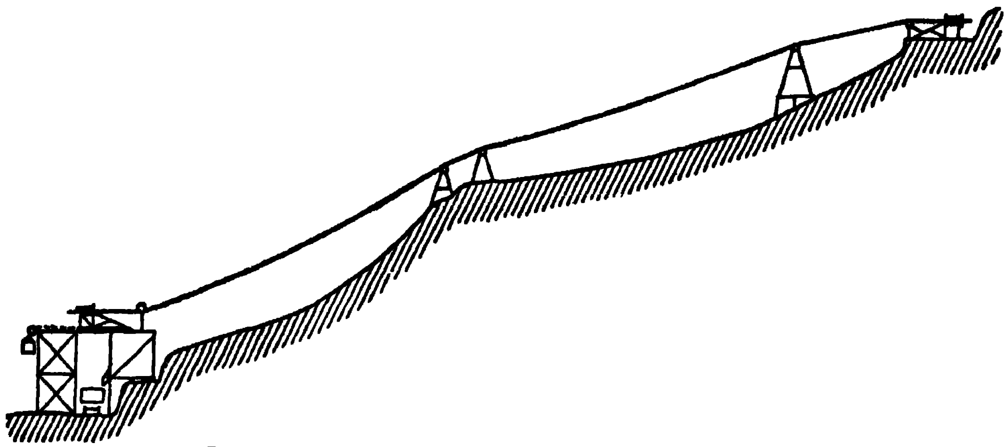

Fig 41. Profile of a Mono-cable Tramway, Clip Type

rollers mesh with the rope strands and the tapered surfaces cause them to grip the rope. Both styles are released at terminals, when the side wheels take the load. The BOX-HEAD, of whatever design, has 2 wheels on one side. At a terminal, an angle or a junction station, a shunt rail is placed parallel to the running rope, a few inches from it and at such a grade that when the box-head wheels engage the rail, the box-head lifts off the rope and runs on the rail. The rail system can be arranged to suit conditions as for bi-cable tramway stations, and lead the carriers to loading or discharge points; or it may simply overcome a gap where the running rope is deflected or interrupted. The rail leads the carrier to the point where it is replaced on the running rope, by depressing the rail with respect to the

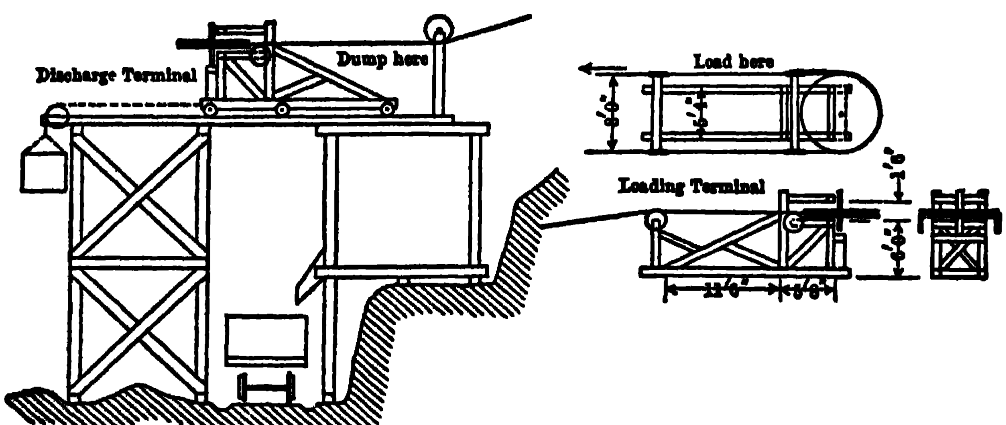

Fig 42. Terminals, Mono-cable Tramway, Clip Type

rope (4). By grading the rail the carrier coasts to or from its stopping points and may sometimes attach itself to the running rope automatically. The rail, if long, may be replaced by a moving chain, which conveys the carriers at about one-third the rope speed across the gap to the attaching point on the running rope (Maker 4, Art 29).

Controlling machinery for the running rope is best located at highest point of the line and preferably includes a grip sheave (Fig 29); to which, for manual control, brake wheels are attached. For power drives or automatic control, the grip-sheave shaft is geared, or a bull gear is bolted to the sheave. See Art 14, 15 for data on power machinery applicable to mono-cable tramways

Towers are usually pyramidal, of steel, with a cross beam at the top to support the sheaves. For light lines, 3-legged towers may be used; with 2 legs on a line normal to center line of tramway and 1 on the center line. The cross beam for the sheaves is attached to the first 2 legs. On moderately heavy lines, 4 sheaves in an equalizing frame are used on the loaded side and 2 on the empty side. In case of a sharp angle over a summit, the tower is replaced by a structure carrying several groups of 4 sheaves each. On light lines, 2 sheaves may be used on the loaded side and 1 on the empty side.

Running rope is usually Lang lay, 6 strands of 7 wires and hemp center; a more flexible rope is sometimes used; rarely, one with wire-strand core. For severe service, plow-steel rope may be needed. Rope sizes are $^5/_8$ to $1\,^3/_8$ in. Initial safety factor should be 6, so that the factor will not fall below 4.5, after rope is worn. Bending stresses are reduced by high rope tension, and those due to large angle over a tower bv multiple sheaves.

Installations. Some of the longest tramways yet built are mono-cable, made up of a series of sections operating in tandem (Makers 4 to 8, Art 29).

Examples. Hollinger Consol Gold Mines, Canada, has a 3.75-mile line, over flat country, driven by 100-hp motor; it holds the capac record for mono-cable, of 190 tons per hr; buckets, 19 cu ft, run at 527 ft per min. During 1934, the tramway averaged over 162 tons per hr while operating crew was on duty, including repairs. From 1927, when started, to June 17, 1935, it carried 5 756 634 tons. During a representative year, transport cost was (cents): loading buckets, 1.23; unloading, 1.56; operating (including power and maintenance), 2.1; repairs and replacement of cable, 1.6; total, 6.49¢ per ton. The running rope, replaced 1938, carried 2.5 million short tons (26). Maker 4, Art 29.

Tilmanstone Colliery, Kent, England, hauls coal to bunkers in Dover harbor (28). Line is over 7 miles long. Loading terminal is at elev of 198 ft; line rises to 357 ft, and drops to 89 ft. Capac, 120 tons per hr. From bunkers, ships are loaded by belt conveyers at 1 000 tons per hr. Buckets hold 1 450 lb coal; running rope, 1.25 in; speed, 390 ft per min; bucket spacing, 138 ft; time interval, 21.4 sec, requiring 60–65 hp. Line is in 2 sections: the first, 18 090 ft, is straight, from loading terminal to a control station at 261 ft elev; the second, to discharge terminal, 20 222 ft, contains 2 angles and passes through twin tunnels about 0.25 mile long. Two divisions were necessary, due to wt and length of the line. The control station contains the driving machinery and tension mechanism for both divisions. At this station and the 2 angle stations, the box-heads leave the running rope at incoming points and coast on rails to the outgoing point, taking the rope automatically. Total cost of tramway, about £120 000, or $15 per ft. Started, Feb, 1930. Operating cost at full capac, 9.8¢ per ton (Maker 4, Art 29).

Indian Copper Corp, Chota Nagpur, India, has a 31 050-ft tramway, over rolling country, with 1 horiz angle to make a crossing normal to river with span of 975 ft (25) (Maker 4. Art 29). A single endless running rope, at light tension, serves entire line. When built in 1928, capac was 40 tons ore per hr and return freight, delivering 100 loads of 800 lb per hr; bucket spacing, 201 ft; time interval, 29 sec; running rope, 1 in, 6 by 7 Lang lay; breaking strength, 70 000 lb; speed, 420 ft per min. Capac was increased to 70 tons per hr in 1933, with larger rope. First rope carried 743 000 tons; second, 712 000 tons; replacement cost, 1.3¢ per ton. Operating cost for 1 month in 1931 (after line had been running 3 yr, single shifts), for labor, power, stores, repairs and supervision, 5.25¢ per ton, for 16 000 tons. Adding 1.3¢ for replacing first rope, total cost was 6.55¢ per ton. A later company report gives cost of 5.5¢ for the entire line. Labor, all native at low wages, was approx 32¢ per man per day, 13 men and foreman being required.

Maker No 4 has also built tramways for Central Provinces Manganese Ore Co, India (97 650 ft), and Rahman Tin Mines, Malay States (7 600 ft).

Cost of materials for a mono-cable tramway, steel construction, f o b England, 1938, is stated by one engineer as approx: (*a*) capac, 20 tons per hr; line material, $1.83 per ft; terminal machy and frame, $3 640. (*b*) capac, 100 tons per hr; line, $4.40 per ft; 2 terminals, $6 800.

Operating cost (stated in general terms by Harrison Roe, *So Af Min & Eng'g Jour*, Aug 22, 1936) for either mono- or bi-cable tramways, about 2 miles long and carrying 15–150 tons per hr, is between 2¢ and 4¢ per ton-mile, at English wages. On short lines, cost is higher, as same labor is required and its cost distributed over fewer miles. On long lines, direct cost may be lower, but more obstacles may tend to increase cost.

General data. Longest mono-cable tramway yet built in one unbroken line is 31 200 ft (nearly 12 miles of running rope); capac, 55 tons per hr. In rugged country, practical length of a tramway, or a section, is about 3 miles. Spans to 3 000 ft can be operated where capac is moderate and tension in running rope is high, but these favorable conditions seldom occur together. Usually, a span of 1 000 ft causes severe stresses and is near the practical limit. In general, spans on bi-cable tramways can be longer than on mono-cable. Capac is limited to about 150 tons per hr by size and wt of running rope needed; max size in use is about $1\,^3/_8$ in; max speed, 400 ft per min. As heavy loads increase bending of running rope, the max is about 1 800 lb. Grades of 50% are possible, but 40% is about the practical limit.

24. DESIGN OF BOX-HEAD MONO-CABLE TRAMWAYS

The economic size of individual loads, determined by experience, is about 1% of hourly tonnage; with small capac they may exceed and with large capac may be under it. For lines carrying 10 tons per hr, loads are 350–400 lb and ratio is nearly 2% of hourly tonnage; for 100–150 tons per hr, loads are about 1 800 lb and ratio is 0.8–0.55%. Speed of running rope is about 400 ft per min; distance traveled per hr divided by number of loads gives the carrier spacing; see Eq 26 (Art 2), which reaches same result by different analysis.

For a tramway of moderate gradient, over rolling country where towers can be placed at short intervals, the running-rope tension at highest point determines size of rope; for tension due to loading, see Eq 29 (Art 2). As the wt per ft in the equation must include that of the running rope, the rope size is found by assuming a wt, say 1 lb per ft for lines carrying 20 tons or less per hr, and 2 lb for heavier tonnage. Total tension equals the above, plus half the wt applied to tension sheave at lower end, which may be taken as 10 000 lb, and a cast-steel rope with a breaking strength 6 times this tension is chosen. The actual wt of this rope is then used in Eq 29, giving a closer value for tension. By a few trials a suitable rope is found; if a rope of cast steel is too large, use a plow-steel rope. The tension wt at lower end must be such as to prevent excessive sag; it may be the only source of tension in the running rope for some distance from lower end. Here the need for large tension can be reduced by making the tower spacing less than at higher parts of the line. Tension varies from a max at the highest point to a minimum at the lowest. If rope is too small, there may be steep slopes at upper ends of inclined spans, exceeding those at which box-heads will hold. These slopes may be reduced by shortening the spans and holding the rope nearly up to its chord. Attempts to decrease sag by increasing the tension wt at lower terminal sheave adds to rope tension throughout the line, which must be considered. On clip tramways, steep slopes offer no difficulties from endwise slipping.

After the proposed profile has been plotted, the tramway can be laid out by methods analogous to those in Art 5, 6. The process is simpler than for a bi-cable tramway, as the running-rope tension is less for the wt carried than that of track cables; hence the rope can follow the topography more closely. The running rope is supported on each end of top beams of towers by 24-in sheaves, and, to limit bending stresses, the deflection over any sheave must be moderate. On clip-type mono-cable tramways, where running rope is 0.625 to 1 in, and tension is low due to light loading, one 24-in sheave is set on each end of tower beam; for larger tensions, one 36-in sheave, or a pair of 24-in, may be used on loaded side. On box-head tramways, the running rope and its tension are often large, so that the rope approximates the curve of sheave, if only one is used, giving high bending stresses. Hence a series of 4 to 6 sheaves with equalizers is set on loaded side to distribute bending; fewer are needed on empty side. If a tramway makes large vert angles over summit towers, 2 series of sheaves may be used; or, in a severe case, a summit structure with several clusters of sheaves may be substituted for a tower. Such structures are like Fig 26, except that the running rope and sheaves would occupy the top instead of cable and saddles. In making a large deflection angle over a sheave the rope tends to conform to the sheave, causing great bending stresses. But, with a small deflection the rope curve has a much larger radius than that of the sheave (see Sec 12). Thus, in a series of sheaves at 36-in centers, and a chord deflection of 2° at each, if the rope is assumed to bend to a uniform curve like a solid steel bar, the radius of rope curve will be 86 ft (Fig 12 and accompanying discussion). The total deflection angle between tangents to rope on both sides of a summit, divided by chord deflection angle between sheaves, gives the number of sheaves required.

Long spans. If the country is rough and a long span is needed to cross a depression, the tension required by this span influences the total tension. The tension in this span is found by transposing Eq 2 (Art 1) thus: $t = ws^2 + 8h$, in which w = wt per ft of running rope, plus the uniformly distributed wt per ft of loads on span (see discussion of Eq 33, Art 6). If the long span has a steeply inclined chord, the tension formula must be modified as under "Horiz tension," Art 1. If the long span is near the upper end, its tension may not exceed that due to difference in elev between that point and the lower terminal; but, if near the lower end, the required tension must be supplied by the tension weight; this affects the whole line and may need too large a rope. If so, the line may be in 2 sections, one including the long span, the other having a tension due to its gradient and a moderate tension weight; or, it may be best to change to a bi-cable tramway.

Example illustrating design of a mono-cable tramway for 150 long tons per hr (4): horiz length, 8 125 ft; fall, 623 ft; max horiz span, 690 ft; permissible sag when loaded, 52 ft; assumed position of long span's lower end, 4 200 ft from lower terminal and 300 ft above it; gradient of span chord, 1 in 15; loaded carriers, 2 464 lb, spaced 140 ft, giving uniformly distributed load of 17.6 lb per ft;

assume 1.25-in plow-steel running rope, at 2.7 lb per ft, breaking strength, 115 600 lb; then, total load is 20.3 lb per ft. These data, substituted in Eq 22 (Art 2), give slope of tangent to rope at lower end of long span, 0.2348, and at upper end, 0.3681, corresponding to grades of 13° 13′ and 20° 13′ respectively. The horiz tension at any point of a rope curve, from Eq 17 transposed, is: $t = ws^2 + 8h \cos \alpha$, in which $\alpha = 3° 49'$ inclination of chord, and $\cos \alpha = 0.9978$. Solving, the horiz tension in long span is 23 284 lb. Rope tensions at ends of this span, by Eq 4 (Art 1), are: lower, 23 900; upper, 24 800 lb. From upper end of span to upper terminal, the rise is 277 ft in 3 235 ft horiz; this gives rope tension due to loading (Eq 29, Art 2) of 4 400 lb, which added to upper span-end tension gives max rope tension at upper terminal of 29 200 lb. As the rope's breaking strength is 115 600 lb, the safety factor is 3.96. For these conditions, the tension wt at lower terminal = 2 × (23 900 − 4 400) = 39 000 lb. **Note.** In this example, of a tramway built in 1912, the author had to assume some data not given by Blyth (4), but the results are close to his final figures. The author believes the conditions are too severe for a single-rope line, and that a bi-cable, in which max traction-rope stress will not exceed 10 000 lb, would be preferable.

25. SPECIAL APPLICATIONS OF TRAMWAYS

In the U S, tramways are chiefly for long distance transport over rough country. In Europe, where industrial plants may be cramped for space, aerial transport leaves the ground free for other purposes. This fact has emphasized certain features less common elsewhere. The first cost of such installations is secondary to low operating cost, safety or effic.

Industrial tramways must provide for loading and discharging at fixed points, which often results in angles, steep grades, and automatic loading and discharge.

Examples. (*A*) A complicated bi-cable system was installed at Imperial Chemical Industries, Billingham, England (29), comprising a main line, feeder tramway and several minor lines. Main line carries 170 tons per hr, plus 35 tons per hr from the feeder. Locked-coil cables are 2 1/16 and 1.25-in respectively; breaking strengths, 300 000 and 110 000 lb. Traction rope is 15/16-in, flattened strand; breaking strength, 58 000 lb; driven by an 8-ft triple-groove sheave, geared to a 60-hp motor. Buckets weigh 1 200 lb and carry 3 500 lb; they rotate for dumping when latch is released by tripper, and are righted by a finger on the bottom, contacting with a spiral rail. Carriages have 4 wheels; wheel base, 3 ft 8.5 in (Maker 6, Art 29). At another part of the plant, 104 tons ore per hr are brought from a mine, and dumped at treatment points by a bi-cable tramway (Maker 5). Traction rope is driven from loading terminal, and the line contains 2 angle stations which the buckets pass without detaching. The cables terminate at the plant and the carriers travel on rails, though still hauled by the traction rope. The rail section is at an elev of 60–85 ft, to leave the ground unobstructed. To limit the number of structures, and to protect men working below from spill from buckets, the rails are supported by floored bridges of light trusses. Buckets dump automatically at a series of bins. (*B*) At a dynamite plant, a complicated tramway was installed to deliver explosive "dope" to any of 3 mixing houses (13). A carrier took the siding at the desired point, as determined by a "selector" on its carriage, set by the dispatcher at the loading point. As the dope is highly inflammable, the loads are spaced far apart on the rope, to prevent fire from spreading in case of accident in any one building (Maker 1, Art 29).

Aerial dumping provides for dumping loads at any point along the line, by continuous or reversible tramways. On continuous BI-CABLE LINES, a tripping device, set at any desired dumping point, is suspended from the track cable, has a finger to release the bucket latch and allows the load to drop. If the load is large, the tripper may be a sizeable frame, guyed to the ground to prevent the supporting cable from snapping upward when the load is suddenly released and so throwing the empty bucket off the line. When the tripper is to be shifted to a new position, a man goes out in a bucket, releases its clamps, slides it along cable and reclamps it. Maker 5 (Art 29) attaches a small wire rope to the frame, for moving it along the cable by a hand winch at one of the towers. On REVERSIBLE TRAMWAYS, a tripper like the above may be used; or a mechanism in the carriage trips the latch: (1) when a carrier has traveled a predetermined distance, a slow-moving disk with a crank pin pulls the latch, the disk being driven through gearing by a carriage wheel; (2) a device on the carriage comes into action when direction of travel is reversed, and releases the latch (Makers 1, 5, Art 29). The device is well adapted to single-rope lines. The reversal can be made manually, or automatically by switches controlling the current driving the motor. When done manually, a load can be discharged at any point, permitting the material to be stacked in different piles. With double reversible lines, the travel of loaded carrier harmonizes with that of the empty; the loaded carrier being at the outer end when the empty is at the loading chute. The dumping point can be at one point for a period and then moved (4). Maker 5, Art 29. With the MONO-CABLE SYSTEM, the tripper is suspended from a stationary rope stretched above the tramway, between 2 adjacent towers. The tripper frame has a supporting sheave to keep the rope and tripper in the proper relation for dumping. The towers carrying the stationary rope are extended

upward, and from them the rope goes to dead men or to a winch; the tripper can then be moved by shifting the rope.

Stocking ore. A Scottish iron plant has a bi-cable tramway (30, 31) (Maker 6). Ore from R R cars goes to a hopper, is conveyed to 2 storage areas, dumped into piles and reloaded by steam shovel into cars going to furnaces. The piles are 35 ft high and 90 ft base diam. One area is served by outgoing cable, the other by the return cable. From the loading terminal the cables rise steeply to two 45-ft towers, 125 ft apart, a cable going to each dumping area; there they terminate in 2 angle stations, connected by a cross cable. These stations have large sheaves to deflect the traction rope, with track rails for the buckets, which are dumped by trippers. Buckets hold 4 000 lb; lock-coil track cables, 2-in; traction rope, 1-in; capac of line, 300 tons per hr. Buckets are filled and pushed into the running-rope attacher by 2 men; after dumping, they return, are detached automatically, and coast to filling chute.

Dumping of waste material, as for building embankments, resembles stock-piling, except that the pile is constantly growing. If on level ground, guyed steel towers, slim or mast-like, as high as 250 ft, have been used. When they are buried in the pile, the line is extended on new towers (32). As such tramways usually run up hill, a power drive is needed (Art 14). DUMPING TRESTLES make very high towers unnecessary. A tramway is built to the dumping terminal; the buckets run onto rails on a lattice truss trestle, inclined upward at angle of repose of the waste (say 35°). At end of trestle is a large return sheave for the traction rope, the buckets dumping as they pass around it. The trestle is extended as required (Makers 5 to 8, Art 29). Dumps have thus reached heights of 500 ft. For waste disposal, several types of tramway are suitable: twin-cable (Art 22), single- or double-reversible (for moderate tonnage and distance) (Art 20), and mono-cable (Art 23).

Loading ships with bulk material. Where ships can not be docked, tramways are sometimes used. The discharge terminal may be built on bins on an island-like wharf, where water is deep enough for ships; the intermediate towers being on pile foundations. From the bins, the ship is loaded by belt conveyer or other means (Makers 1 to 8, Art 29).

Freight tramways for bulky materials, built as adjuncts to RRs, to carry goods over difficult topography, must be designed for necessary clearance over summits. Carriers are buckets, crates, tanks, hanging platforms, or chain slings for barrels, lumber and pipe (Makers 1 to 8, Art 29).

Passenger tramways. On ordinary tramways, 2 persons are carried in long buckets, sitting facing each other. Some Rocky Mtn mines have no other means of transport in winter.

Special passenger tramways. About 50 have been built from 1912 to 1936 by Makers 7 and 8, for various services, chiefly in mountainous regions. Most of them are of double reversible type (Art 20), with 1 car suspended from each track cable; cars hold 20–35 persons; grades, up to 50%; carriages have 8 or 12 wheels, with equalizers to distribute the load; speed, 100–300 ft per min. A double reversible passenger line of Bleichert design (Maker 1, Art 29), began operation in 1938 on Cannon Mtn, N H; horiz length, 5 000 ft, with 3 towers; rise, 2 022 ft; cars, hung from 8-wheel carriages, hold 27 persons; running time, 5.5 min; locked-coil track cables; terminal sheaves for running rope, 13 ft diam; shock absorbers reduce fore and aft oscillation and brakes seize running rope in case of accident. There is an auxiliary rope and mechanism to land passengers from a stalled car. Similar Bleichert and Pohlig tramways have been built in the Tyrol and Swiss Alps.

CABLEWAYS

26. GENERAL DESCRIPTION (see also Sec 5)

A cableway comprises: (*a*) fixed track cable; (*b*) carriage running on cable; (*c*) hoisting or fall rope, to raise and lower load by tackle suspended from carriage; (*d*) hauling rope to move carriage back and forth; (*e*) 2 towers; (*f*) hoister at head tower; (*g*) carriers of various types. Fig 43, 44 show typical designs.

Track cables are up to 3 in diam. locked coil, cast-steel, or plow-steel where load stress is great. At each end is a swivel socket, for turning the cable to distribute the wear from carriage wheels. For cables 2 in diam and over, ball-bearing sockets are used. At one end, cable is anchored; at other end, a take-up tackle provides tension.

Carriages for light loads have 3 track wheels; for heavy loads, as many as 8, mounted in equalizing frames, which also carry the head-block sheaves for hoisting and dumping tackles, provide connections for the hauling rope, support the button rope, and carry the tower horn for collecting the fall-rope carriers. On large cableways, 6-wheel carriages operate in tandem, with considerable space between them, one being rigged with the hoisting tackle, the other with the dumping tackle; this distributes the load on the cable, and checks the swinging of the carriage when brought to a stop.

Hoisting ropes are cast- or plow-steel, $^5/_8$–1 in, with 6 strands of 19 wires; wear on rope due to bending is kept low by using large tower sheaves. The rope runs from drum to the head-tower sheaves, thence through the fall-rope carriers, over the carriage sheaves, around fall-block sheaves, and ends at the carriage. The tackle is usually reaved, so that 4 parts of the rope carry the load. The fall-rope carriers support the rope at intervals, to

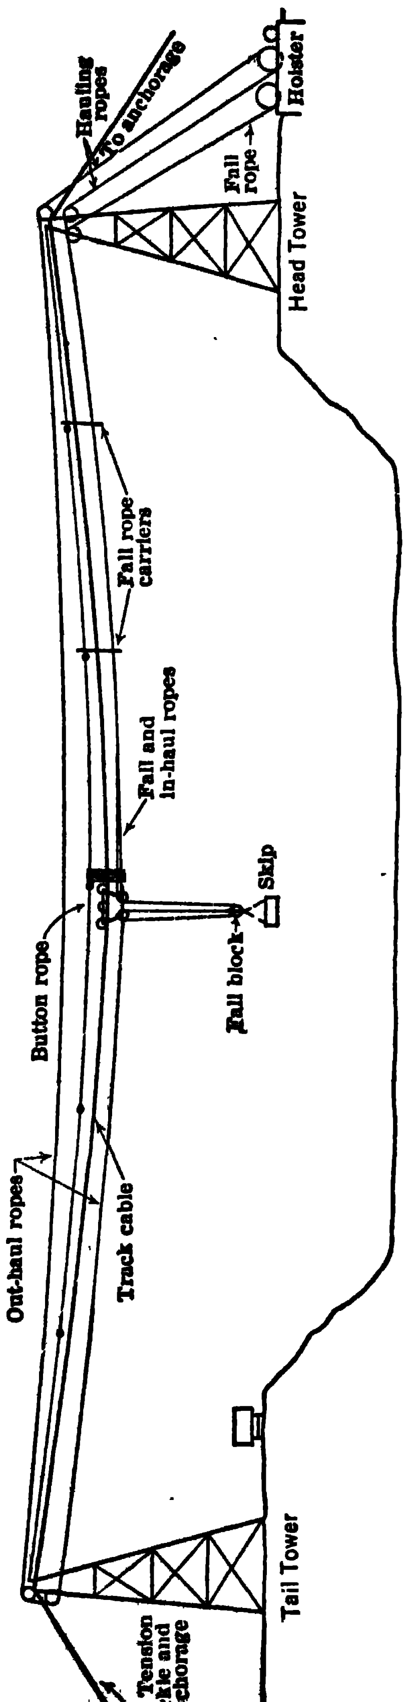

Fig 43. Cableway with Fixed Towers

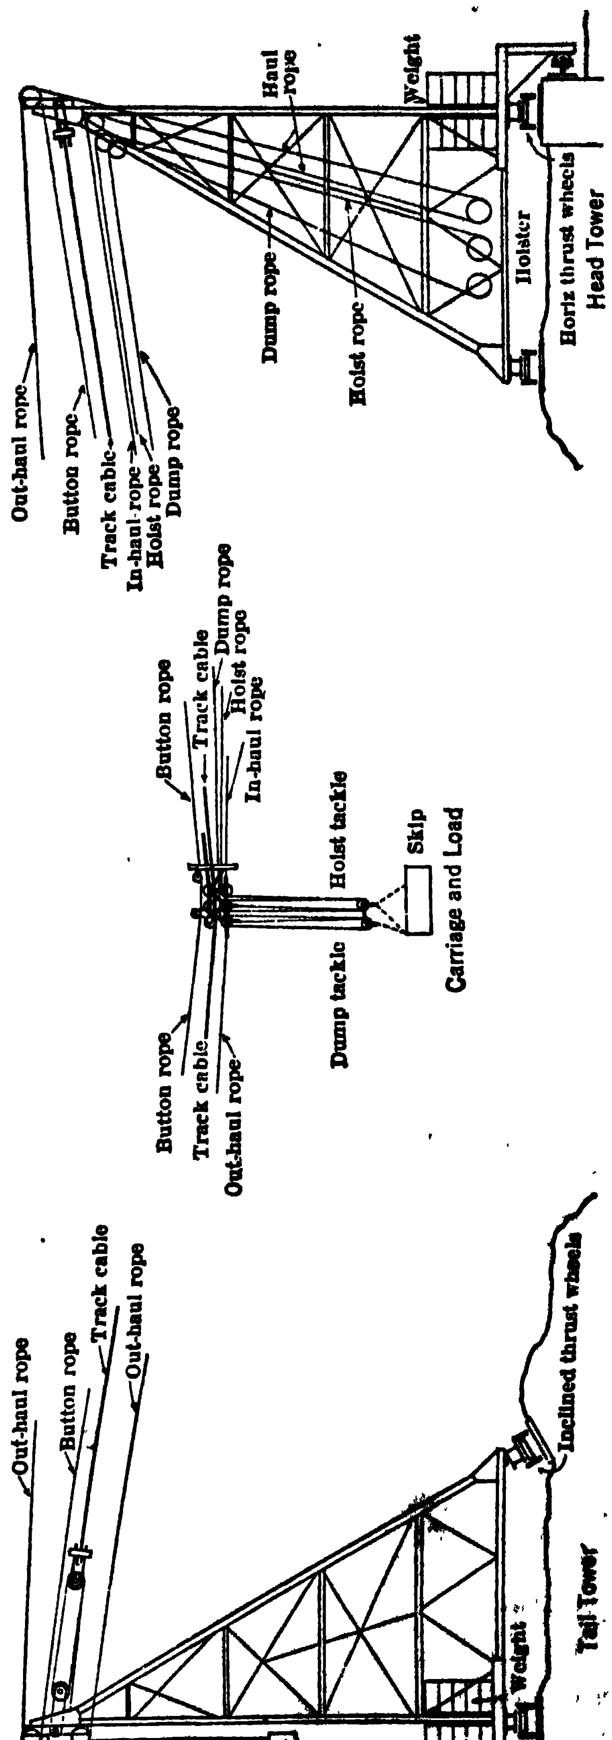

Fig 44. Cableway with Movable Towers

prevent undue sagging when there is a light load. The rope-supporting system consists of a stationary button-rope, on which are placed buttons of different diameters, increasing in size toward the tail tower; the carriers being fitted with rings of correspondingly increasing sizes, through which the button-rope passes. These carriers are stored on the horn on the tower end of the carriage, the one having the largest ring being next to the carriage. As the carriage travels from the head tower, the first button passes through all the rings except the outer one, which is smaller than the button; this pulls the carriers off the horn one by one and sets them on the cable. On the return trip, the carriers are picked up by the horn, and kept ready for next trip.

The entire load sometimes hangs from the fall block and is dumped or detached manually; or, when the skip is dumped mechanically, the main fall block is attached to a chain bridle on the open end of skip, with a second block on the rear end, which is raised by a dumping rope. In the latter case, the dumping rope goes back to a third drum on the hoister. Drums, ropes, and tackles for hoisting and dumping are identical, and operate in unison until a skip is to be dumped, when the speed of one line is slowed by a clutch and brake on that drum, and skip is tilted. The 2 fall blocks permit handling extra heavy loads, by attaching both to a single load.

Hauling rope has one end linked to near end of carriage, passes to sheave on head tower, then down to make several turns on a concave-faced drum on the hoister; returns to head tower sheave, passes above the track cable to top of tail tower, thence around a sheave and back to the carriage. The rope is usually the same size as the hoisting rope, but has less bending stress, and may be of larger wires, to withstand surface wear due to slippage on drum.

Towers at each end support the entire equipment and must be high enough for loads to be hoisted to the elev desired at any point. Stationary towers are often 150 ft and movable towers 100 ft high; usually of steel. Contractors prefer steel, with bolted connections, so the towers can be taken down and re-used. For STATIONARY TOWERS, the cables are anchored back of the tower (Fig 43). When the back cable has the same slope as the normal main-cable slope, the resultant stresses are nearly vert, and a 4-leg pyramid tower is suitable. Sometimes guyed A-frames or masts are sufficient. MOVABLE TOWERS are used when the cableway must be moved at intervals, to serve a large area. They are usually steel, mounted on platforms on railroad-like trucks, with wheels on multiple tracks. As they can have no anchored back stay, the cables terminate at the towers, which are designed to take the horiz tension. This has developed a tower design (34) with vert back legs in tension and inclined front legs in compression; a massive weight being placed close to the vert legs (Fig 44). Towers are moved by a winch in lower parts a rope, anchored at both ends, is given a few turns on the winch drum, and the tower pulls itself along the rope. For heavy cableways (as at Conchas Dam, with 1 650-ft span) each tower has 2 motors, geared to 4 of the supporting wheels.

Movable cableways are of 2 kinds: (*a*) both towers travel on straight tracks; (*b*) 1 tower is stationary, the other moving on a circular track, with the stationary tower as center of arc. When both move their winches are operated in unison by a switch in head tower; rate of travel, 50–150 ft per min. At Norris Dam, 2 cableways (spans, 1 925 ft) cover an area 500 ft long in their travel (36).

Hoister comprises: (*a*) hoisting drum, holding the rope in one layer; (*b*) hauling drum, having wide enough face for the rope, with several laps, to travel to and fro across it (for light work; a capstan-like drum is used); (*c*) dumping drum; (*d*) small auxiliary drum for moving towers. Hoisters are elec-driven; controlled like elec hoisting engines (Sec 12).

Carriers. Skips are used for excavated material; chain or wire-rope slings for large rocks, quarried stone, or heavy equipment; bottom-dump buckets, sometimes as large as 8 cu yd, for depositing concrete.

27. DESIGN OF CABLEWAYS

Data required: 1, plan and cross-sections, or contours, of volume to be excavated, the sections showing probable max depth of excavation; 2, position and elevation of discharge points; 3, kind, size, and wt per piece, or per cu ft, of material to be handled; 4, quantity handled, tons per hr; 5, nature of power to be used.

Weight of load sometimes depends on size of individual pieces or units. In stripping it is usually determined by quantity of loose material to be handled per hr, although wt of single blocks of stone may be the controlling factor.

Time between loads is time to hoist load, transport and dump it, return empty skip to pit and change connections to a loaded skip. Speed of hoisting is usually 300 ft per min,

but may be up to 400 ft; lowering time is usually less than for hoisting; with regenerative braking, speed can be one third greater. Max speed of carriage along cable, 1 800 ft per min; usually, 1 200 ft. Max distance hauled is about 80% of span; aver distance, rarely more than 60%. Hence, time per load $= \dfrac{2 \times \text{depth of pit}}{\text{hoisting speed}} + \dfrac{2 \times \text{distance hauled}}{\text{hauling speed}} +$ **0.5 min, the last item being allowance for changing and dumping. Round trips are often made in 2 or 3 min. As cableways are intermittent conveyers, with limited max speed, large tonnage can only be handled with large loads.**

Size of cable depends on gross load, span and allowable deflection. In beginning a design, assume a deflection of 0.05 of span, when load is at center; if this deflection gives towers of reasonable height, it is adopted and tension in cable is found by solving Eq 14 (Art 2) for t; but, as both w and t are unknown, see Table 1 for the relation between them; w can be expressed in terms of t. For 1.5 to 2-in locked-coil, cast-steel cables, $t = 9\,300w$ (approx); for 2 to 3-in plow-steel, $t = 12\,600w$, when the minimum safety factor used is 3.5. If the 5% deflection requires undesirably high towers to clear obstacles, the tension is increased by using: (a) larger track cable; (b) cable of higher grade steel; (c) a smaller safety factor, unless the minimum factor of 3.5 has already been used in the trial calculation. This factor is small, but sufficient where the max load is definitely known, because the strength of cable is accurately determined and not subject to shock loading. Also, a taut cable suffers less from bending under the wheel load than a slack one. On long spans, the deflection increases faster than the span, due to wt of cable (see Eq 14), and it is often 0.06 or even 0.065 of span; on short spans, it may be less than 0.05, if load is light and cable taut.

Tension tackle for track cable is of wire rope; it must be long enough to connect socket on end of cable with the anchorage, when the cable has been drawn near to final position with ordinary tackle. At first the tension rope is passed over only part of the tackle sheaves; then, as cable becomes tighter, the rope is threaded over the others for the final pull, and is clamped; it may be pulled by a winch-head on the hoister, or by a special drum.

Path of load. Tension is max when load is at lowest point, and decreases as load moves either way. This variation is unknown, hence the equations of Art 1 for deflection, which involve tension, can not be used for determining deflection with load at various points. Path of load may be found approx by assuming that the two supports A and B (Fig 45) are the foci of an ellipse. Then lines $AC + CB$ equal the major axis, and the ellipse can be calculated. If origin O be at center of span, and OC be deflection due to wt of cable and concentrated load at center, then $OC = H$ (Eq 14, Art 2) = the semi-minor axis, while CB = the semi-major axis of ellipse. The ordinates of any point P are x and y. The equation of an ellipse referred to its center is:

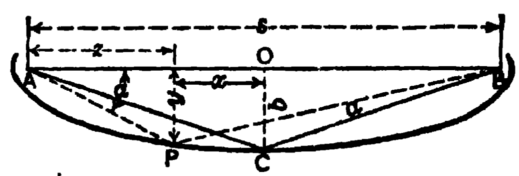

Fig 45. Path of Load on Cableway

$$a^2y^2 + b^2x^2 = a^2b^2, \quad \text{or} \quad y^2 = b^2(a^2 - x^2) + a^2 \tag{39}$$

But $b = H$ and, from Fig 45, $a^2 = H^2 + (s^2 + 4)$; hence, by substituting a series of values for x, corresponding values of y can be calculated and path of load determined for a number of points. If z be distance of load from end of span, the deflection at the load is $y = z \tan \alpha$, which gives slope of chord AP when load is near tower, and this is practically the slope of cable. From last expression, or from path of load, it is seen that the cable becomes so steep, as load approaches either tower, that it is not feasible to run the carriage within 10% of the span from either tower.

This method of finding path of loaded point assumes that the sum of the 2 chords AP and PB is constant for all positions of load, which is not quite true. As load approaches tower, the long section of cable will sag and raise the load a little higher than position indicated by Eq 39. The deflection is further decreased by the pull of hoisting and hauling ropes, which take a varying part of load in holding carriage on the inclined part of cable. These errors are all on safe side, as path of load is usually ascertained to make sure that the load will clear some object. The same problem occurs with single heavy loads on reversible tramways (Art 21). Bib 10a treats of cable spans and length of curve when stretch of cable is included.

Towers on stationary cableways are designed chiefly to resist the vert resultant of the cable tensions; those for movable cableways have a base, parallel to line of cableway, of approx half the height. Hence, to overcome the pull of the track cable and other ropes at top of tower, a balance weight of more than twice these tensions is required at rear of the tower to resist rotation about lower end of inclined front leg. Towers must also be designed to resist a moderate side pull, if cable system is out of line, and to resist wind press acting on the tower and on the half span of cable and ropes. For towers of movable cableways, these side forces require additions to the weights on the bases. These weights are usually precast concrete blocks, which can be removed when towers are dismantled.

Examples of cableways. Advances in practice began about 1910, with 2 plants at GATUN LOCKS, Panama Canal: spans, 800 ft; cables, 2.25-in; load, 6 tons; 85-ft steel towers on parallel tracks; elec hoisters, 150 hp; traveling speed, 1 800 ft per min: hoisting, 335 ft. U S RECLAM SERV, N Mex, 3 plants: spans, 1 420 ft; loads, 10–15 tons; elec hoister, 300 hp. BUFFALO FILTER plant, N Y, built 1925. Two spans, 900 ft; load, 15 tons; 85-ft towers, on parallel tracks, traveled 150 ft per min by engines in towers. MADDEN DAM plant, Canal Zone, built 1932, marked further progress in heavy-duty work: span, 1 265 ft; gross load, 25 tons; buckets for concrete, 8 cu yd, 20 tons gross load; rock skips, 10 cu yd; cables, 3-in locked-coil; 2 carriages ran tandem, each on 6 wheels, with equalizers; 3-drum hoister, driven by 400-hp motor; traveling speed, 1 200 ft per min; hoisting, 300 ft. Steel towers, movable 410 ft by 100-hp motor, were on 32 wheels, in 4 groups, with equalizers, running on 2 tracks, 80 ft apart, at 66 ft per min (20, 21). All the above installations were built jointly by Makers 1 and 12 (Art 29).

From 1932 to 1938, 9 other plants were built for 25-ton loads; and 6 for 15 to 20-ton. Largest of these were 2 spans of 2 575 ft for HOOVER DAM, Ariz. Hoisters driven by 500-hp motors; 3 tandem drums, 53-in by 70-in face. Traveling towers moved at 50 ft per min by a concave-face winch drum in each tower, geared to 100-hp motor, and controlled from head tower to run in unison. On upper deck of each tower were 2 50-cu ft compressors for operating brakes and clutches. Tandem 6-wheel carriages, 40 ft apart, were used, preventing oscillation of buckets due to the long drop of 700 ft; hoisting and dumping lines were $^7/_8$-in plow-steel rope, running through a 4-part tackle; roller bearings for all tower sheaves and fall blocks. Track cable, 3-in locked-coil, had 6% deflection with load in middle of span; it terminated at tail tower in swivel sockets for turning, to distribute wear, and was tautened by a 10-part take-up tackle, with 1.5-in rope. On this dam were 3 other similar cableways, with shorter spans (34, 35). NORRIS DAM, Tenn, has twin cableways, each for 18-ton load, but can be combined to lift 36 tons; spans, 1 928 ft; 3-in cables; towers movable (36). BOULDER DAM, Ariz, cableway was designed for 150-ton loads (largest on record). Span, 1 256 ft; loaded RR cars can be lowered from canyon rim to the bottom, about 600 ft below dam. Track cable comprises 6 super plow steel, 3.5-in Lang lay ropes (6 × 37), with wire centers, placed at 18.5 in centers. Carriage has 48 wheels, 24 in diam, 8 on each cable. Hoisting is done by 2 super plow steel 1 $^1/_8$-in ropes, with hemp centers, each reeved through twin fall blocks, to make two 8-part tackles to an equalizing frame from which load is suspended. Hoisting ropes wind on 2 drums, 13 ft diam by 17 ft face, each driven by a 175-hp dc motor, but operating in unison. Two hauling ropes, same as hoisting ropes, wind on a third drum, geared to a 400-dc motor. Speeds: traversing, 240 ft per min; hoisting, 120 ft for loads under 40 ton and 30 ft for heavier. Towers: a 100-ft 4-leg steel tower at one end, with tension take-up; at other end, a steel and concrete saddle; at both ends, the cable is anchored in concrete, which fills a 60-ft tunnel. Cableway is a permanent equipment for the power plant (37).

All of above installations were supplied jointly by Makers 1 and 12, Art 29.

28. OTHER FORMS OF CABLEWAYS

Light cableways are used for sewers, subways, and similar long, narrow, shallow excavations (Fig 46). Towers are single A-bents, 25–40 ft high; whole plant designed for portability. After an excavation has been made for length covered by 1 span, plant is moved ahead for another section. Spans about 300 ft long and fall rope carriers usually dispensed with, as empty bucket keeps hoisting rope taut. But if loads are hoisted near center of span and run to tail tower, a single-fall carrier may be run out on track cable and

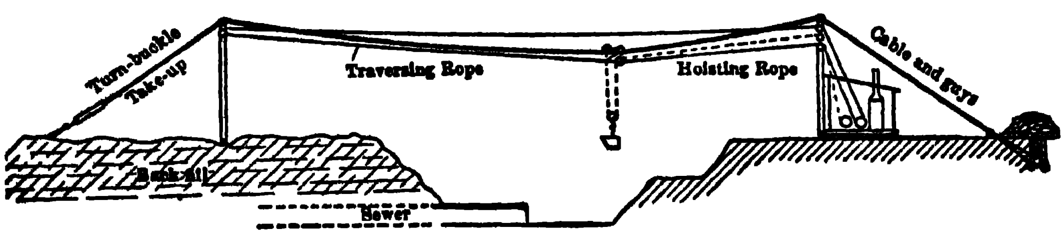

Fig 46. Diagram of a Small Cableway

fastened by a chain dropped to the ground. It is set where it will not interfere with carriage, but will hold up center of hoisting rope when carriage is at tail tower.

Equipment. Machinery for a portable cableway for a net load of 2.5 tons on a 300-ft span consists of: 1.5-in cable, with anchorage and take-up fittings; $^5/_8$-in hoisting and hauling ropes; carriage with 12-in wheels and 16-in sheaves; fall block with 16-in sheave, to give a 2-part tackle; 2 fall rope carriers; 5 1-cu yd self-dumping and self-righting tubs, 48 in wide by 45 in long by 31 in deep; 30-h p reversible hoister, cylinders 8.25-in diam by 10-in stroke, drum 24 in diam by 26 in face, hauling drum 25 in diam in concave face; vert tubular boiler, 42-in diam by 90 in high; engine car with 10 by 16-ft timber platform, housed and mounted on four 15-in wheels; 180 ft of 25-lb T rail; 2 towers of 8 by 10-in timbers, 30 ft high, with 1-in galvanized guy ropes. Engine and boiler can be replaced by elec hoister.

Capacity. These plants will hoist net load of 2.5 ton at 225 ft per min, and convey it at 450 ft per min. If tubs are loaded in a trench, 30–40 loads can be handled per hr.

Operating cost. Labor: 1 engineman, 1 fireman (if steam-driven), 1 signalman, and 2 dumpmen, when loading wagons or dumping into a hopper. One man can dump buckets when machine is back-filling rear end of trench. These cableways can be moved in 2 or 3 days with good organization, if new anchorages (deadman and slings) are set in advance. Force: 5 laborers, 1 handy man, and part of foreman's time.

Semi-permanent cableways have towers, A-frames, or masts of wood or steel. Track cables, 6 by 7 standing rope or locked-coil cable; anchorage is weighted with rock or concrete blocks. Hauling rope is 0.5 in or larger, with fall-rope carriers of button type. Carriage may have 3 track wheels, and, with fall-block, make a 2 or 3-part tackle. Buckets are bottom-dump, or skips with knock-off at open end; tripped by hand, or mechanically by a clamp on hoisting rope above the fall-block, or by an arm on the carriage; either device engages a lever on the skip and releases the load. Hoisters are run by steam, oil or elec (Makers 12, 13, Art 29). These inexpensive cableways are applicable where heavier plant is not warranted.

Inclined cableways ("Blondins") have a high head tower at discharge end and a low one at other end. The carriage is held at loading point by an endless rope, passing around a brake sheave at head tower; this rope merely holds the carriage in position. When loaded skip is hoisted to carriage, the brake on the holding rope sheave is released and the hoisting rope pulls carriage up the inclined cable. At discharge point, the carriage is held by a "gate," while the load is dumped and empty skip hoisted to the carriage again. On raising the gate, the carriage returns by gravity. As one rope does both hoisting and hauling, resistance to hoisting with a 3-part fall must be less than hauling resistance; hence, the fall-block stays against the carriage during hauling. This requires a grade of about 25% in the cable, and limits this type to short spans and favorable conditions.

Excavating cableways are adapted to cases requiring mechanical excavation before transport. GRAB-BUCKET type (with clam-shell or orange-peel bucket) operates with regular equipment (Art 26), except that an extra hoisting rope and drum are needed, with extra sheaves in towers and fall-rope carriers. As resistance to lifting the bucket out of the soil after filling adds to the load, heavier cables and operating ropes are needed than when digging stresses are absent (Maker 12, Art 29). Another type of grab bucket operated by one fall rope has been adapted to cableways having grade of 10°–15°; fall rope hauls carriage and load up grade, the return being by gravity. This outfit is limited to about 500 ft max span. The carriage is latched to movable stops, attached to cable at loading and discharge points and the fall block is hooked to carriage when fully raised. Dumping is automatic. After dumping, the bucket is hoisted until fall block hooks to carriage and unlatches latter, when it is free to return by gravity, latches to stop which unhook fall block which descends for a new load. Carriage thus shuttles between 2 stops, the position of which may be altered.

Stocking and reloading can be done with cableways and grab buckets. Usually, one man can operate the cableway. With stationary towers, a long narrow pile can be stocked; if tail tower travels on a curved track, so cableway can take various radial positions from head tower, a triangular pile can be made; if both towers travel on parallel tracks, a rectangular pile of any length can be stocked. These cableways usually have spans of 500–1 000 ft (Maker 12, Art 29).

Existing plants have following features: (*a*) Span, 420 ft; 3.5-cu yd clam-shell bucket; capac, 350 ton per day of hard and soft coal; max 1 000 ton; both towers travel. (*b*) Span, 996 ft; 3.5-cu yd clam-shell bucket; capac to 225 ton per hr, when stocking and 175 ton when reclaiming; max, 2 200 ton coal in 9 hr. Head tower is stationary, and 246 ft high to permit bucket to clear obstructions; tail tower, 90 ft high and travels on a curved track. Due to conditions, operator is at a distance from head tower and runs elec hoist by distant control. During 1924–25, it handled 283 000 net tons, cost for labor, power and lubrication, 3.5¢ per ton. (*c*) Span, 725 ft; 3.5-cu yd clam-shell bucket; aver capac, 222 net tons per hr. Towers travel on parallel tracks. Total cost for handling first 200 000 net tons, 1.77¢ per ton.

Slack-line cableways are used to strip orebodies or coal seams near the surface (Sec 10), reclaim mill tailing for retreatment, build earth dams, and dig canals (Sec 3). They comprise a track cable, a carriage from which a skip-like scraper is suspended, hauling rope, high head tower and low tail tower, and a drum on hoister for rapidly varying the track cable tension. Spans, usually 300–1 000 ft. Towers may be fixed; or tail tower movable, for a triangular area; or both towers movable, to serve a rectangular area. Speeds: for digging, 100–200 ft per min; hauling, 300–600 ft. Economical loads: $^1/_3$ cu yd for 300-ft span, to 3.5 cu yd for 1 200 ft; digging depth may be 80–100 ft below water line, with total lift of 150 ft or more. Some large plants handle 10 to 15-cu yd loads (38, 39).

In operation, by slackening the cable, the carriage runs down by gravity until the scraper reaches the loading point; the hauling rope then pulls scraper toward head tower, and when filled the cable is tautened to lift the scraper and simultaneously the hauling rope pulls it to dumping point, where the carriage engages a stop on the track cable. Thus, one operation digs, conveys, elevates and dumps, and at less cost per cu yd, than any other means; all controlled by 1 man at head tower (40,41). These cableways are long-distance excavators, useful where material is to be delivered at a high point, for which a drag-line (Sec 27) is not applicable. By adding an out-haul rope, they can work with a flat span, the load being dumped near tail tower.

29. MAKERS OF TRAMWAYS AND CABLEWAYS

1. American Steel & Wire Co, 350 Fifth Ave, New York: bi-cable tramways, passenger tramways, wire rope, track cables
2. Riblet Tramway Co, W 29 Main Ave, Spokane, Wash: bi-cable tramways
3. Interstate Equipment Co, 18 W Jersey St, Elizabeth, N J: twin-cable tramways (Lawson type), bi-cable tramways (successor of Broderick & Bascom)
4. Ropeways, Ltd, 152 Great Portland St, London, England: Roe mono-cable tramways, bi-cable tramways, cableways
5. British Ropeway Engineering Co, 14 High Holborn, London: bi-cable tramways (Bleichert type), mono-cable tramways, cableways (taut- and slack-line)
6. R. White & Sons, Widnes, Lancashire, England: waste disposal plants, mono-cable tramways, bi-cable tramways, movable dumping trestles
7. Bleichert Transportanlagen, Leipzig, Germany: bi-cable, mono-cable and passenger tramways, cableways (taut- and slack-line)
8. J. Pohlig Aktiengesellschaft, Köln, Germany: bi-cable, mono-cable and passenger tramways, cableways
9. Ceretti & Tanfanisa, Milan, Italy: tramways and cableway (in use, but present manfg activity uncertain)
10. John A. Roebling's Sons Co, Trenton, N J: tramways and cableways designed for specific projects, wire rope
11. Most wire rope makers build occasional tramways or cableways of moderate capac
12. Lidgerwood Manfg Co, 775 Lidgerwood Ave, Elizabeth, N J: taut-line cableways, hoisters
13. Sauerman Bros, 438 S Clinton St, Chicago: slack-line and taut-line cableways, hoisters

McGRAW-HILL PUBLISHING COMPANY, NEW YORK

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

UNDERGROUND MECHANICAL LOADING, CONVEYING AND HANDLING *

1. INTRODUCTION

Mechanization of work formerly done by hand has greatly increased the effic of mine labor, thus reducing production costs to meet the long downward trend of the all-commodity price index (1). Mechanization has also tended to offset the pressure of depletion. The U S Bur of Mines began investigation of mechanical loading in metal mines in 1919 (2). Output figures for mechanization in coal mines were first compiled by the Bureau in 1923, but the data by type of units employed were not available until 1926 (3). For a more detailed statement, see Bib (4).

Early loading machines in metal mines followed the design of surface plant for handling earth and rock, as scrapers, belt conveyers and RR shovels. The initial design of coal-loading machines incorporated more original ideas, to meet the relatively simple mining conditions in flat seams. In both fields, the first attempts to design loading machines for operating within the prescribed spaces for minimum clearances resulted in many construction weaknesses and failures. These have been largely overcome, so that the present-day loaders are flexible, economically priced, of low heights and narrow widths, and have speeds and tonnage capac far in advance of current mining requirements.

Metal-mine loaders comprise scrapers, shovels and conveyers, operated by compressed air or elec; coal machines are mobile-loaders, scraper-loaders, pit-car loaders, and other conveyers; most of them having elec drives. All machines of shovel type involve the principles of digging, lifting, swinging or backward transfer, for loading cars; also "crowding" and gathering broken material by rotating arms or blades onto a self-discharging conveyer; scrapers have the same cycle of loading, transferring to dumping point and discharging, by use of ropes, actuated by a separate power unit. Sometimes scrapers are used for conveying over long distances.

Importance of mechanization. Primarily, increased wage rates are responsible for mechanization in mines. IN COAL MINES, the influence of wage rates on mechanization has been exemplified in Ill, Ind and the Rocky Mountain regions, which early adopted mechanical loading to reduce costs and maintain their competitive position, usually against hand-loading mines having lower wage scales. Further evidence of the wage influence is furnished by rapid increase in mechanization in Eastern and Southern coal fields, following the upward trend of wages beginning with the bituminous code. The industry-wide problem of reducing costs to combat the use of oil or elec is another factor in recent progress of mechanization (4). IN METAL MINES, the period since 1879 has been marked by progressive depletion, which in some fields has largely offset the discovery of new deposits (5); the necessity for cost reduction in utilizing lower-grade ore has been shown by the adoption of mechanization in the iron mines of Minn and Mich, and lead mines of S E Mo and the Tri-State zinc area. Faced with increased wages, shorter working hours and higher taxes, all branches of mining are realizing the need of further savings in cost.

Trends in mineral technology are best measured in terms of output per man: from 1880 to 1929, iron mines recorded an increase from 234 to 2 560 ton; coal (anthracite and bituminous), 422 to 930 ton; copper, 9 290 to 44 900 lb of metal; phosphate rock, 90 to 1 206 ton (6). Though iron, lead and zinc mines have long experimented successfully with mechanical handling and loading, machines have not been adopted as widely as in coal mining, and there are no statistics to show the number of units in use, or tonnage produced.

For coal, statistics are available from 1926 to date, showing that mechanically loaded coal increased from 1 879 000 ton in 60 mines in 1923, to 47 177 000 ton in 317 mines in 1935 (5). In 1935, 13.5% of the underground production of bituminous coal and 21.2% of anthracite was loaded mechanically. In 1936, the combined coal production mechanically loaded or mined by stripping was 112 309 958 ton, or 22.75% of total output of both classes of coal (7). Table 1 shows trends in mechanical loading, conveying and handling, in terms of sales of equipment in 1937, compared with number of machines in preceding years (8). A survey based upon reports from 11 makers of shovels and 8 makers of scrapers and scraper hoists, shows yearly number sold for use underground in metal and nonmetallic mines, as given in Table 2 (1). Many earlier types were installed before 1923.

* Due to the great changes in equipment since the Second Edition of the book was published, most of this Section has been rewritten by Mr. Dake. Incorporated in the Section are data on the subjects hitherto contained in Article 92 of Section 10. Articles 9 to 13 herein, originally written for the First and Second Editions by Lincoln de G. Moss, are included in this revision.

Table 1. Sales of Mechanized Loading Equipment in 1937, Compared with Number of Machines in Use in Preceding Years

	Number of machines in use, as reported by mine operators								1937 Machines sold, reported by 28 makers
	1929	1930	1931	1932	1933	1934	1935	1936	
Bituminous mines;

(1) Number of units not reported in these years. (2) Reported as face conveyers (hand-loaded) shaker drives, and duckbills. Sales in 1937 are not exactly comparable with number in use in 1936, due to uncertainties in defining what constitutes a conveyer. (3) Penn Dept of Mines.

Table 2. Sales of Underground Shovels and Scrapers in Metal and Non-metallic Mines

Figures show sales in continental U S, not including exports to contractors on construction projects (subject to revision)

Year	Scraper loaders (hoists or complete units)	Shovel loaders	Year	Scraper loaders (hoists or complete units)	Shovel loaders
1923	254	57	1931	126	2
1924	341	18	1932	104	14
1925	373	15	1933	62	12
1926	284	36	1934	67	23
1927	414	39	1935	135	44
1928	363	32	1936	249	70
1929	645	35			
1930	335	22	Totals	3 752	419

As effected by geographical distribution of mechanical loading, equipment differences, wage rates and physical conditions, the coal areas where mechanization advanced farthest to 1935 were the northern Rocky Mountain states, Ill, and Ind, where seam conditions were favorable and wage rates, from 1923 to 1933, compared with the southern and eastern fields, were relatively high. In 1936, 92% of the deep-mined output of Wyo was mechanically loaded; in Mont, 83.2%; in Ind, 65.6%; and in Ill, 63.6%. In 1935, the proportion of the W Va output mechanically loaded was 2.1%, and in 1936, 7.4%, while Ky records 1.4% in 1936. Recently, market conditions and higher wages have stimulated mechanization in the Appalachian region, and a large part of the equipment sales reported by makers in 1937 went to the bituminous fields of the east and south. The largest installations of mechanical loading equipment seem to have been in W Va in 1936 and 1937. Types of mechanized equipment sold from 1933 to 1937 are shown in Table 3 (8).

Table 3. Mechanized Equipment Sold to Coal Mines, 1933 to 1937 (*a*)

	1933	1934	1935	1936	1937	Percent increase (+) or decrease (−)	
						1937 over 1936	1937 over 1935
Mobile loaders	41	55	115	344	292	− 15.1	+153.9
Scrapers (*b*)	65	34	22	28	29	+ 3.6	+ 31.8
Conveyers (*c*)	396	610	681	994	1 095	+ 10.2	+ 60.8
Pit-car loaders	18	26	28	11	32	+190.9	+ 14.3

(*a*) As reported by 29 makers, 28 of whom were canvassed each year from 1933 to 1936. (*b*) Reported as scrapers, or scraper haulers and hoists. (*c*) Includes hand-loaded conveyers, duckbills and other self-loading heads. A number of these, in 1936–1937, were used with mobile-loading machines.

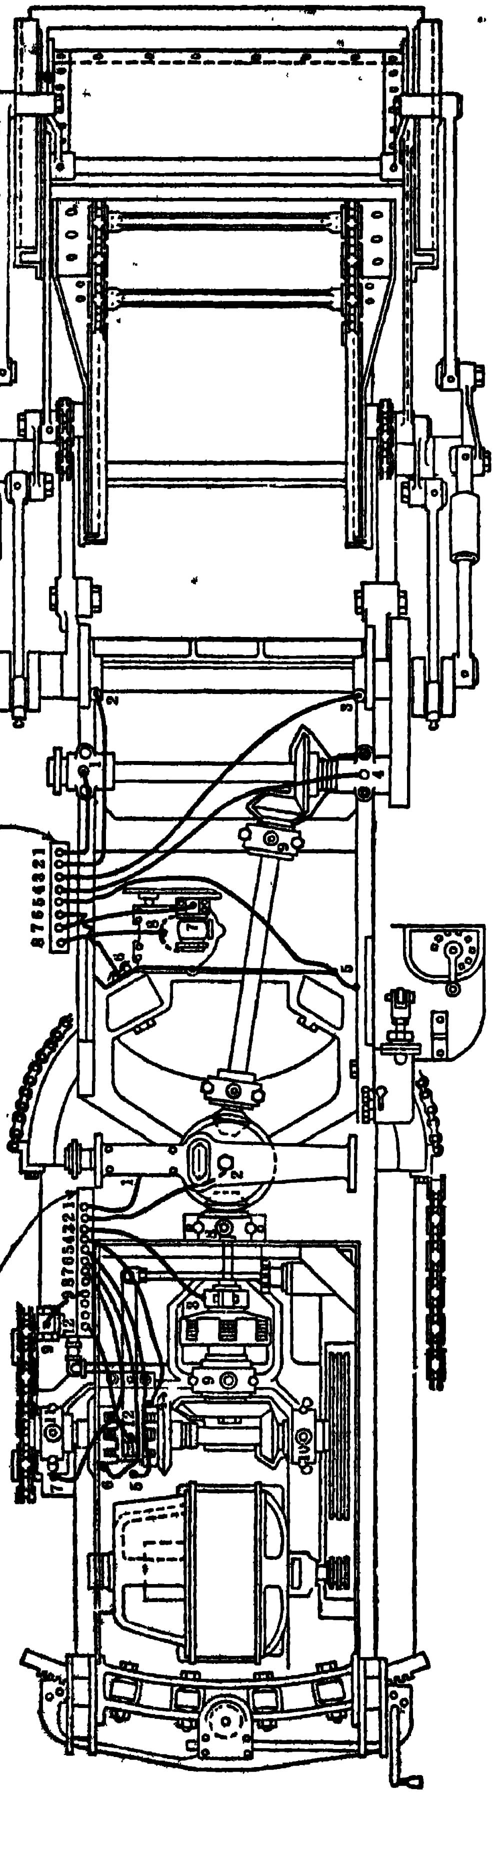

Fig 1. Myers-Whaley Shoveling and Loading Machine

2. TYPES OF MECHANIZED COAL MINING EQUIPMENT

Though many types have been invented since the introduction of the Stanley Header from England in 1888, progress has been measured in terms of evolution or elimination, and only the major units now being used commercially are herein described.

Mobile Loaders

Mobile loaders are those using: (*a*) shovels; (*b*) gathering devices. The Myers-Whaley and others of class (*a*) force the shovel forward to enter the broken coal; then the loading head is tilted, and discharges backwards onto a receiving plate and into the conveyer. Machines of class (*b*), as the Jeffrey, Clarkson and Goodman, have a continuous chain on each side of a conveyer; the chains moving in opposite directions, and carrying "flights" running horiz on the floor to undermine the face and gather broken coal into the conveyer. Joy machines have 2 gathering arms on opposite sides of the loading head, which pull down and sweep the standing coal into the conveyer, for delivering to cars. Myers-Whaley, Jeffrey, Clarkson, Goodman and Umeco machines are track-mounted; the Joy, caterpillar mounted. Mobile loaders comprise scrapers, self-loading conveyers, pit-car loaders, and types within each class, and are described here in chronological order of their development.

Myers-Whaley shoveling and loading machine (Myers-Whaley Co, Knoxville, Tenn). The first was installed 1908, by Windrock Coal and Coke Co, Tenn. An automatic shovel (Fig 1) is mounted on a swinging jib, pivoted on rear end of main frame. The jib carries a conveyer, delivering from the shovel to a second conveyer on a rear frame, also pivoted for lateral movement. The truck wheels are driven by a reversing clutch, worm and chain drive, for moving forward or backward. The shovel itself is wide and short, supported in inclined guides at the rear and moved by driving rods; it has side pieces, connected to the rods for tilting. The two sets of driving rods are synchronized, so that the shovel lip travels in an orbit, its rear end traveling in a plane inclined to the horiz. When front end is lifted, the material slides onto a receiving plate below and between the guides, and thence to the conveyer. The machine is driven by a hydraulic motor on the chassis; 4 levers

control the major movements, one for forward and backward movement of the entire machine, another operating the motor which swings the jib section, a third raises or lowers the rear conveyer and the fourth adjusts height of the shovel. By lateral adjustment of the rear conveyer, the material is loaded directly behind, or into cars standing on side tracks. These machines are of 2 types: (*a*) for rock work (Fig 1); (*b*) the "Automat," for car loading in coal mines. The No 3 Automat is designed for 4-ft headroom, from top of rail to roof, and 45-in traveling clearance; the No 4 for 5-ft headroom and 4.5-ft clearance. Both have permissible (inclosed) motors, for use in gaseous mines (Table 4).

Joy loaders (Joy Mfg Co, Franklin, Pa). An experimental loader was installed in Sommers No 2 mine, Pittsburgh Coal Co, Pa, in 1916. The successful forerunner of present types was installed in same mine, 1917. The loader is mounted on a self-propelling chassis, and comprises: (*a*) gathering head with rotating arms, actuated through multiple-disk clutches set to slip at overloads, which sweep the coal into a conveyer delivering to mine cars; (*b*) caterpillar traction, having gaged lugs to act as wheel flanges for moving about on mine track, and allowing free movement off-track, when loading from floor at working faces. These loaders have 2 kinds of conveyers: types 8 BU, 7 BU and 11 BU have a single-strand flexible conveyer from gathering head to end of discharge boom, which swings through an arc of 45° on each side of center line; and types 5 BU and 10 BU, 2 double-strand conveyers, one from gathering-head to a discharge hopper, which is a part of the second conveyer and is mounted on a boom swinging through an arc of 90° on each side. The gathering head moves vertically, and discharging conveyer is adjustable vert and horiz by hydraulic pressure, controlled through a multiple-acting valve, placed close to clutch levers and motor starter. All the above loaders have a single motor for tramming, loading and conveying, and are operated by 1 man. The Joy Junior, built especially for thin seams and conveyer transport behind the machine, has 2 motors in tandem, one for the hydraulic system and one for each caterpillar, for locomotion and steering. Its total height is 26 in. A few models are made with uninclosed elec equipment, but are approved by U S Bur of Mines. For lowering through mine shafts of small section, the loaders may be disassembled into 3 parts: gathering head, chassis and discharge conveyer. Typical units are shown in Fig 2, 3; specifications, for thickness of coal seam from 30 in up, are given in Table 5.

Jeffrey loaders (Jeffrey Mfg Co, Columbus, Ohio). This Co, one of the first in the field, now offers 2 types of mobile loaders: the 44 class, C, CC, D, DD, E and EE, was

brought out in 1929. In the self-propelling, track-mounted 44-DD and 44-EE machines (Fig 4), the gathering conveyer has a jib with continuous chain "flights" running partly on mine floor to sweep the coal upward, through a trough, into the discharge conveyer. The latter is raised or swung right or left for loading by rope drums, which also feed it into the

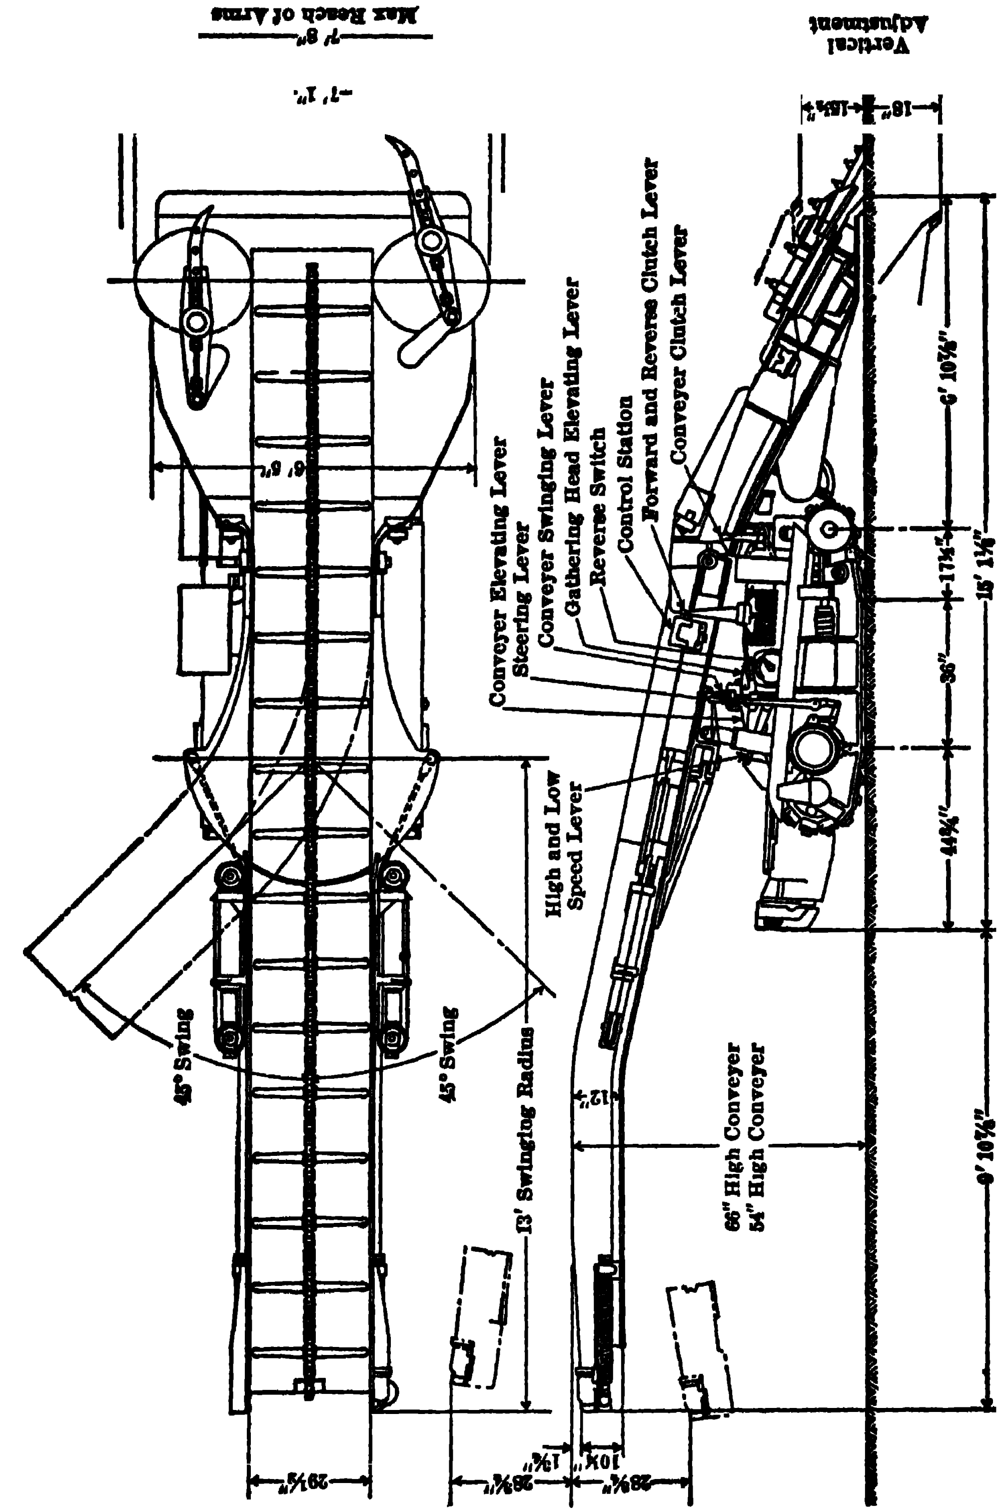

Fig 2. Joy 11-BU Loader

coal. The chassis carries the controls for all movements. There are 2 motors, in both non-permissible and government-approved types, one in gathering head and one in the chassis. Machines are in 3 sizes, high, standard and low (Fig 4), for rated loading capacities of 1 to 2 ton per min. Max heights above rails, 43–60 in; overall lengths, 37.5–47.5 ft.

The track-mounted L-400 machine, rated at aver of 3 ton per min (max 6 ton in loose coal) is single-motored; height, 40 in above rails. The gathering head carries a double-chain conveyer, one chain running clockwise; the other, counter-clockwise, on which are mounted "flights" meeting to form an upward-drag conveyer. Flights run horiz at level of mine floor to undermine standing

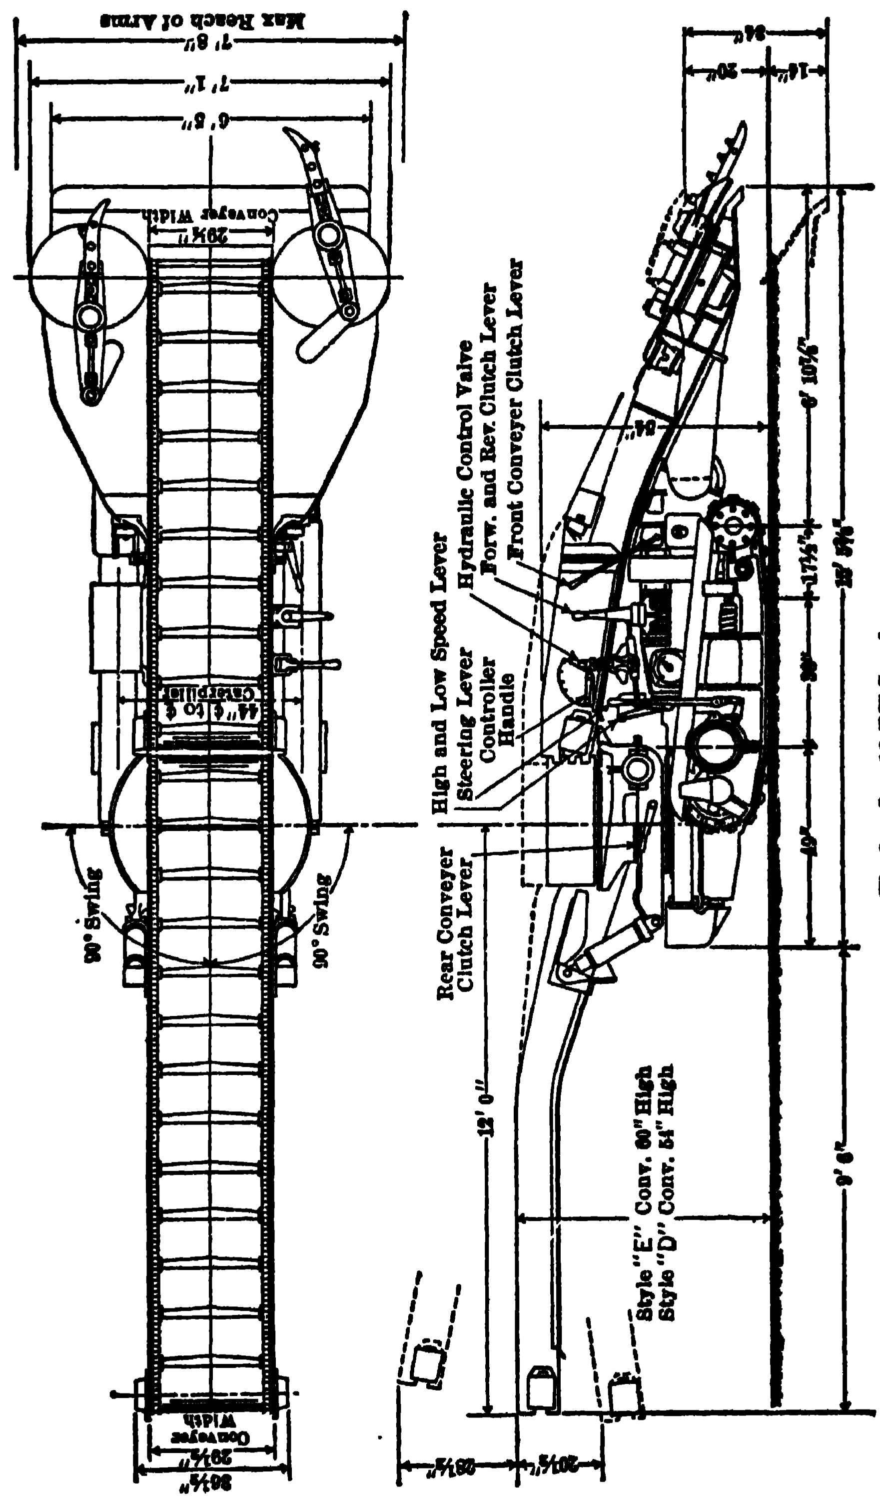

Fig 3. Joy 10-BU Loader

coal, and gather it with minimum crowding action. Discharge conveyer is flexible single-strand, adjustable horiz through 40° on each side of center line, and 18 in vert above and below normal level line of the boom, which is pivoted on main chassis. The chassis carries the motor and power take-off for all movements, and supports gathering and discharge conveyers at the same pivot points. Hydraulic cylinders on the chassis guide movements of both conveyers, with a central

starter and "finger-touch" control, for one man operation. The L 400 has 2 tramming speeds, slow "sumping" and fast traveling, an automatic cable-reel, trolley pole being optional.

Clarkson loader (Clarkson Mfg Co, Nashville, Ill) is track-mounted with 3 main units: gathering head, main frame and discharge conveyer (Fig 5). The gathering head, of 24-in

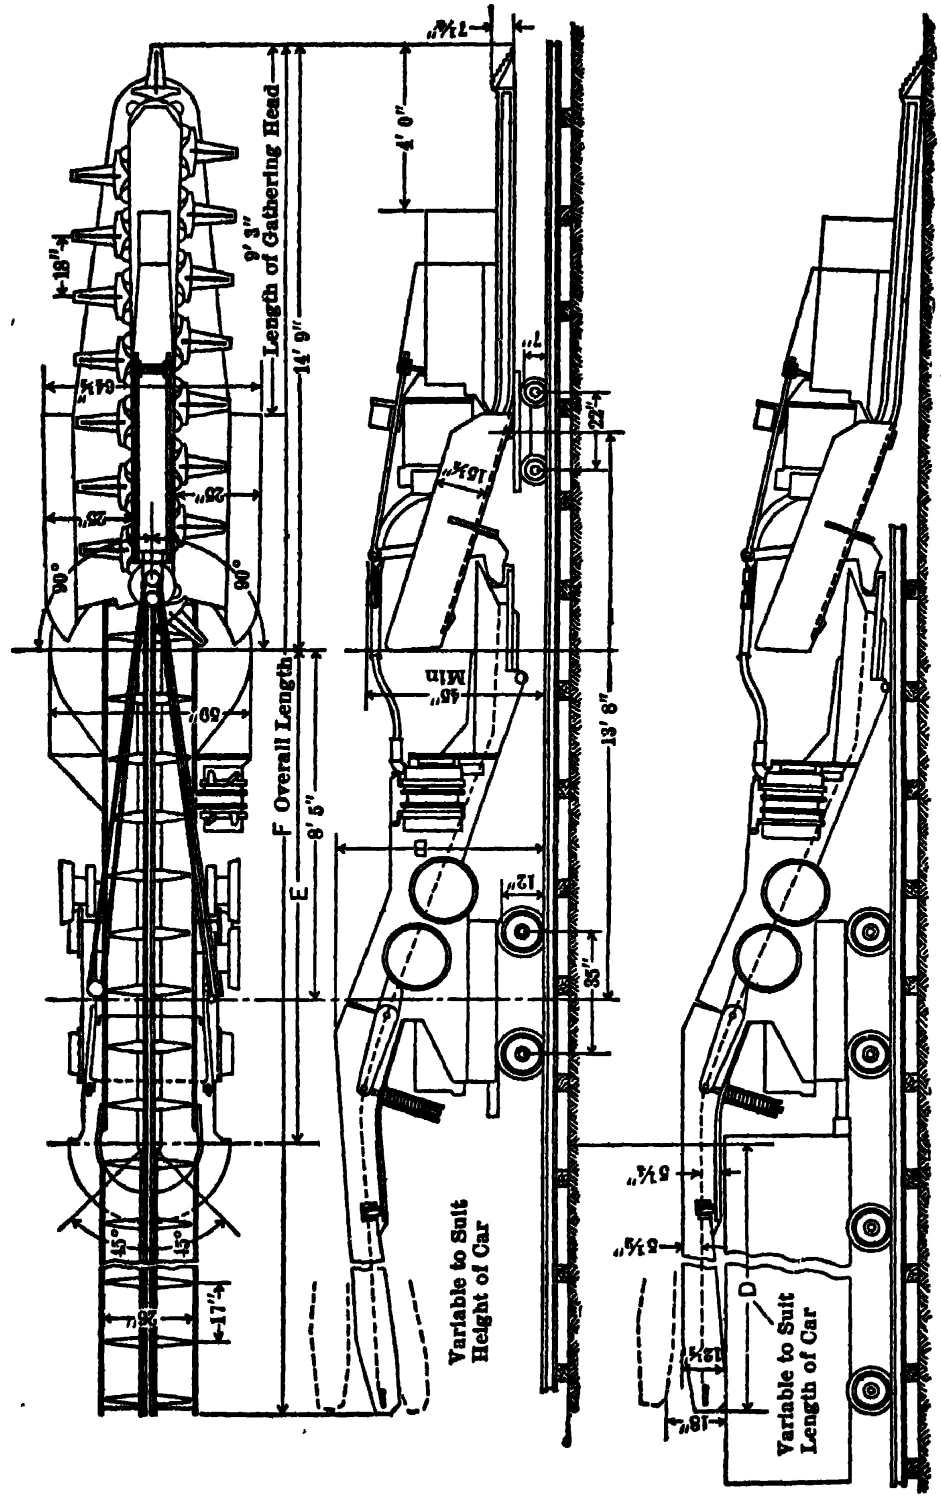

Fig 4. Jeffrey Loaders, High, Standard, and Low Types

I-beams, serves as a conveyer trough and as a base for attaching side plates and angle irons to form the foundation for the 20-hp gathering-head motor, placed under rear end of conveyer. Two deck plates form the loading head proper, which carries on either side gathering chains revolving in opposite directions. To the chains are attached large, pointed picks

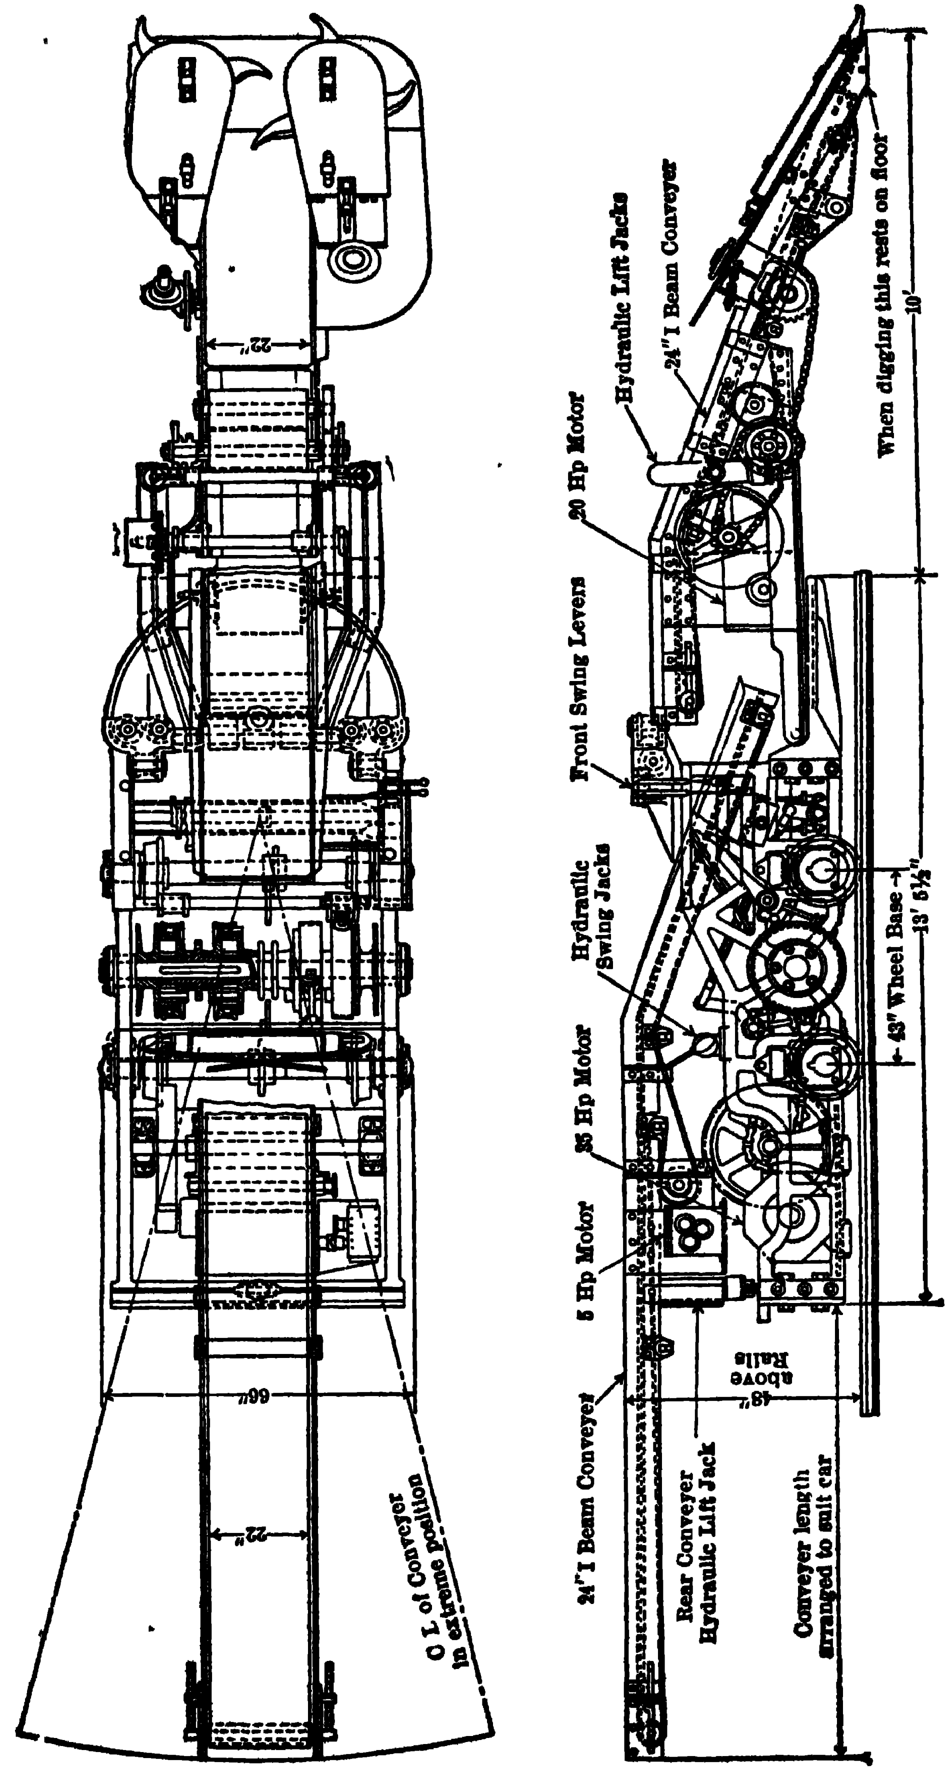

Fig 5. Clarkson Loader

to loosen and carry the coal upward to the belt conveyer in the I-beam trough. The gathering head is adjustable by hydraulic jacks, and is moved mechanically to either side of the center line. Main frame is supported by heavy axles in a 4-wheel truck, a front bumper acting as a swing support for the gathering head, and a rear bumper as a special support for the rear conveyer. The 35-hp motor is in the main frame, with one-man controls for all movements. The discharge conveyer, having a 22-in belt and driven by a separate 5-hp motor, is adjustable both horiz and vert; wt, 18 500 lb; length, 13 ft; width, 66 in; height, 48 in; capac, 2 ton per min.

Goodman loader (Goodman Mfg Co, Chicago) installed their first shovel for coal loading in 1924 and in 1933 the first track-mounted conveyer unit was operated in Ill and Ind mines. Type 260 loader (Fig 6) has a gathering head and front and discharge conveyers.

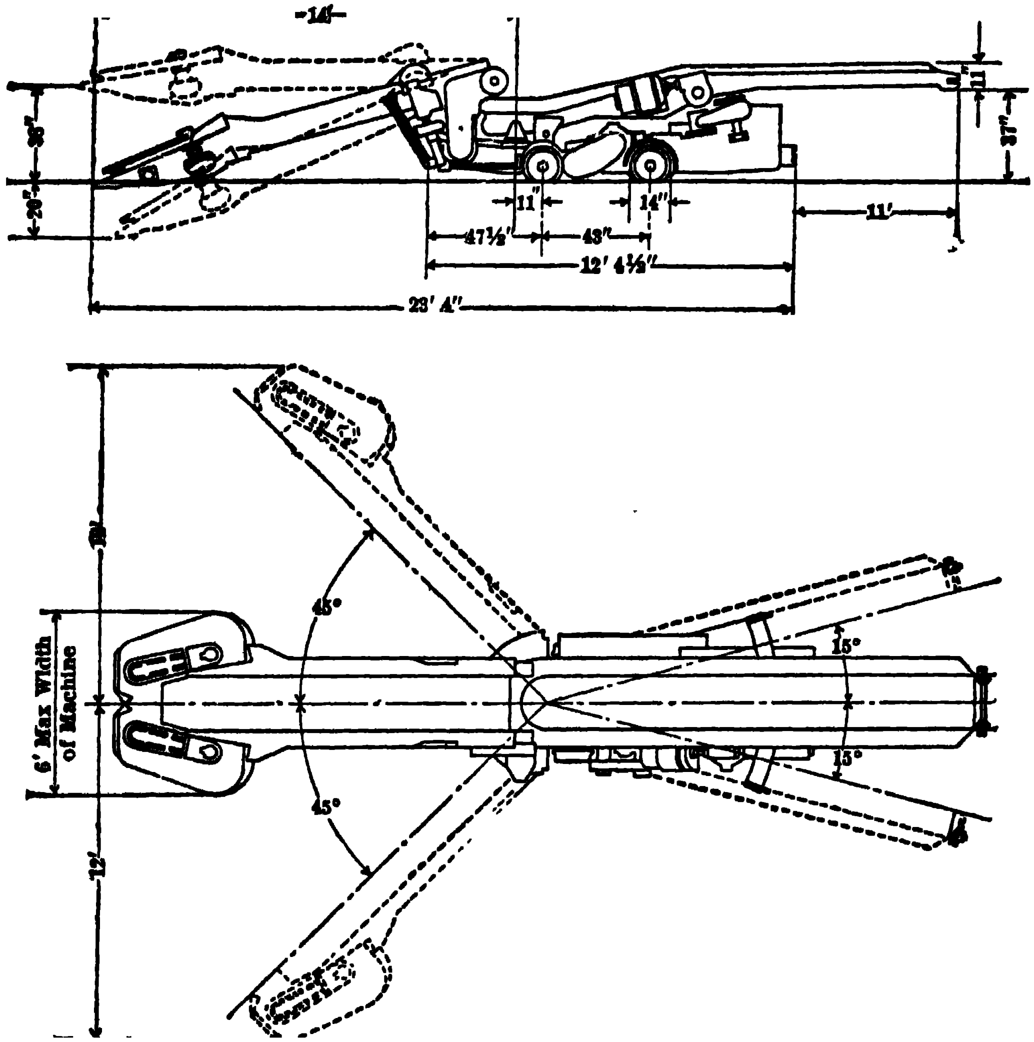

Fig 6. Goodman Loader, Type 260

The head carries 2 chains running in opposite directions, with 4 digging arms and 4 snubbing arms, equally spaced and alternated on each chain; is adjustable vert from 20 in below to 38 in above the track, and can swing 45° on each side of center line. Gathering mechanisms are mounted on each side of the main drag-flight conveyer, all protected from excessive shocks by a slip-clutch sprocket geared to main motor. The chassis, supported at 4 points by floating axles, carries the transmission gearing for low and high tramming speeds, the 50-hp main motor, and the discharge-conveyer elevating motor, with all controls for one-man operation. The discharge conveyer, driven by a separate motor, is also of the drag-flight type, and is adjustable vert from 11 in above to 37 in below the level line of the boom, which swings 15° on each side of center line. This machine has a max clean-up width of 24 ft, and can work in coal seams to 60-in thickness. Wt, 13 ton; height, 54 in. A new Goodman 360 loader, similar in general to type 260, and designed for seams as thin as 4.5 ft, appeared in Jan, 1938.

Umeco loader (Utility Mine Equipment Co, St Louis) installed their first mobile loader in 1933. The latest type, placed in the St Louis and O'Fallon Coal Co's mine, Ill, in 1936, is track-mounted, with 2 continuous-chain gathering mechanisms, one on each side of the conveyer. Arms extending ahead of the gathering apron sweep the coal upward and into a drag-flight conveyer, delivering to the discharge conveyer, pivoted at rear of the chassis. The loading head is adjustable 54 in vert and swings through an arc of 90°; the rear conveyer has a vert adjustment of 24 in and swings through 60°. A 15-hp motor drives the gathering head, a 10-hp the chassis, and a 5-hp motor the rear conveyer. Height above rails, 33 in; overall length, about 30 ft; width, 5 ft; approx wt, 11 ton; loading capac, 4 ton per min.

Scraper Loaders (See also Sec 3)

The first anthracite scrapers were used by Lehigh Valley Coal Co in 1914 (10). In 1916, the Evans scraper (Goodman Mfg Co) and others were installed by the Hudson Coal Co, Scranton. Evans and Goodman scrapers were first used in bituminous fields by the Penna Coal and Coke Co in 1917. The Goodman 23-B scraper was the forerunner of several types and sizes by that Co. The number of scraper loaders in coal mines declined from 1930 to 1937, according to makers' reports (11), due to the facts that effic scraper operation demands very favorable mining conditions, adequate roof span and roof control (12); and because improvements in mobile loaders and conveyers have widened their fields of use since 1934.

Scrapers are primarily for use on long faces, though sometimes applied to entry and room loading. The equipment comprises a movable hoist, driven by compressed air or elec; ranging from 5 to 125 hp, with 2 or 3 drums, independently controlled, which carry the lengths of wire rope for traversing the working face. One rope fills and hauls the scraper to discharge point; another, attached to the back of scraper and threaded through a sheave anchored at far end of the face, pulls the scraper for re-loading. Scrapers are usually "hoe" and "box-shaped" (Fig 7, 8); or modified "Hoe" type (Fig 9) and are bottomless. Table 7 shows their capacities (13). They sometimes have teeth, to dislodge standing coal when pulled along the face. Due to their shuttle-like movements, scrapers are well suited to very thin seams, where cost of removing enough roof or floor material to permit use of mobile loaders would be prohibitive. However, the horiz clearance needed for scrapers to pass between face and props prevents their use except under favorable mining conditions, or where longwall mining can be adopted. In coal mines, the scrapers usually discharge into a feeder or elevating conveyer to the mine cars; or, for development work, utilize a car-

loading slide. Depending upon seam thickness, face length, operating speed of scraper, and overall effic and coordination of work, scraper-loading output ranges from 25 to 300 ton per shift. Coal weighs 50–75 lb per cu ft. For wt of soils and other substances, see Sec 3. Number of men per crew depends upon above factors, plus variables in seam characteristics, which may or may not demand heavy timbering and other non-productive work. Computation of mucking capac of a scraper involves: (*a*) size of body; (*b*) aver rope speed; (*c*) distance; (*d*) overall effic. The relation of these factors is expressed by $\frac{Cx+Tx+Sx+E}{2D}$ = cu ft handled, where C is scraper capac, cu ft; T, gross time, min; S, aver rope speed, ft per min; E, overall effic; D, distance scraped, ft.

Self-loading duckbill conveyers (Goodman Mfg Co) have a flat, funnel-shaped loading head which moves upon the floor and to which is attached one or more troughed pans, forming a continuous conveyer from face to point of discharge. The pans, mounted on rollers in cradles, and linked together are actuated by a compressed-air or elec motor, geared eccentrically to give a slow forward-thrusting motion and quick-lifting return to the conveyer. Loading-head is a telescoping double-trough, swiveled at its connection with main conveyer to allow movement along the face, and has a manually controlled ratcheting device to extend the duckbill into the prepared coal, or to retract it after the face has been cleared to depth of cut; a conveyer section is then added to continue work on a freshly prepared face.

Self-loading shaking conveyers have limited application, due to increased maintenance costs if the max distance for which they are designed is exceeded. They operate best in flat workings, or

where gradients are slightly in favor of load. Handled by 2 or more men; tonnages per shift vary widely with different seam conditions.

Hand-loaded conveyers, most used for coal, comprise: shaking, chain-and-flight, and belt conveyers. All are portable and have a compressed-air or elec motor, to which is attached a series of standardized conveyer sections as the face is advanced. In length, the sections usually conform to the aver depth to which coal cutters work, extensions being added as face advances. In room loading, conveyers are moved into position after the

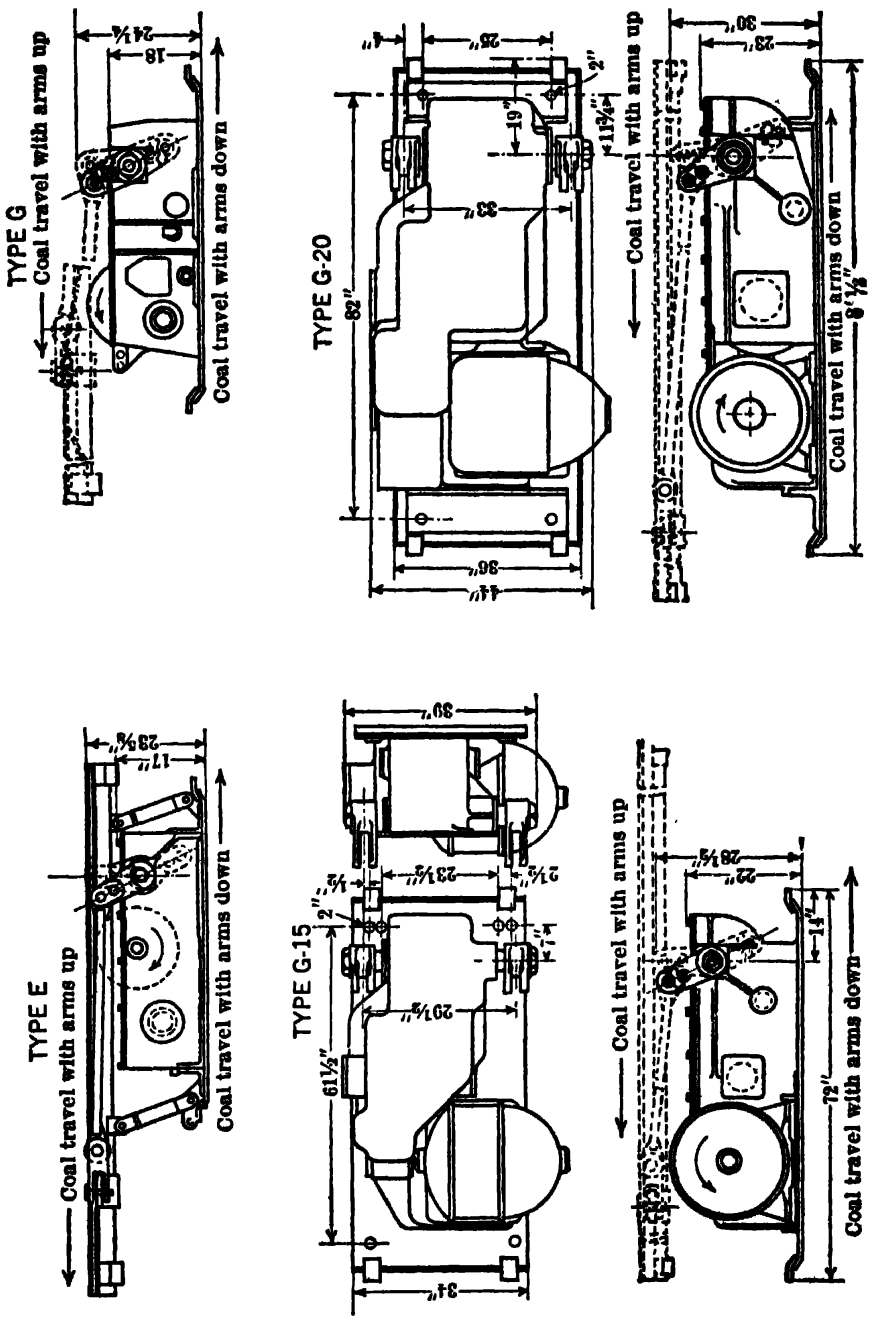

Fig 10. Goodman Shaker Conveyers

undercut is finished, and the shot-holes are drilled and fired; hand shovelers load the coal on to the conveyer.

Face conveyers discharge into the room conveyer, which is placed along either room-rib, and extended as work advances. The room conveyer delivers direct to mine cars, or, in multiple-conveyer workings, to a cross conveyer and cars at a central loading point; or to a main-line conveyer belt, for transport to shaft-bottom or to surface. Though the work of loading onto conveyers is less than for hand loading cars, the conveyer method is classed as mechanical loading only insofar as it reduces the height of shoveling, and provides continuous transport, thereby increasing production per man. But, its effect in

initial cost reduction over hand loading into cars is always worth consideration, aside from its tendency towards later replacement by complete mechanization. The saving shown by aver hand-loaded conveyer installations is reduction in amount of manual labor, or cost saving due to increased effic of working cycles and improved transport facilities.

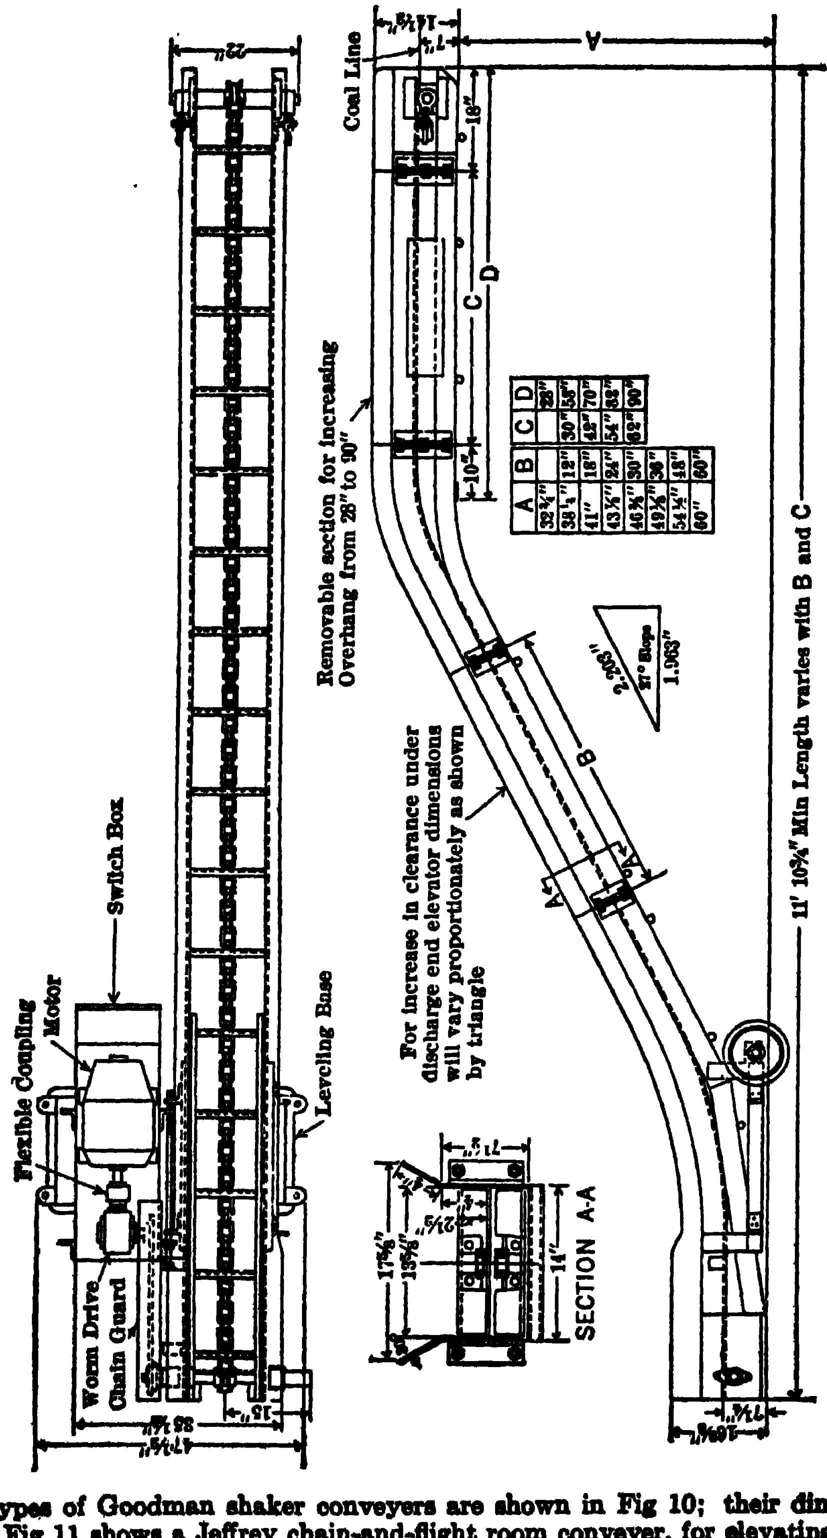

Fig 11. Jeffrey Chain-and-flight Room Conveyer

Four types of Goodman shaker conveyers are shown in Fig 10; their dimensions in Table 8. Fig 11 shows a Jeffrey chain-and-flight room conveyer, for elevating coal from room to mine cars. Weights: head end, 450 lb; tail end, 220 lb; standard section, 133 lb (all less power unit and chain); 10 hp motor, 1 050 lbs; chain and flights per ft, 5.2 lb. Fig 12 shows a typical Joy main-haulage belt conveyer; Table 9 giving weights of parts. Nearly all hand-loaded conveyers now have larger power units, greater widths and higher

speeds for coordination with high-speed car loading machines; or, in some flat-seam mines, for discharging at the surface (16).

"Rubber-tired haulage" is a recent development; a combination of mobile loader and storage-battery tractor, with trailer traveling on the mine floor from loader to conveyor, which discharges into mine cars.

Pit-car loaders, designed to decrease height of lift in hand-loading, were first introduced by Jeffrey Mfg Co in 1916, though it was not until 1928 that large-scale pit-car loaders were installed in Ill and Ind mines. They are low conveyers, on which the coal is shoveled at almost floor level, for elevation and delivery to a car (Fig 12). From 2 to 4 men pick down and shovel the coal on to the loader, which is moved from face to face as required. Output per man averages 20-24 ton, in 5- to 6-ft seams.

3. VARIABLE FACTORS AFFECTING TYPE OF INSTALLATION

Local conditions must be studied carefully, profit realized depending upon: (*a*) mental attitude of management and men towards machines and knowledge by mine foremen of the principles, and the selection of crews who will endeavor to modify old practices to fit the machines; (*b*) for coal, the minimum, aver and max thickness, and pitch of the seam, determine size and power of equipment for given conditions, and to handle loads at top speed on adverse gradients; (*c*) character and texture of coal affect mode of drilling and blasting and manner of preparing faces to load out; (*d*) size and shape of undercut block, and sizes of coal desired, affect the choice of loader capac per min and power required; (*e*) depth of cover overlying the seam and character of roof limit the width of working places, and determine the method of mining; (*f*) character of floor. Soft fireclay may absorb enough moisture to bog down machines and track, or scale off and mix with the coal while being loaded; hard floors reduce the grade on which caterpillar machines can maneuver, and increase the cost of maintaining rails for track-mounted machines. Use of mechanical loaders is not much affected by timbering, as systems now employed, even under adverse conditions, afford protection, while assuring enough clearance for loading and moving; (*g*) types of loaders suitable for advancing or retreating pillar and long-wall methods are important; the mechanical gathering of coal can be slow or rapid, with consequent high or low cost per ton. Changing from hand to complete mechanization requires an aver increase of 1-kw hr of power per ton of production.

Kinds of equipment for mechanized handling of coal from working face to surface preparation plant must be compared for different outputs, to determine loader output and cost per ton. Also, a proper balance is necessary between the capacities of coal cutters and loading machines, to avoid overtime labor rates. Bottom-, center- and top-cutting methods affect results of drilling and blasting, as well as of mechanical loading. An added cost of removing banded impurities by careful cutting may reduce the cost of surface picking or cleaning plants. Mechanical loading profit depends on net reduction in total costs, not in reducing certain phases of operation. For example, while "overshooting" may reduce face-loading costs, the resulting increase in fine sizes of coal lowers the sales receipts, and might mean a net loss on mechanized operation, as compared with hand loading. Tonnage per working face and concentration of working places determine the most economical capac, size and type of mechanical loader. Development in wide workings can be done by all loaders, but it is as impractical to apply slow-speed, low-capac units under favorable thick seam conditions, as to use high-speed, heavy-duty machines for thin seams or other adverse conditions. Thus, a loader of given capac can not be applied as economically to double-entry development in a thin seam, where shooting on the shift is prohibited, as in 5 parallel headings where blasting is permitted at any time. Small tonnage from isolated parts of a mine can be profitably loaded mechanically if the size of crew, plus the added productive capac of loading machines, is balanced against all limiting physical conditions. This is also true where adverse conditions impose more deadwork cycles, which, in turn, curtail available loading time. Tonnage produced per total employes, not the tonnage per machine-loader shift, determines the percentage reduction of mining costs. Also, the dimensions and aver capac of cars serving the loader, or the peak capac of conveyers from machines to central loading points, or to the surface, affect the aver tonnage per shift. Track arrangements for quick car changes behind loading machines, and the type of conveyers used, relative to the time for adding or taking off sections of conveyer also affect tonnage per shift. The number of cars in relation to length of haul, the round trips per shift, and the effic of dispatching loads and distributing empties, are often factors in economical mechanization. Conveyer transport, from working face to a central loading point, has largely replaced small-capac cars; and multiple conveyers, for continuous movement of coal from face to surface, have reduced the investment for transport in new mines. Tipple and preparation capac also affect the decision as to introducing mechanization.

In changing from hand to mechanical loading, where the seam has banded impurities, the waste may be separated underground or the entire product delivered to the tipple, thus requiring more pickers; in either case, this cost must be deducted from the savings due to mechanization. The saving by mechanical loaders also depends upon contract tonnage and day-wage rates, relative to output per man. As labor approximates 60% of total mine costs, an analysis of all operating conditions is necessary in comparing hand loading with expected results from mechanization. Since most of the variations are in development and tonnage production, all handling costs should be segregated, from face to main-line transport, and thence to preparation plant; supplemented by cost of mine maintenance, preparation, engineering, management, overhead charges, supplies and power. Table 10 contains an itemized list of these variables.

Table 10. Mechanization Variables

21. Conveyers and their capac
22. Aver length of main haulage and tonnage per trip
23. Type, number and capac of cars
24. Dispatching system and effic
25. Cutting methods and costs
26. Drilling and blasting costs
27. Loading methods and costs
28. Yardage and deadwork costs
29. Contract and day-wage rates

4. COMPARISON OF MECHANIZED COAL-MINING METHODS

Mobile loaders. Their application to multiple-entry development (see Sec 10, Coal Mining Methods), where break-throughs and room necks are turned at right angles, causes difficulty in laying track on curves of a radius permitting easy access of large machines. The difficulty may be met by driving these openings at angles less than 90°; or increasing the number of entries to 3 or 5, with tracks through crosscuts for flexible car transport. The multiple-entry systems simplify movements of cutting and loading machines, give more working places, cause less interference with mining, timbering, track extension and loader operation, and increase production.

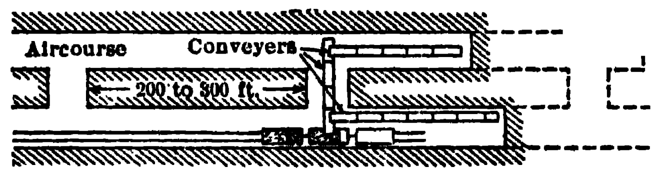

Fig 13. Conveyer Setup for Driving Haulageway and Aircourse Simultaneously

Conveyers may be used in development work for advancing a haulageway and air courses alternately, or driving both simultaneously (Fig 13). Although the latter plan increases equipment cost, it gives faster development, probable lower operating cost, and better timing of the working cycle.

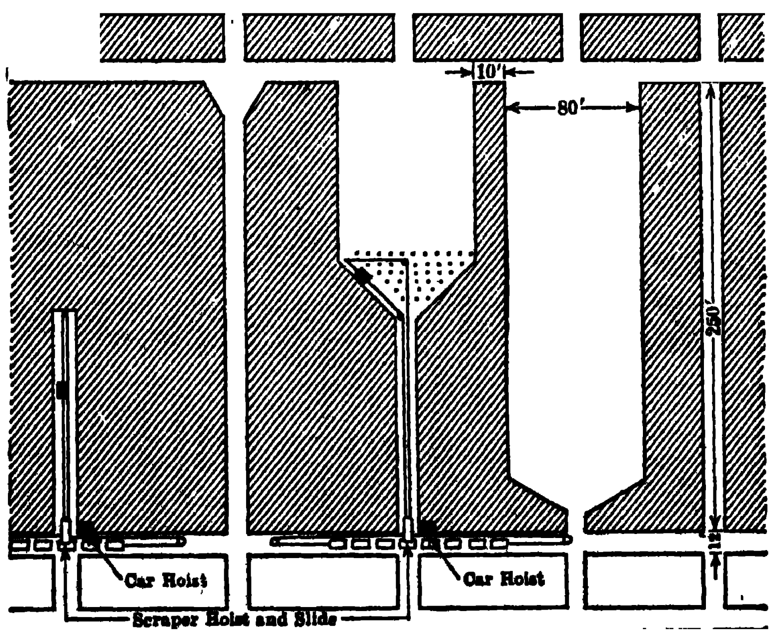

Fig 14. Scraper Loading in Rooms on the Retreat System

Scrapers, with inclined slide for loading cars in a single heading, and rooms mined on the retreat by a V-system, may be used in development (Fig 14). Scraper loading is also used for block and longwall work.

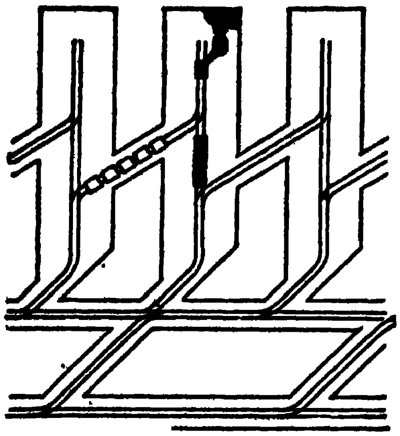

Fig 15. Mechanical Loading for Room-and-Pillar

Modified systems of mechanical loading, resulting in greater concentration of work, and more flexible trackage for cars behind the loader, are shown in Fig 15–18. The layouts in Fig 16, 17 are adapted to weak roofs close to the face. The "funnel system" of timbering uses 3 or more steel rails or H-beams, on temporary props, set to allow working clearance for the loader and which are moved forward after each cut, permanent timbering being set behind (Fig 17). Where roof is strong enough to allow driving wide rooms, the props may be centered, with a curved track along the face, for loading into several cars while moving past the machine (Fig 18). In the thick coal seams of Ill, a modified room-and-pillar system has triple main and double panel entries, all break-throughs and room-necks being at 45°. Two mobile loaders, 2 coal cutters and

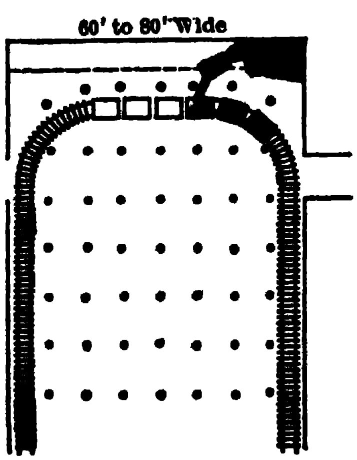

Fig 18. Loading on Circular Track

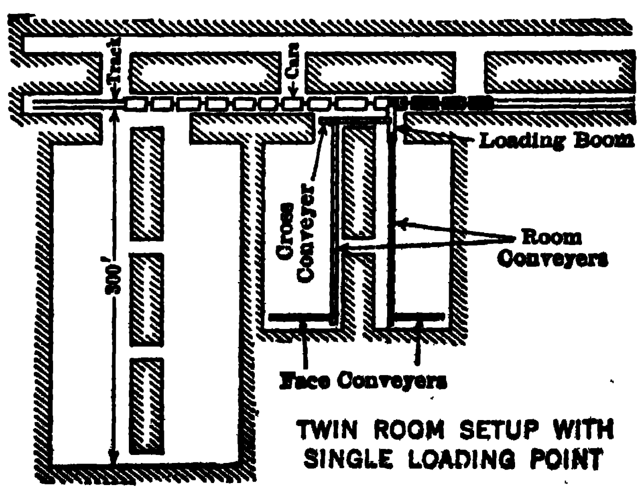

Fig 19. Face Conveyers for Rooms

2 drilling crews rotate work in 9 rooms on each side of panel entries, one development loader, double-shift, keeping pace with 4 room loaders on single shift.

Room production by conveyers (Fig 19). A twin-room set-up, with one loading point, requires a cross conveyer to the car loading boom. Fig 20 shows combination Joy chain-and-flight conveyer, with trough-belt for transport to surface (first installed in Goose Creek mine, Ky, in 1937). In the thick coal seams of Ind, the advancing rooms are double-tracked and break-throughs cut half through the pillars on both sides to give more faces for concentrated loading (Fig 21). High-tonnage production is made by mobile loaders in 6.5-ft seams in Ind and northern West Va; and complete pillar extraction by mobile loader and conveyer in a 42-in seam, southern West Va (Fig 22). Ideal face preparation for mechanical loading requires a completely loosened face, without excessive breakage of coal.

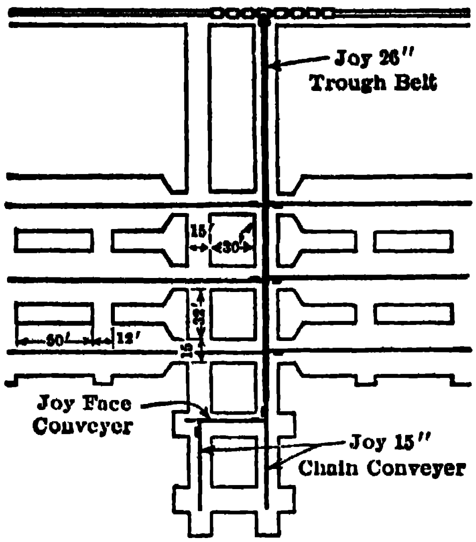

Fig 20. Joy Chain-and-flight and Trough Belt Conveyers

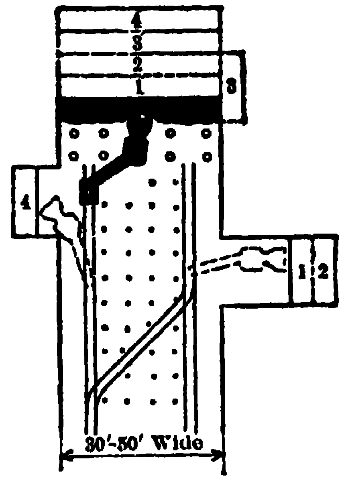

Fig 21. Double-tracked Room in Thick Indiana Coal Seam

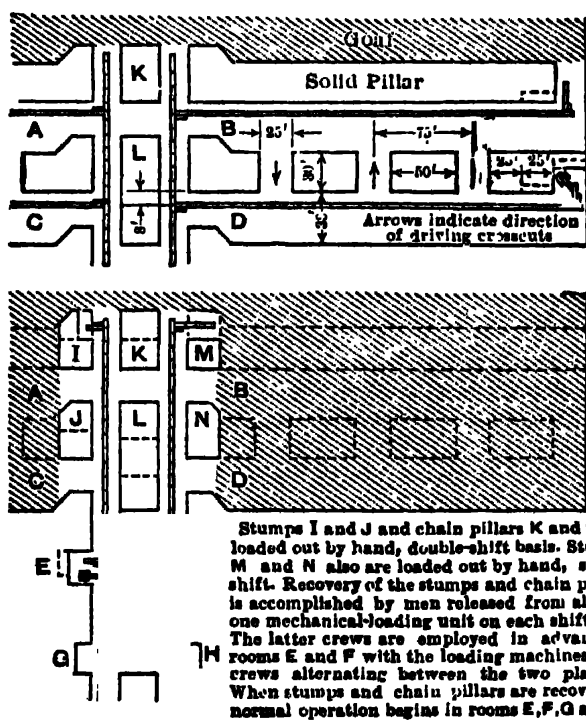

Fig 22. Pillar Extraction by Mobile Loader and Hand Conveyers

5. TRANSPORT FOR MECHANIZED MINING

Both locomotive haulage and machine loaders require heavy rails, up to 70 or even 90 lb on entries, instead of the former 30–40 lb. Cars also are larger; in 1938, an Ill mine introduced a 10-ton car (14-ton capac with sideboards). In room-and-pillar mining with mobile loaders, ideal car servicing requires trackage for continuous trips of empties pulled past the loader. Recent conveyer transport behind loaders permits continuous movement of coal from face to car-loading point or to surface. Typical mobile-loader installation, with conveyer transport is shown in Fig 23. Fig 24 shows hand loading onto multiple conveyers, discharging into a main-line unit delivering to cars at the entry, with one loading machine for the panel. Rubber-tired haulage recently installed, comprises tractor-trailer units running from loading machine to a central dumping point, for delivery to surface. For mines already having mechanical loaders, this equipment affords flexibility of haulage at relatively small capital cost. The added equipment cost at a mine of Ingle Coal Co, Ind, in a 6-ft seam, was about $23 000, of which $10 750 was for 5 tractors, $3 410 for 5 trail cars, $2 000 for dump hopper-feeder-conveyer, $4 440 for 2 transfer trucks, $1 200 for 30-kw battery-charging generator, and sundries $900. Already in use were 2 cutting machines, 2 loaders, 2 elec drills and the tractor batteries. With this equipment a force of 23 men delivered 900–1 000 ton of mine-run (720–800 ton clean coal) to the slope bottom every 7 hr. Max product per shift, 1 035 ton of mine run (830 ton clean coal); aver, July 1938, 750 ton prepared coal.

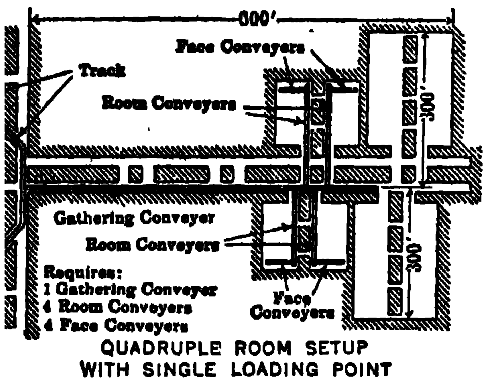

Fig 24. Quadruple Room Setup for Hand-loaded Conveyers, with One Machine Loading Point

6. COORDINATION OF MEN AND EQUIPMENT

Operating cycles are: (*a*) face preparation, cutting, drilling and blasting; (*b*) loading and transport; (*c*) clean-up, timbering, track or conveyer extension. Loader crews are 12–18 men for large machines in thick seams, to 5 or 6 men for small units in thin seams; correct number depends on character of seam, mining method, and kind of auxiliary equipment.

Profit possibilities. The following example is based on conditions in certain mines east of Mississippi River, and aver wage rates. The assumed type mine has favorable operating conditions, including good roof and a 5-ft coal seam; output, on deciding to change from hand to machine loading, 2 500 ton per shift. Development plan, room-and-pillar panels, with triple main entries, was continued with mechanical loading. To maintain same tonnage, 2 loaders were used in narrow work; 4 for wide work. Table 11, 12 show men and wages for delivering output to the main-line parting. Based on aver time distribution for

the loaders after partial coordination was effected, optimum estimates were made of loading rates and time factors for delays (Tables 13, 14). With 23.2% (580 ton) of total product from 2 crews on development, and 76.8% (1 920 ton) from 4 crews on room faces, an aver output of about 27.25 ton per man-shift, at cost of 23.23¢ per ton, was expected. Two weeks after installation, time studies on one wide-work machine for 4 shifts, showed (Table 15) that 86.43% of time, or $92.06 in wages, went to loading, car changing and moving machine from face to face, and 13.57% ($14.46) to time lost waiting for empties, and late starts at face. Output was 8 tons less per unit crew, and labor cost 9¢ more per ton than forecast. It might seem that, if lost time could be saved, 57 min would be gained for loading, car and machine moves, or about 13.5 more tons loaded per shift than in Table 14. But, total possible output would still be 124 ton below original estimate; and further study shows actual loading rate is 2 ton per min (not 2.5); that car-change time is double the estimate, and that the loader moves take 20% more time than warranted by distance covered. Also, it was found that the cutting machine men were not making the cuts for best blasting results and rapid loading. The shot-holes were not drilled horiz as planned, and the breaker, rib and top shots not placed high enough. Excessive time for car changing and moving the loader was partly due to lack of crew experience, and to the fact that at first only alternate crosscuts were tracked.

Table 16 shows aver of 3 consecutive-shift studies of 1 loader, which moved from face to face as per estimate. Face preparation gave loading rate of 1.4 ton per min, only 0.1 ton

Total	108.7	0.2589	$27.58

less than estimated, but car-change behind the loader was 25% slower, due to light locomotive used, requiring 3 two-car trips to load out 1 cut; heavier locomotive saved a third of the time. Faulty dispatching of empty cars called for more storage partings near working places. Idle time of development crew, due to car shortage, cost $46.59, or 20% of wage charge. Records covering narrow- and wide-work machines for the first 6 months of mechanical loading are in Table 17. These machines loaded about 74% of daily output in 6% less time than estimated; total tonnage, about 4% less. But avoidable delays showed a corresponding increase, totaling 109 min. Table 18 classifies avoidable delays, and, using the direct cost factor for each operation, the dollar losses for the 108 shifts in Table 17 were: faces not prepared, $687.96; transport, $1 172.88; power, $306.72; supplies, $192.24; maintenance, $618.84; total, $2 978.64. The 25.89% avoidable lost time for 1 loader is $11 914.56 for the 4 wide-work loaders. About 78% of room preparation losses were due to delays by cutters, drillers and shotfirers, and 22% to incomplete tracklaying and timbering; hence, it was decided that cutting and blasting, and distribution of supplies be done on night shift, track and timbermen on day shift to follow the loading cleanup of wide faces; also, because transport losses accounted for more avoidable delays than other operations, all main and secondary trackage was realined, regaged, ballasted, and curve radii lengthened and banked for higher speed. With an indicated loss of $5.25 per machine shift for wrecks and derailments, about $2 168 could thus be saved in labor cost. As maintenance losses were about $2 475 for the 6 months, all equipment was tested daily. Table 19, 102 time studies for first 6 months of mechanical loading, shows a nearly perfect production cycle, only 3.86% of time being lost by delays. This high effic is due to concentration of working places

Kathleen mine, Union Colliery Co, Dowell, Ill. In 1935, daily output of 4 600–4 700 ton was by 16 machines, in a 7.5–8-ft seam. Rooms, 26–28 ft wide, on 45-ft centers; depth, 250–300 ft (23).

Robinson Run mine (24), Christopher Mining Co, West Va, in a 6.5–8-ft seam, produced 15.6 ton per man-shift by mobile loaders on pillar work (Table 21).

Talleydale mine, Snow Hill Coal Co, Ind, in 1936 installed 7 machine loaders in a 5–6.5-ft seam. Product in one day was 2 268 ton, by 144 men underground (Table 22).

Pemberton Coal Co, West Va, hand loading onto conveyers in a 32–40 in seam gave aver output of 10.6 ton per man, delivered to main haulage, for 10 months in 1935 (Table 23).

Jewel Ridge Coal Co, Va, by triple shifting of 6 hand-loaded face conveyers (2 hp each), 6 room conveyers (10 hp each), and one 1 500-ft belt conveyer (25 hp), product was 18 000 ton per month, from a 38-in seam, with 33 1/3 men per day; shift tonnage per loader, 8.75.

Eureka Coal Co, Paris, Ark, working a 18–24 in seam, the normal product from about 1 600 ft of longwall face, with 4 conveyer units, was 345 ton per 7-hr shift.

Due to varying costs, mining conditions, and fluctuation in coordination of manpower and equipment, no general formula for savings by mechanization is possible; but some light is obtained from Table 24, from statistics of National Bituminous Coal Comm, covering mines producing more than 50 ton a day in Ill and Ind.

Table 24. Costs of Mechanized Mining in Bituminous Coal Mines

Mine classification	District No 10, Ill 9 mos, ended Dec, 1937: Tonnage	District No 10, Ill 9 mos, ended Dec, 1937: Av cost per ton	District No 11, Ind 9 mos, ended Dec, 1937: Tonnage	District No 11, Ind 9 mos, ended Dec, 1937: Av cost per ton

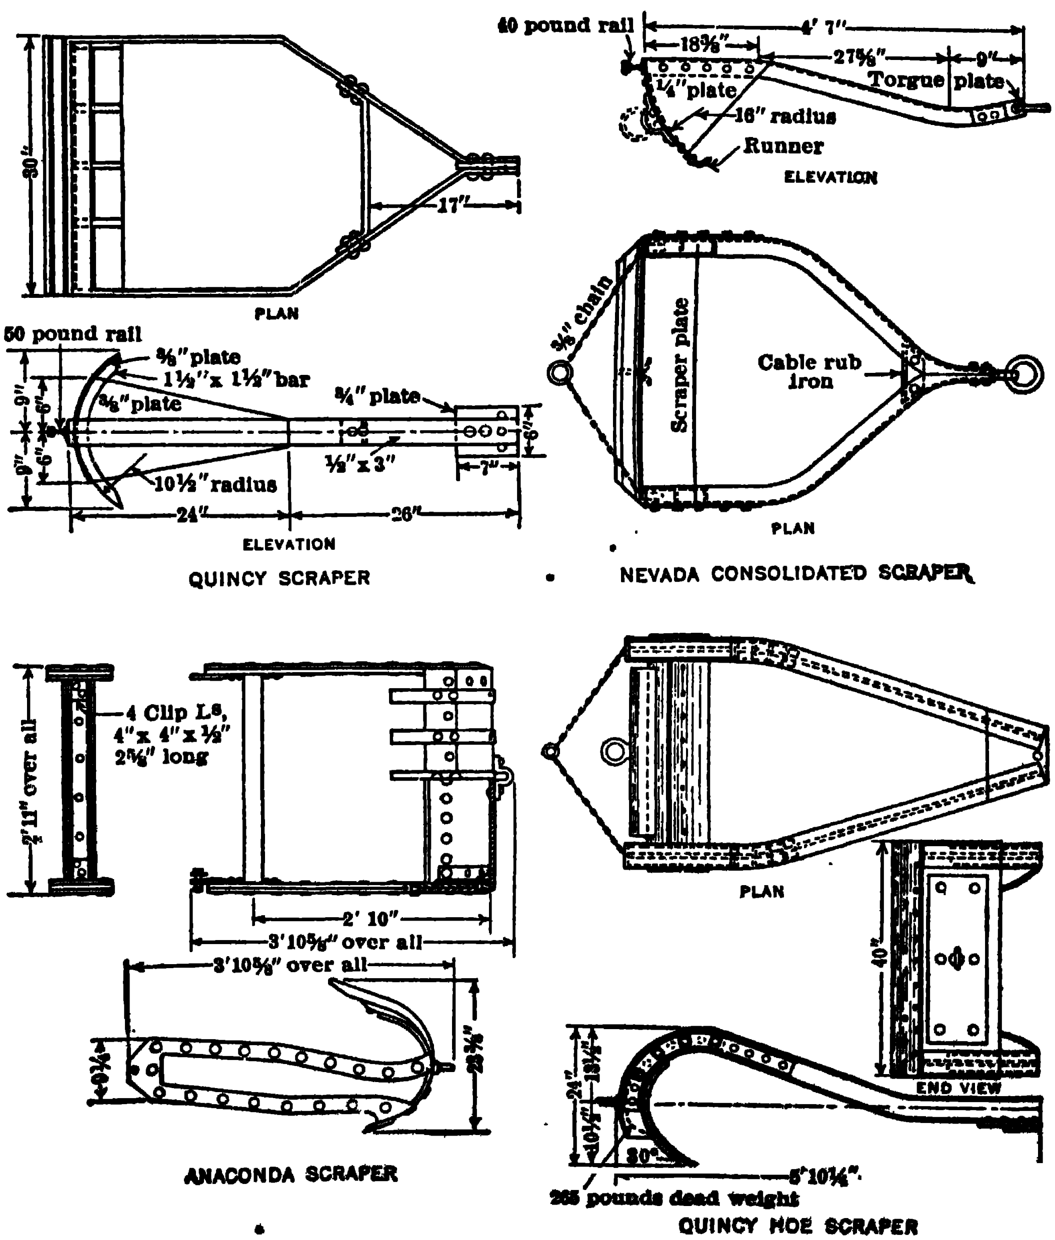

Fig 26. Types of Scraper Loaders with Slusher Hoists

7. TYPES OF MECHANIZED METAL-MINING EQUIPMENT

Underground metal-mine loaders were at first of the steam-shovel type, requiring large clearances; latterly, more compact designs have been evolved, as the Armstrong, Myers-

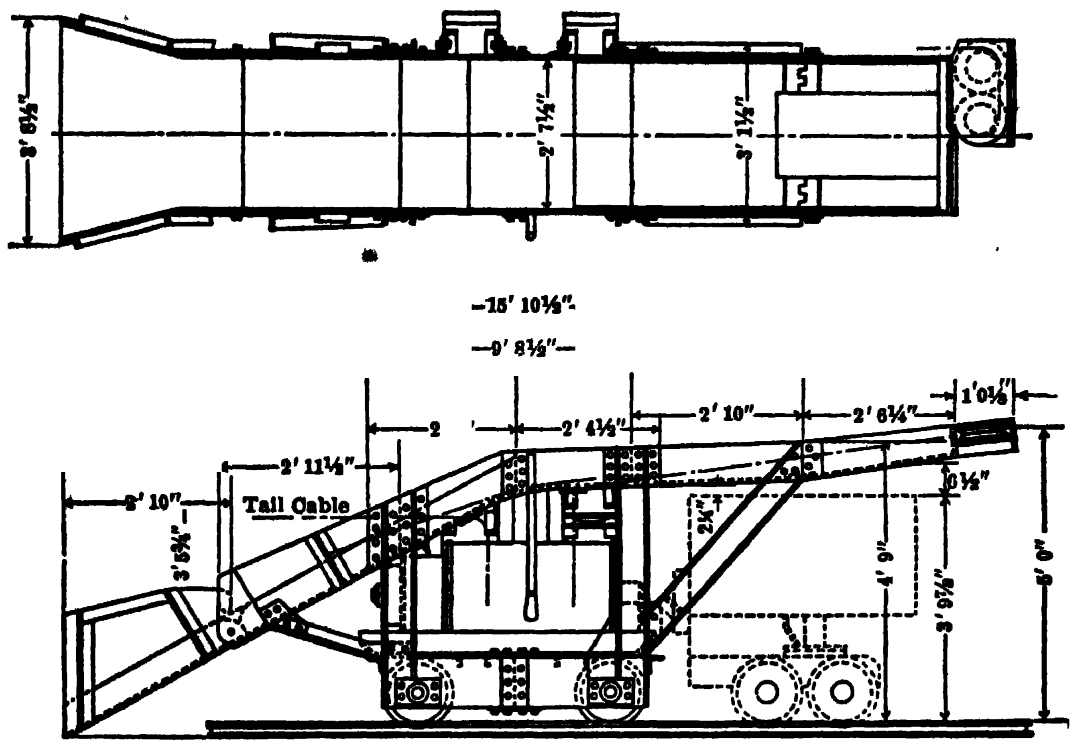

Fig 27. Slide for Scraper-loading of Cars

Whaley, Nordberg-Butler, Conway, Hoar, Eimco-Finlay, Gardner-Denver, and Sullivan. Meanwhile, scraper (slusher) loading was developing in several districts in U S and Canada, and is now common in the Lake Superior iron and copper mines, iron mines of the south, Tri-State lead and zinc districts, copper deposits of Ariz, Utah and Nevada, and wherever workings are too flat for gravity loading. The history of mechanical loading to 1923 in mines other than coal was published jointly in 1924 by the U S Bur of Mines and the Missouri School of Mines (27).

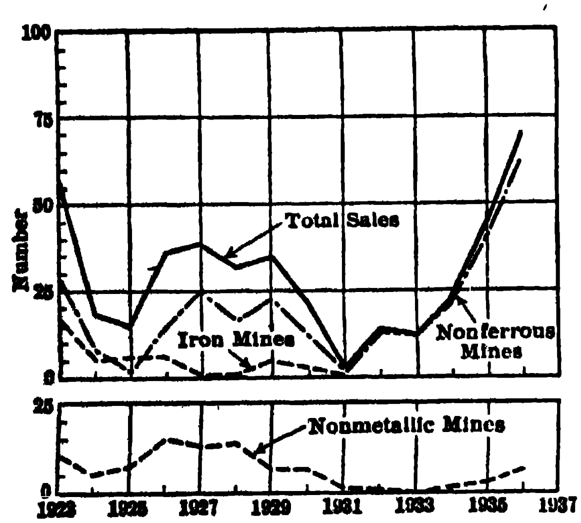

Fig 28. Installations of Underground Shovel Loaders (U S Bur Mines, from reports of 11 makers) (28)

Scraper loaders were first used in the Mich copper mines and iron ranges from 1915 to 1917, and in the Tri-State area in 1919, and proved their possibilities when shortage of manpower and rising wages made labor-saving devices necessary; and, following the war, declining prices of metals further stimulated cost reduction. From 1923 to 1929 sales of scraper equipment were large (Fig 25), but dropped during the depression, with some recovery since 1933. From 1929 to 1933, scraper sales to metal and nonmetallic mines totaled 3 752 hoists or complete units, made by: Sullivan Mach'y Co, Gardner-Denver Co, Lake Shore Engine Works, Goodman Mfg Co, Vulcan Iron Works Co (Denver), Vulcan Iron Works (Wilkes-Barre), Lidgerwood Mfg Co, and Sauerman Bros. Ranging in motor size from 7.5 to 150 hp, scraper and slusher haulers and hoists of double-drum type, have rope capacities of 165–1 000 ft per drum;

weights, 1 450-10 315 lb. Fig 26 shows types of scrapers, as used with slusher hoists; a typical slide for scraper loading of cars is in Fig 27.

Mobile loaders. The earliest of these were the Marion, Thew, Hoar, Osgood, Nordberg-Butler, Conway, Harnischfeger and Myers-Whaley, followed by the smaller Gardner-

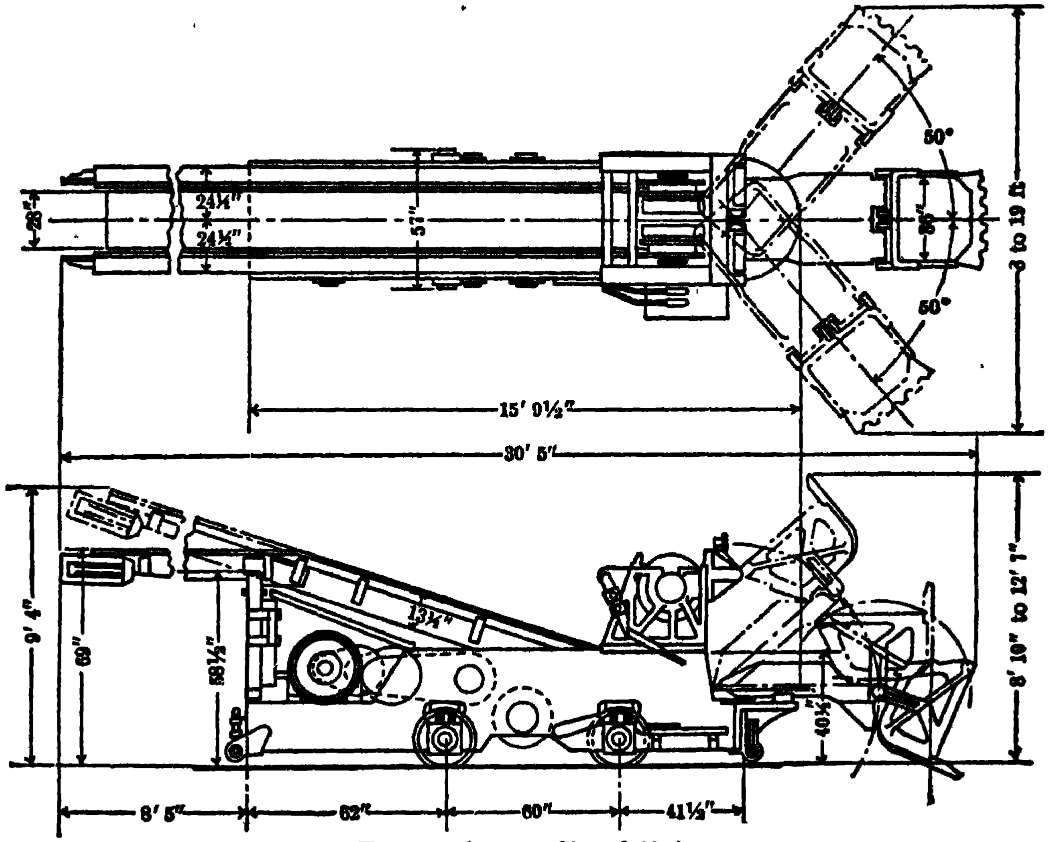

Fig 29. Conway Shovel 60-A

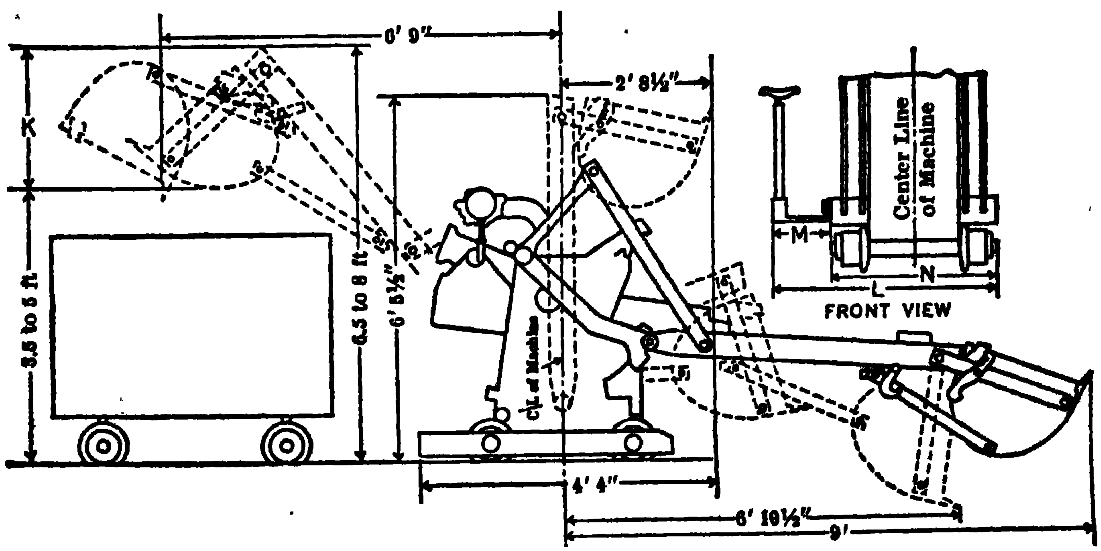

Fig 30. Nordberg-Butler Shovel

Denver, Eimco-Finlay and Sullivan. These 11 makers furnished the data in Table 2 and Fig 28. From 1923 to 1931 mobile loaders were designed chiefly for open stopes; since 1932, smaller units, for headings or tunnels, have predominated. Unlike the gathering machines used in coal mines (Joy, Jeffrey, Clarkson, Goodman and Umeco), loaders for metal and nonmetal mines employ the shovel movement only. This principle, embodying crowding,

lifting and discharging, is used in all machines, from the Marion and Thew shovels to the arc-swing loading head of the Myers-Whaley and Conway (which discharge on to conveyers delivering to cars), and the smaller later Eimco-Finlay, Gardner-Denver and Sullivan machines, in which the bucket is swung completely over, for discharge into the mine car. The larger machines are generally powered by elec motors; the smaller are air-driven (Fig 28).

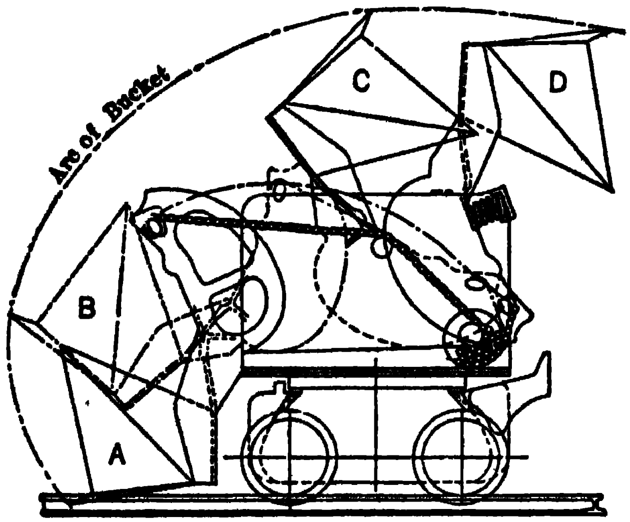

Fig 31. Eimco-Finlay Loader

Examples. Myers-Whaley shovel, for rock and tunnel work, has some resemblance in the chassis design to the coal-loading "Automat" of the same makers (Art 2), but embodies dipper movements similar to those shown in Fig 29. Conway shovel, sold by the St Louis Power Co, and built by the Goodman Mfg Co, has a dipper on a swinging boom, discharging on to a belt, and thence to the car. The digging mechanism is swung horiz, and raised and lowered by a hoist at front end of machine, and is driven through 2 planetaries, each with a drum and hoist chain. The propelling unit is similarly actuated. Made in 8 sizes. Dipper capac of the 60-A shovel, 13.5 cu ft; 5 loading cycles per min; belt widths, 28 in; hp, 60; wt, 15 ton. Nordberg-Butler shovel (Fig 30). The dipper is operated by 2 pistons of a direct-thrust air cylinder, for taking its load, raising to the revolving position and dumping ahead, to the side, or to the rear; revolving power is from a 2.5-hp air motor. Speed of work, 3–3.5 dippers per min. Shovel is moved by hand, and will operate in a tunnel 5.5 ft wide. Domestic shipping wt, about 5 170 lb. Gardner-Denver loader is a small machine for tunneling and mining, using about the same volume of air, at 45–90 lb, as an ordinary rock drill; wt, 4 000 lb; overall width, 33.5 in; length, 69 in; height, with bucket lowered, 52.75 in; minimum headroom, 76 in; clean-up width, 96 in. Eimco-Finlay loader is in 2 sizes, weighing 3 950 and 5 900 lb; operated by 2 special Ingersoll-Rand air motors, one for propelling and crowding, the other for digging, lifting and dumping. The patented rocker arm action in its different positions is in Fig 31. Sullivan loader, for narrow headings, has a rocker-arm action similar to the Eimco, but with a positive centering device for dumping into middle of car when on a curve (Fig 32).

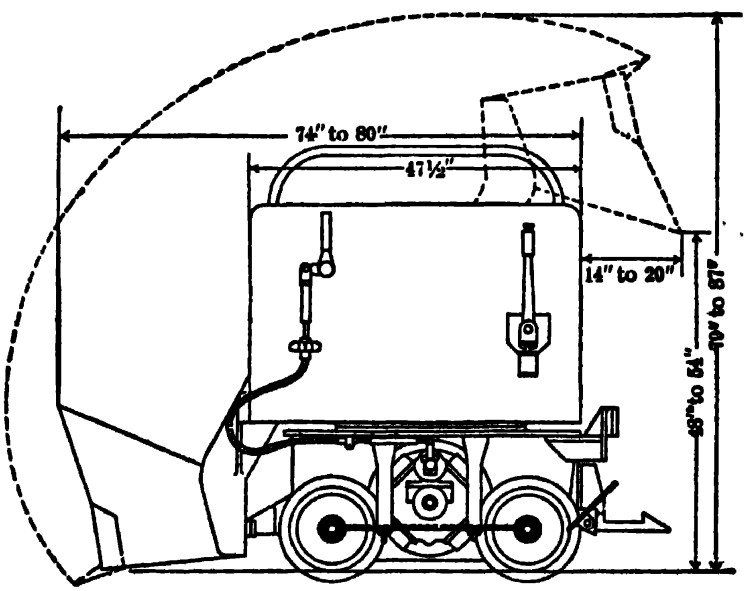

Fig 32. Sullivan Loader, for Narrow Headings

8. COMPARISON OF MECHANIZED METAL-MINING METHODS

The same mine may profitably employ mechanical loading in one section and gravity or hand loading in another (28). But, although most ore and country rock will probably continue to be handled by gravity systems, the improvements in design and effic of mechanical

loaders point to their wider use as wage rates tend to rise. In general, loading machines and scrapers are recommended for development headings, haulageways and flat workings, for delivery to mine cars, ore pockets, or to conveyers; scraper haulers, for inclined shafts or winzes, or stopes up to 30°, to conveyers or cars (35).

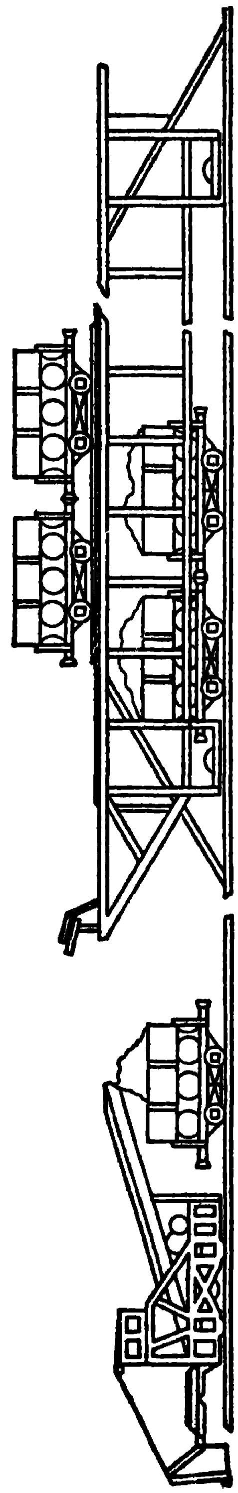

Fig 33. King Car-passer, for Machine Loader

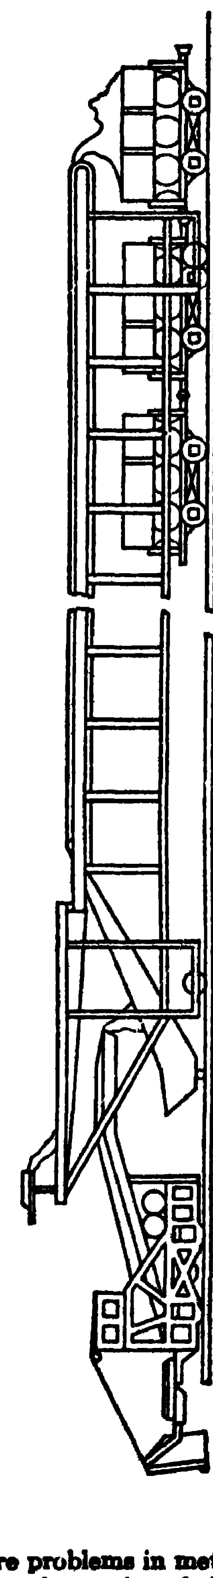

Fig 34. Dixon Conveyer for Machine Loader

Car servicing for track-mounted loaders presents more problems in metal mining than in coal; adits and drifts are generally narrow, double-track openings being driven only where increased effic of loading machine will warrant added cost. Simplest "side switch" for light cars behind a loader in narrow headings is a TURN SHEET, the empty being "kicked

off" the track onto the plate to allow the loaded car to pass. Cars are also changed in narrow workings by the "CHERRY PICKER," a movable frame carrying an air hoist, which raises an empty from the track, to allow the loaded car to pull away from the loader. KING CAR-PASSER (Fig 33) is a steel frame about 150 ft long, traveling on rails on each side of main-line track, with a hinged ramp at each end operated by an air hoist. Track is laid up the ramps and along the deck, for cars to pass to the loader. Both ramps are raised when loaded car is to be pulled out (36). DIXON CONVEYER (Fig 34) has a long belt on a frame like that of the King. A hopper-like hinged trough at front end receives material from the loader, and transfers it to the conveyer which loads car at the rear (36). CALIFORNIA SWITCH, widely adaptable for car changing behind loading machines, consists of a portable combination of siding and switch superimposed on the main track, with tapered end rails and a spring switch at each end, for cars to pass on either side from the permanent track. The empties are pulled from one siding to the loader by a small hoist, the loaded cars being pulled away on the other track. The entire siding is moved forward, as a unit, by the loader or the locomotive (36).

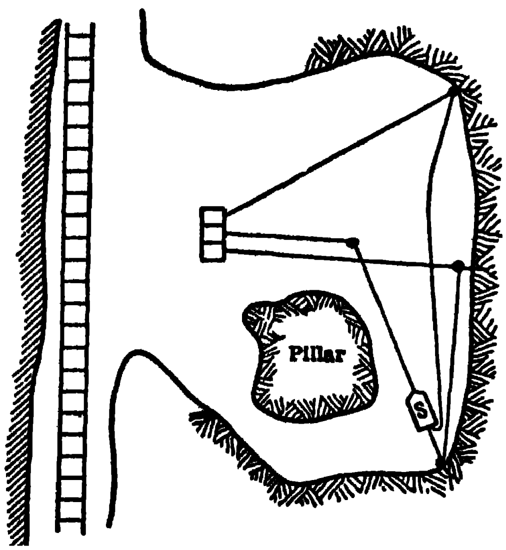

Fig 35. Scraper Loading from Stope; 2 Tail Ropes

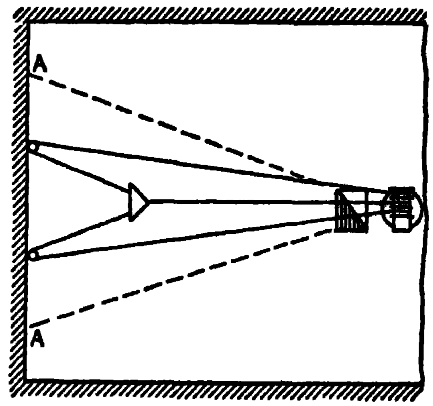

Fig 36. 3-drum Hoist for Mucking a Large Area

Scraper loading by 3-drum hoists. Fig 35 shows setup, with 2 tailropes, in a large flat stope; Fig 36, a setup for mucking horiz cut-and-fill stopes, and spreading the waste where ore passes are obstacles to free spreading. Work in cut-and-fill stopes can be done by placing the mucking hoist in one panel, the filling hoist in another (13).

Examples of Mechanized Metal Mining

Colorado River Aqueduct (36), 91 miles of 16-ft tunnel, were driven with machine loaders at aver speed per heading of 18 ft per day of three 8-hr shifts; aver cost per cu yd of excavation, \$3.90. Crews were from 18–20 men; skilled wages, \$5–\$6; unskilled, \$3.20–\$3.80.

United States mine (U S Smelting, Ref and Min Co, Bingham, Utah). Cost of hand mucking, 35.8¢ per ton; with Eimco-Finlay loaders, 28.7¢; a saving of 20% (38).

Suyoc Consol Mining Co (Philippines) drove a 12 by 12-ft tunnel 9 450 ft. Speed with hand mucking averaged 250 ft per month; afterward, with a Conway shovel, 1 327 ft in 1 month at cost of \$14.74–\$17.73 per ft (39).

Butte mines, Mont. Mechanical loading can replace hand work and effect a saving in 7 by 5-ft drifts or larger (40). The small machines are fast, effic and rugged in construction. From 1933 to 1938, machine loading increased from 6 700 to about 500 000 tons, some 50 small loaders now being used. Aver loading time, 4 min per 4-ton car. Track arrangements for car servicing are shown in Fig 37.

Scraper loading on the MICH IRON RANGES showed a marked increase of output per miner per day, from 2.9 ton in 1923 to 5.96 ton in 1929; distances scraped, 20–100 ft (13). RAIMUND NO 1 MINE, Birmingham, Ala (Republic Steel Corp) uses both hand and scraper loading (41). Double-drum elec hoists, carrying 500 ft of rope, are driven by 35-hp motors. Box scrapers, weighing 1 900 lb, capac 1–1.5 ton, handle 100–150 ton per 8-hr shift in heading work. At the PARK-UTAH MINE (42), scrapers have been used in square-set stopes, handling 2 000 ton in 1 month with 4 men on each of 2 shifts, the setup being on the timbering. LA RUE MINE, Mesabi Range (42), uses both underground and surface conveyers, for ore dipping about 15°. Belt haulage with elec shovels, first installed for mining large

rooms, were abandoned, as the roof was too treacherous for the 16-ft span required for the shovels. Scrapers and elec hoists are now used for top-slicing and sublevel caving. Scrapers of 1 cu yd are hauled from the face by 20-hp hoists, for delivery to a 1.5-cu yd scraper and 40-hp hoist, which in turn delivers to a surface conveyer by which the ore goes to RR cars or to stock pile. This system, involving use of 4 440 ft of 30-in belt conveyer, of which 2 135 ft are underground and 2 305 ft on surface, handle up to 400 long tons per hr.

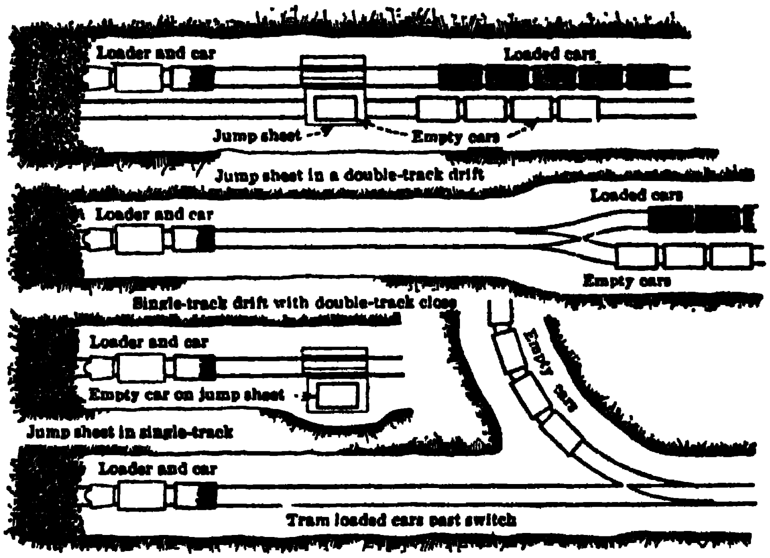

Fig 37. Car Servicing for Small Machine Loaders in Butte Mines

Within the past decade, mechanical handling of ores and rock has embraced all forms of loading equipment. In general, as shown by the preceding examples, the saving in cost over hand loading ranges from 10 to 50%, and furnishes ample incentive to study the problem for every set of local conditions.

Details of Conveyers and Elevators (L. de G. Moss)

These find their widest application in coal mines, but some are used in metal and non-metallic mines (30, 31, 32).

9. CHAIN AND BUCKET CONVEYERS

Buckets or pans bolted to chain links form a continuous moving trough, delivering at the head sprockets by inverting (Fig 38). The kind of material determines the shape of buckets. The ends must be shaped to permit buckets to pass around sprockets: for sticky materials, all sides are sloped. For intermediate delivery the buckets are hinged at one end, with guide wheels at the other, which drop on a depressed curved track to spill the load (Fig 39). The dumping ends must be open, and, owing to shock of dumping, speed is reduced to about 50 ft per min; with fixed pans, speed may be 80–100 ft per min. Roller chains with closed and bushed bearings are best. Capacities reach 1 000 tons of stone per hr. Power required, 2 to 4 hp per hr per ton-mile on level track. Clean tracks and well lubricated

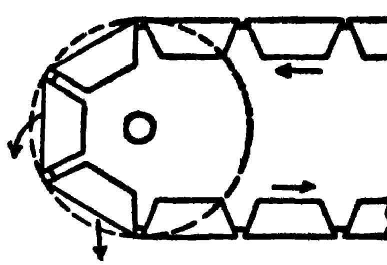

Fig 38. Bucket or Pan Conveyer

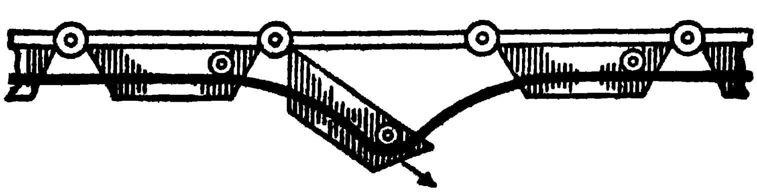

Fig 39. Mode of Dumping

rollers are essential. Conveyers on steep upgrades are uneconomical, because a large part of dead wt pulls on the head-shaft bearings. Grades may be up to 30°. Inclines do not cause decrease in capacity, as in flight conveyers.

10. CHAIN AND BUCKET ELEVATORS

Types. CENTRIFUGAL-DISCHARGE elevator has 1 or 2 strands of chain with outstanding buckets (Fig 40). Linear speed of buckets = speed of chain, except when turning over sprockets. For proper relations of chain speed and head sprockets, see Fig 41. For very gritty material, one strand of chain can be used, driven by a toothless traction wheel. They may run vertically. Faults of centrifugal elevators: high veloc of discharge breaks up lumps which should be kept intact; chute lining wears rapidly; high speed reduces life. It is the cheapest form of elevator. PERFECT-DISCHARGE elevator (Fig 42) runs between 80 and 200 ft per min. The chains are deflected inward by 2 choke or snub sprockets, to secure better delivery. This principle can not be applied to single-strand elevators, nor to belt and bucket elevators. CONTINUOUS-DISCHARGE elevators (Fig 43) run 60 to 80 ft per min, and are preferred for stone, sand, and minerals. The buckets, with no spaces between them, have lips to serve as small chutes. GRAVITY DISCHARGE (Fig 44) gives a clean delivery by using 48° V buckets, bolted to chain, with a horiz run at top. Roller chains are needed, owing to horiz portion of delivery track and chute.

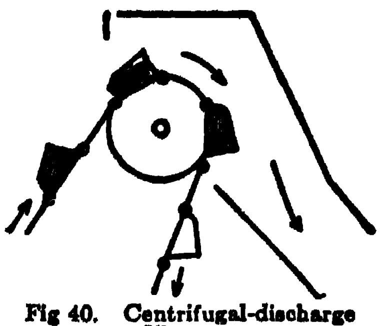

Fig 40. Centrifugal-discharge Elevator

Buckets are commonly of sheet steel, No 8–16 gage. A better design has C-I ends, with renewable steel body. Malleable-iron buckets are most durable. Standard elevators have not yet been made so that the bodies of the buckets form the links, as in dredging elevators, with obvious advantages for large units.

Chains. Short-pitch chains give the more uniform speed; long-pitch causes swaying due to rhythmic variations in speed. Large conveyers should have enclosed pins with bushings. The Ewart detachable-hook chain is satisfactory for temporary or light service. SLACK must be prevented by screw-geared take-ups, having a gape of more than length of 1 link. They should be placed at the foot of the elevator, where all slack accumulates. It is sometimes necessary to put them under the head-shaft bearings,

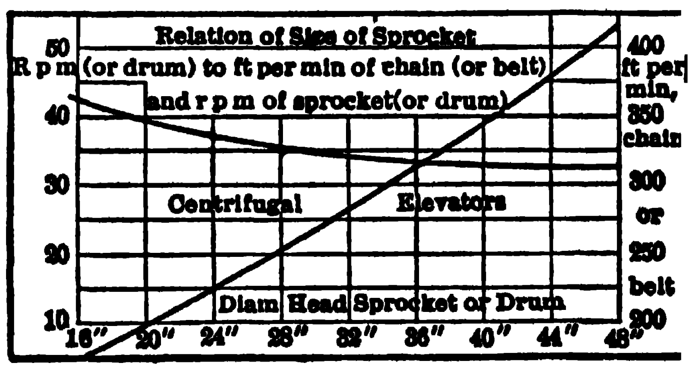

Fig 41
